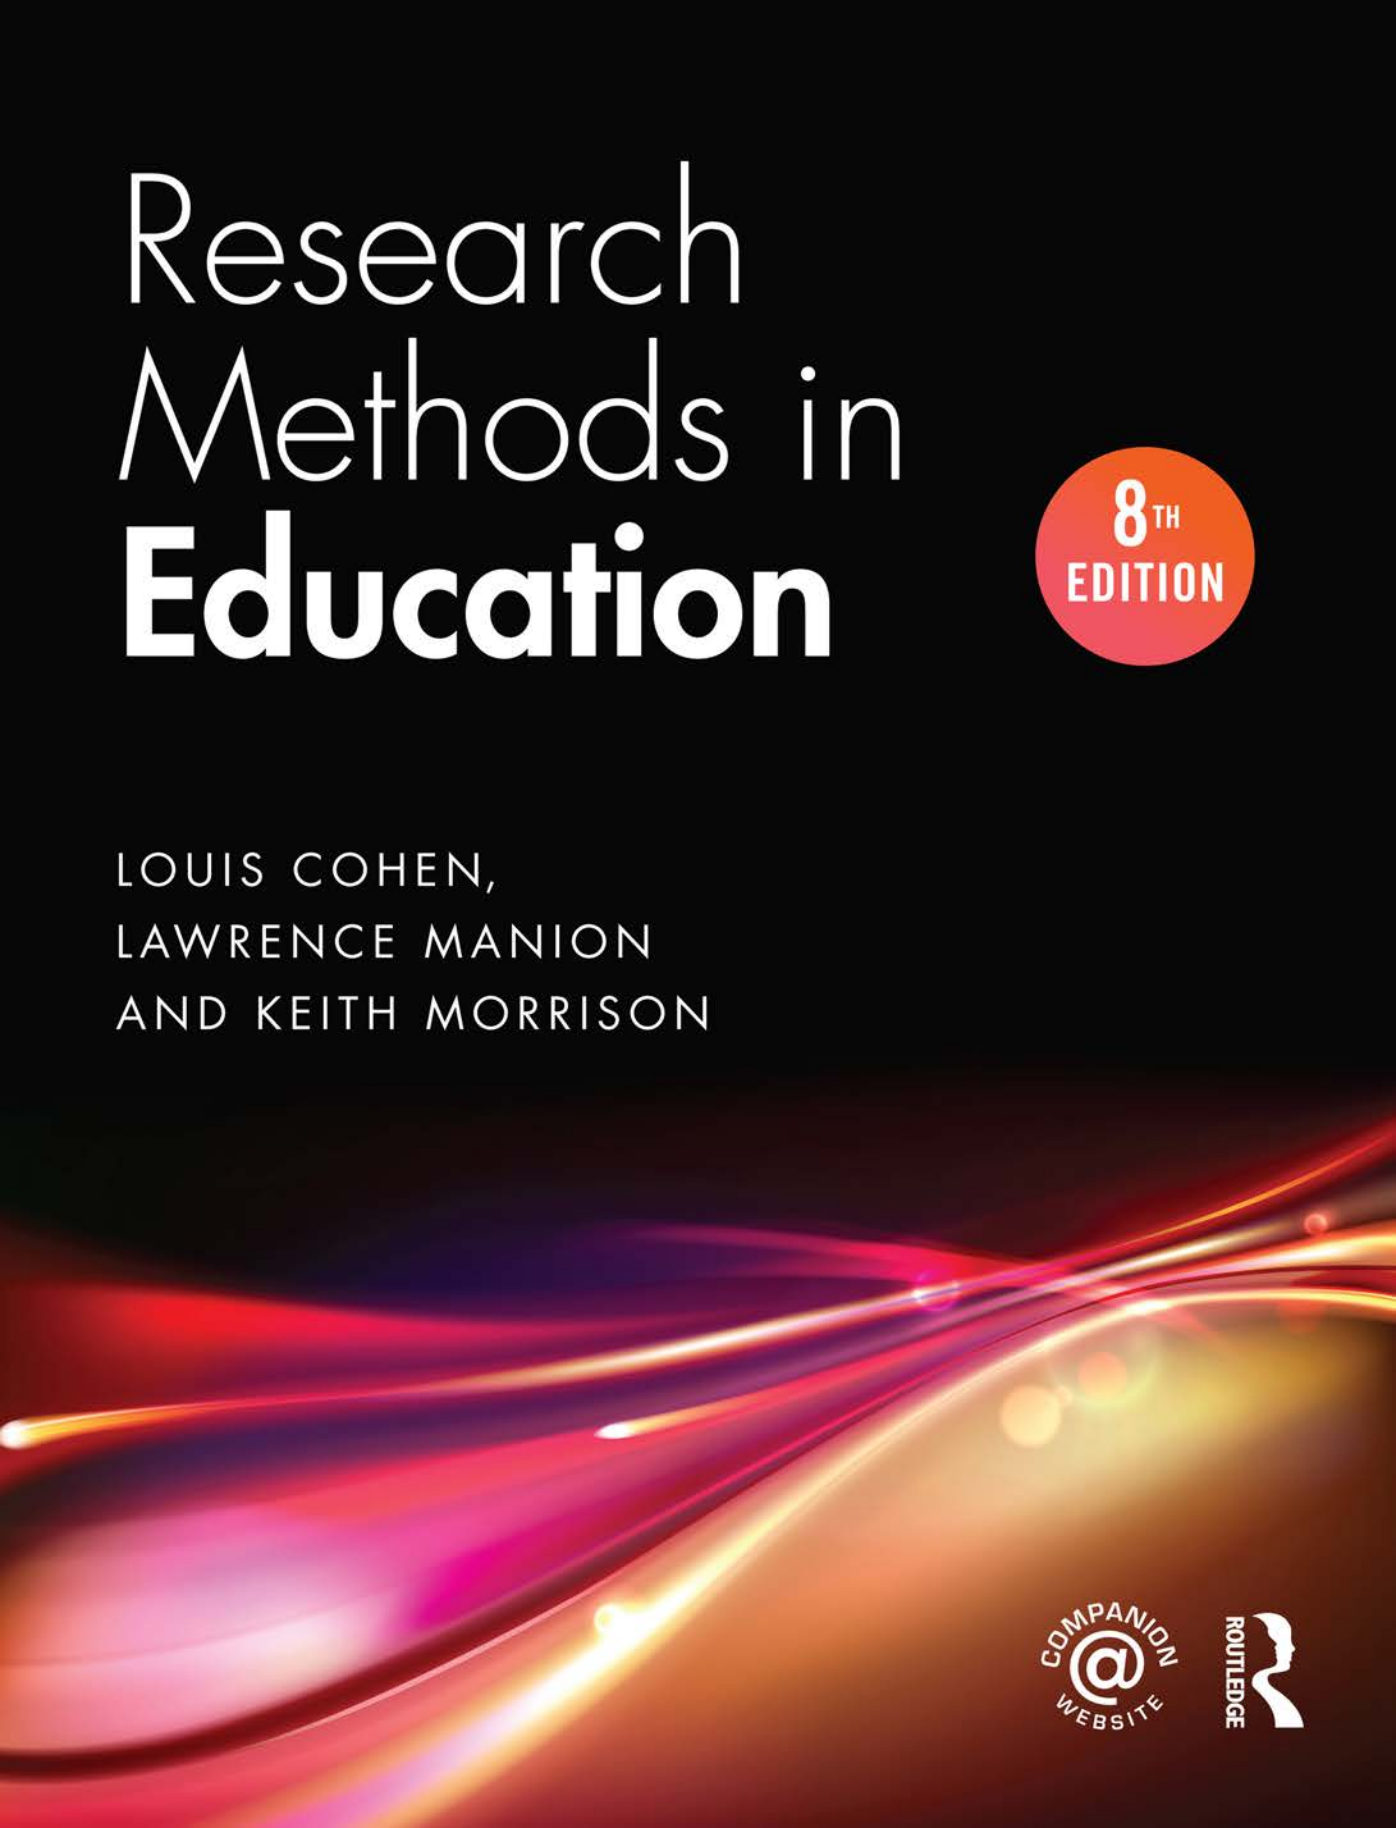
Research Methods in **Education**

8TH EDITION

LOUIS COHEN,
LAWRENCE MANION
AND KEITH MORRISON



Very much still the key text for 'all' education students and researchers. Cohen *et al*. continue to update *Research Methods in Education*, with new theoretical, ethical, virtual and mixed methods information. It's worth noting the impressive web page and links to materials for all chapters which is still the benchmark when looking at the competition for books in this area of social and education research.

Dr Richard Race, Senior Lecturer in Education, Roehampton University, UK

A clear enhancement on the already well-established text. The new edition addresses an important need to explain research design and question setting in more detail, helping guide the newcomer through the research process from inception through analysis to reporting.

David Lundie, Associate Professor of Education, University of St Mark & St John, UK

Research Methods in Education is a unique book for everybody who has to undertake educational research projects. The book gives an in depth understanding of quantitative and qualitative research designs and offers a practical guide for data collection and data analysis. It is an essential 'friend' for teachers and students from various disciplines who are not familiar with social science research.

Dr Ellen P. W. A. Jansen, Associate Professor, Teacher Education, University of Groningen, The Netherlands

Research Methods in Education continues to offer an excellent route map, a well-structured and inspiring travel guide, for students engaging in research. It works across levels, and while it provides clarity for the beginning researcher there is plenty here to aid the seasoned researcher with an open mind to new approaches and emerging practices. A superb text that provides guidance for my own research as well as for students and partners in research projects.

Peter Shukie, Lecturer in Education Studies and Academic Lead in Digital Innovation, University Centre at Blackburn College, UK

Research Methods in Education is, besides being my personal favorite research methods book, a deep as well as a broad handbook useful both for undergraduate teacher education students as well as researchers and PhD students within educational sciences. In this new edition, new chapters are added emphasising both quantitative and qualitative methods in combination with thought-through discussions about how to mix them. The book can be used when planning a project and then throughout the whole research process and is therefore a complete methods book.

Karolina Broman, Senior Lecturer in Chemistry Education, Umeå University, Sweden

Comprehensive, well written and relevant: the eighth edition of *Research Methods in Education* offers the background for methods courses at different levels. The new edition keeps the strong focus on education studies. Excellent extensions will make the book an even more popular basis for classes on both qualitative and quantitative methods.

Felix Weiss, Assistant Professor for Sociology of Education, Aarhus University, Denmark

Research Methods in Education, Eighth Edition is an up-to-date, one-stop shop, taking education research students from conceptualization to presentation. With this book on your library shelf, you are good to go.

Dr Fiona McGarry, Lecturer in Research Methods, University of Dundee, UK

The eighth edition of *Research Methods in Education* contains a wealth of up-to-the-minute information and guidance on educational research which will be of immense value to researchers at all stages of their careers and across the education domain from early years settings to higher education. As research and education move into increasingly fluid and complex dimensions, *Research Methods in Education* will support students, researchers and practitioners in charting a course through these changing waters as they seek to create new knowledge about effective teaching and deepen our understanding of how learners learn.

Julia Flutter, A Director of the Cambridge Primary Review Trust, Faculty of Education, University of Cambridge, UK

As a doctoral supervisor I know that my students routinely return to *Research Methods in Education* as they develop their own research projects. This text has always been a mainstay on our reading lists but this new edition now features additional research topics and new perspectives on a wider range of research methods. As with previous editions this book is clearly organised and well written and appeals to a wide audience of experienced and novice researchers alike.

Dr Val Poultney, Associate Professor, University of Derby, UK

Research Methods in Education

This thoroughly updated and extended eighth edition of the long-running bestseller *Research Methods in Education* covers the whole range of methods employed by educational research at all stages. Its five main parts cover: the context of educational research; research design; methodologies for educational research; methods of data collection; and data analysis and reporting. It continues to be the go-to text for students, academics and researchers who are undertaking, understanding and using educational research, and has been translated into several languages. It offers plentiful and rich practical advice, underpinned by clear theoretical foundations, research evidence and up-to-date references, and it raises key issues and questions for researchers planning, conducting, reporting and evaluating research.

This edition contains new chapters on:

- Mixed methods research
- The role of theory in educational research
- Ethics in Internet research
- Research questions and hypotheses
- Internet surveys
- Virtual worlds, social network software and netography in educational research
- Using secondary data in educational research
- Statistical significance, effect size and statistical power
- Beyond mixed methods: using Qualitative Comparative Analysis (QCA) to integrate cross-case and within-case analyses.

Research Methods in Education is essential reading for both the professional researcher and anyone involved in educational and social research. The book is supported by a wealth of online materials, including PowerPoint slides, useful weblinks, practice data sets, downloadable tables and figures from the book, and a virtual, interactive, self-paced training programme in research methods. These resources can be found at: www.routledge.com/cw/cohen.

Louis Cohen is Emeritus Professor of Education at Loughborough University, UK.

Lawrence Manion was Principal Lecturer in Music at Manchester Metropolitan University, UK.

Keith Morrison is Professor and Advisor for Institutional Development at Macau University of Science and Technology, China.

Contributors

Richard Bell, PhD, Honorary staff member and formerly Associate Professor in the Department of Psychological Sciences, University of Melbourne, has written Chapter 29: 'Personal constructs'.

Barry Cooper, PhD, Emeritus Professor of Education in the School of Education, University of Durham, has jointly written Chapter 45: 'Beyond mixed methods: using Qualitative Comparative Analysis (QCA) to integrate cross-case and within-case analyses'.

Judith Glaesser, PhD, Research Associate for Evaluation in the School of Education at Eberhard Karls Universität Tübingen, has jointly written Chapter 45: 'Beyond mixed methods: using Qualitative Comparative Analysis (QCA) to integrate cross-case and within-case analyses'.

Jane Martin, PhD, Professor of Social History of Education and Head of the Department of Education and Social Justice, University of Birmingham, has written Chapter 16: 'Historical and documentary research', and is currently conducting research on Caroline Benn.

Stewart Martin, PhD, Professor of Education at the School of Education and Social Sciences, University of Hull, has written Chapter 23: 'Virtual worlds, social network software and netography in educational research'.

Carmel O'Sullivan, PhD, Associate Professor of Education and Head of School of Education at Trinity College Dublin, has written Chapter 30: 'Role-play and research'.

Harsh Suri, PhD, Senior Lecturer in Learning Futures in the Faculty of Business and Law at Deakin University, has written Chapter 21: 'Meta-analysis, systematic reviews and research syntheses'.

Preface to the eighth edition

We are indebted to Routledge for the opportunity to produce an eighth edition of our book *Research Methods in Education*. The book continues to be received very favourably worldwide; it is the standard text for many courses in research methods and has been translated into several languages.

The eighth edition contains much new material, including entirely new chapters on:

- Paradigms in educational research
- Mixed methods research
- The role of theory in educational research
- Ethics in Internet research
- Research questions and hypotheses
- Historical and documentary research
- Internet surveys
- Meta-analysis, research syntheses and systematic reviews
- Virtual worlds, social network software and netography in educational research
- Using secondary data in educational research
- Statistical significance, effect size and statistical power
- Beyond mixed methods: using Qualitative Comparative Analysis (QCA) to integrate cross-case and within-case analyses.

Whilst retaining the best features of the former edition, the reshaping, updating and new additions undertaken for this new volume now mean that the book covers a greater spread of issues than the previous editions, and in greater depth, catching the contemporary issues and debates in the field. In particular, the following new material has been included:

Part 1:
- Post-positivism, post-structuralism and postmodernism
- Constructionism in educational research
- Subjectivity and objectivity in educational research
- Mixed methods research
- Paradigms, ontology and epistemology in mixed methods research
- Working with mixed methods research
- Stages in mixed methods research
- Value-neutrality in educational research
- The role of theory in educational research
- Types and meanings of theory
- Worked examples of causation in educational research

Part 2:
- Regulatory contexts of ethics
- Sponsored research
- Ethical codes and their limitations
- Ethics and the quality of research
- Power and position

- Reciprocity
- Ethics in data analysis, reporting and dissemination
- Key ethical issues in Internet research
- Challenges to privacy and informed consent in Internet research
- Public and private matters in Internet research
- Ethical codes in Internet research
- Choosing a research project
- Deriving and devising research questions
- Different kinds of research question
- Organizing research questions
- The need for warrants in educational research
- Statistical power in sampling issues
- Sampling in mixed methods research
- Effects of sensitive research on the researcher

Part 3:

- Autoethnography
- Virtual ethnography
- Reflexivity
- Historical and documentary research
- Survey questions
- Low response, non-response and missing data in surveys
- Constructing Internet-based surveys
- Ethical issues in Internet-based surveys
- Typology of case studies
- Generalization in case study
- What makes a good case study researcher?
- Randomized controlled trials
- The importance of randomization
- Concerns about randomized controlled trials
- The limits of averages in randomized controlled trials
- Null hypothesis significance testing
- Participatory action research
- Ethical issues in action research

Part 4:

- Considering the demands on the respondent in questionnaire construction
- Administering questionnaires
- Planning and conducting interviews
- Prompts and probes in interviews
- Interviewing children
- Group interviewing
- Telephone interviewing
- Online interviewing
- Key issues in observations
- Video observations
- Using secondary data in educational research
- Sources and types of secondary data
- Advantages of, and challenges in, using secondary data
- Ethical issues in using secondary data
- Examples of secondary data analysis
- Working with secondary data
- Photo-elicitation

- Provision of images in educational research
- Video and moving images in educational research
- Ethical practices in visual research

Part 5:

- Elements of qualitative data analysis
- Making sense of qualitative data
- Computer Assisted Qualitative Data Analysis (CAQDAS)
- Examples of CAQDAS
- Reflexivity in CAQDAS
- Strengths and weaknesses of CAQDAS
- Advances in CAQDAS
- Ways of organizing and presenting qualitative data analysis
- Examples of coding qualitative data with software (CAQDAS)
- Concerns about coding
- Content analysis with software (CAQDAS)
- Worked examples of using software in analysing visual data (CAQDAS)
- Challenges in interpreting visual images
- Analysing moving images
- Versions of, stages in and concerns about grounded theory
- Moderator and mediator variables
- Confidence intervals
- Concerns about statistical significance
- Hypothesis testing and null hypothesis significance testing
- Statistical power
- Coping with missing data
- 'Safety checks' and assumptions when using statistics (for all the statistics addressed)
- Command sequences for running statistics in the Statistical Package for the Social Sciences (SPSS)
- Reporting statistical analysis
- Cluster analysis
- What to look for in factor analysis output
- Additions to guidance charts when choosing statistics
- Using Qualitative Comparative Analysis (QCA) to integrate cross-case and within-case analyses
- Starting from quantitative and qualitative stances in QCA
- Ragin's QCA
- Worked examples of QCA

A signal feature of this edition is the inclusion of very many extensively worked examples and more figures, diagrams and graphics to illustrate and summarize key points clearly. Several of the tables in Part 5 include SPSS and NVivo output, so that readers can check their own SPSS and NVivo analysis against the examples provided.

To accompany this volume, a companion website provides a comprehensive range of materials to cover all aspects of research (including summaries of every chapter on PowerPoint slides), exercises and examples, explanatory material and further notes, website references, SPSS data files, QSR NVivo data files, together with further statistics and statistical tables. These are indicated in the book.

This book stands out for its practical advice that is securely rooted in theory and up-to-date discussion from a range of sources. We hope that it will continue to constitute the first 'port of call' for educational researchers and continue to be the definitive text in its field.

Part 1
The context of educational research

This part introduces readers to different research traditions, with the advice that 'fitness for purpose' must be the guiding principle: different research paradigms for different research purposes. A major message in this part is that the nature and foundations of educational research have witnessed a proliferation of paradigms over time. From the earlier days of either quantitative or qualitative research have arisen the several approaches introduced here.

This part commences by introducing positivist and scientific contexts of research and some strengths and weaknesses of these for educational research, followed by post-positivist views of research. As an alternative paradigm, the cluster of approaches that can loosely be termed interpretive, naturalistic, phenomenological, interactionist and ethnographic are brought together, and their strengths and weaknesses for educational research are examined. Postmodernist and post-structuralist approaches are also introduced, and these lead into an introduction to complexity theory in educational research. The paradigm of mixed methods research is introduced, and its foundations, strengths, weaknesses, contribution to and practices in educational research are discussed.

Critical theory as a paradigm of educational research is discussed, and its implications for the research are indicated in several ways, resonating with curriculum research, participatory research, feminist research, post-colonial research and queer theory. These are concerned not only with understanding a situation or phenomenon but with *changing* it, often with an explicit political agenda. Critical theory links the conduct of educational research with politics and policy making, and this is reflected in the discussions of research and evaluation, noting how some educational research has become evaluative in nature.

This part includes a new chapter on the role of theory in educational research, indicating its several meanings, its origins and roles in educational research, and what makes a theory interesting and useful. It also includes the discussion of causation in educational research and key elements in understanding and working with causation.

The term *research* itself has many meanings. We restrict its usages here to those activities and undertakings aimed at developing a science of behaviour, the word *science* itself implying both normative and interpretive perspectives. Accordingly, when we speak of social research, we have in mind the systematic and scholarly application of the principles of a science of behaviour to the problems of people within their social contexts, and when we use the term educational research, we likewise have in mind the application of these same principles to the problems of teaching and learning within education and to the clarification of issues having direct or indirect bearing on these concepts.

The nature of enquiry

CHAPTER 1

Setting the field

This large chapter explores the context of educational research. It sets out several foundations on which different kinds of empirical research are constructed:

- the search for understanding
- paradigms of educational research
- scientific and positivistic methodologies
- naturalistic and interpretive methodologies
- post-positivism, post-structuralism and postmodernism
- complexity theory in educational research

Educational researchers cannot simply 'read off' the planning and conduct of research as though one were reading a recipe for baking a cake. Nor is the planning and conduct of research the laboratory world or the field study of the natural scientist. Rather, it is to some degree an art, an iterative and often negotiated process and one in which there are typically trade-offs between what one would like to do and what is actually possible. This book is built on that basis: educational research, far from being a mechanistic exercise, is a deliberative, complex, subtle, challenging, thoughtful activity and often a messier process than researchers would like it to be. This book provides some tools for such deliberation and planning, and hopefully some answers, but beyond that it is for the researcher to consider how to approach, plan, conduct, validate and evaluate the research, how to develop and test theory, how to study and investigate educational matters, how to balance competing demands on the research, and so on. There is no one best way to plan and conduct research, just as there is no one single 'truth' to be discovered. Life is not that easy, unidimensional or straightforwardly understood, just as there are no simple dichotomies in educational research (e.g. quantitative *or* qualitative, objective *or* subjective). Rather, we live in a pluralistic world with many purposes and kinds of research, many realities and lived experiences to catch, many outcomes, theories and explanations, many discoveries to be made, and many considerations and often contradictions or sensitivities to be addressed in the planning and conduct of the research.

Whilst arguing against simple foundationalism, this chapter sets out some conceptions of research which researchers may find helpful in characterizing and deliberating about their studies. The chapter considers paradigms and their possible contribution to educational research, positivism, post-positivism, post-structuralism, postmodernism and interpretive approaches.

1.1 Introduction

Our analysis takes an important notion from Hitchcock and Hughes (1995, p. 21), who suggest that ontological assumptions (assumptions about the nature of reality and the nature of things) give rise to epistemological assumptions (ways of researching and enquiring into the nature of reality and the nature of things); these, in turn, give rise to methodological considerations; and these, in turn, give rise to issues of instrumentation and data collection. Added to ontology and epistemology is axiology (the values and beliefs that we hold). This view moves us beyond regarding research methods as simply a technical exercise to being concerned with understanding the world; this is informed by how we view our world(s), what we take understanding to be, what we see as the purposes of understanding and what is deemed valuable.

1.2 The search for understanding

People have long been concerned to come to grips with their environment and to understand the nature of the phenomena it presents to their senses. The means by which they set out to achieve these ends may be classified into three broad categories: *experience*, *reasoning* and *research* (Mouly, 1978). Far from being independent and mutually exclusive, however, these categories are complementary and overlapping, features most readily in evidence where solutions to complex problems are sought.

In our endeavours to come to terms with day-to-day living, we are heavily dependent upon experience and authority. However, as tools for uncovering ultimate truth, they have limitations. The limitations of personal

experience in the form of common-sense knowing, for instance, can quickly be exposed when compared with features of the scientific approach to problem solving. Consider, for example, the striking differences in the way in which theories are used. Laypeople base them on haphazard events and use them in a loose and uncritical manner. When they are required to test them, they do so in a selective fashion, often choosing only that evidence which is consistent with their hunches and ignoring that which is counter to them. Scientists, by contrast, construct their theories carefully and systematically. Whatever hypotheses they formulate have to be tested empirically so that their explanations have a firm basis in fact. And there is the concept of control distinguishing the layperson's and the scientist's attitude to experience. Laypeople may make little or no attempt to control any extraneous sources of influence when trying to explain an occurrence. Scientists, on the other hand, only too conscious of the multiplicity of causes for a given occurrence, adopt definite techniques and procedures to isolate and test the effect of one or more of the alleged causes. Finally, there is the difference of attitude to the relationships among phenomena. Laypeople's concerns with such relationships may be loose, unsystematic and uncontrolled; the chance occurrence of two events in close proximity is sufficient reason to predicate a causal link between them. Scientists, however, display a much more serious professional concern with relationships and only as a result of rigorous experimentation, investigation and testing will they postulate a relationship between two phenomena.

People attempt to comprehend the world around them by using three types of reasoning: *deductive reasoning*, *inductive reasoning* and the *combined inductive-deductive* approach. Deductive reasoning is based on the syllogism, which was Aristotle's great contribution to formal logic. In its simplest form the syllogism consists of a major premise based on an a priori or self-evident proposition, a minor premise providing a particular instance, and a conclusion. Thus:

All planets orbit the sun;
The earth is a planet;
Therefore the earth orbits the sun.

The assumption underlying the syllogism is that through a sequence of formal steps of logic, from the general to the particular, a valid conclusion can be deduced from a valid premise. Its chief limitation is that it can handle only certain kinds of statement. The syllogism formed the basis of systematic reasoning from the time of its inception until the Renaissance. Thereafter its effectiveness was diminished because it was no longer related to observation and experience and became merely a mental exercise. One of the consequences of this was that empirical evidence as the basis of proof was superseded by authority and the more authorities one could quote, the stronger one's position became.

The history of reasoning was to undergo a dramatic change in the 1600s when Francis Bacon began to lay increasing stress on the observational basis of science. Being critical of the model of deductive reasoning on the grounds that its major premises were often preconceived notions which inevitably bias the conclusions, he proposed in its place the method of inductive reasoning by means of which the study of a number of individual cases would lead to a hypothesis and eventually to a generalization. Mouly (1978) explains it by suggesting that Bacon's basic premise was that, with sufficient data, even if one does not have a preconceived idea of their significance or meaning, nevertheless important relationships and laws will be discovered by the alert observer.

Of course, there are limits to induction as the accumulation of a series of examples does not *prove* a theory; it only *supports* it. Just because all the swans that I have ever seen are white, it does not prove a theory that all swans are white – one day I might come across a black swan, and my theory is destroyed. Induction places limits on prediction. Discoveries of associations of regularities and frequent repetitions may have limited predictive value. We are reminded of Bertrand Russell's (1959) story of the chicken who observed that he was fed each day by the same man, and, because this had happened every day, it would continue to happen, i.e. the chicken had a theory of being fed, but, as Russell remarks, 'the man who has fed the chicken every day throughout its life at last wrings its neck instead' (p. 35), indicating the limits of prediction based on observation. Or, to put it more formally, theory is underdetermined by empirical evidence (Phillips and Burbules, 2000, p. 17). Indeed Popper (1980) notes that the essence of science, what makes a science a science, is the inherent falsifiability of the propositions (in contrast to the views of the method of science as being one of verifiability, as held by logical positivists).

This is not to discard induction: it is often the starting point for science. Rather, it is to caution against assuming that it 'proves' anything. Bacon's major contribution to science was that he was able to rescue it from the stranglehold of the deductive method whose abuse had brought scientific progress to a standstill. He thus directed the attention of scientists to nature for solutions to people's problems, demanding empirical evidence for verification. Logic and authority in themselves were no longer regarded as conclusive means of

proof and instead became sources of hypotheses about the world and its phenomena.

Bacon's inductive method was eventually followed by the inductive-deductive approach which combines Aristotelian deduction with Baconian induction. Here the researcher is involved in a back-and-forth process of induction (from observation to hypothesis, from the specific to the general) and deduction (from hypothesis to implications) (Mouly, 1978). Hypotheses are tested rigorously and, if necessary, revised.

Although both deduction and induction have their weaknesses, their contributions to the development of science are enormous, for example: (1) the suggestion of hypotheses; (2) the logical development of these hypotheses; and (3) the clarification and interpretation of scientific findings and their synthesis into a conceptual framework.

A further means by which we set out to discover truth is *research*. This has been defined by Kerlinger (1970) as the systematic, controlled, empirical and critical investigation of hypothetical propositions about the presumed relations among natural phenomena. Research has three characteristics in particular, which distinguish it from the first means of problem solving identified earlier, namely, experience. First, whereas experience deals with events occurring in a haphazard manner, research is systematic and controlled, basing its operations on the inductive-deductive model outlined above. Second, research is empirical. The scientist turns to experience for validation. As Kerlinger puts it, subjective, personal belief must have a reality check against objective, empirical facts and tests. And third, research is self-correcting. Not only does the scientific method have built-in mechanisms to protect scientists from error as far as is humanly possible, but also their procedures and results are open to public scrutiny by fellow professionals. Incorrect results in time will be found and either revised or discarded (Mouly, 1978). Research is a combination of both experience and reasoning and, as far as the natural sciences are concerned, is to be regarded as the most successful approach to the discovery of truth (Borg, 1963).[1]

1.3 Conceptions of social reality

The views of social science that we have mentioned represent strikingly different ways of looking at social reality and are constructed on correspondingly different ways of interpreting it. We can perhaps most profitably approach these conceptions of the social world by examining the explicit and implicit assumptions underpinning them. Our analysis is based on the work of Burrell and Morgan (1979), who identified four sets of such assumptions.

First, there are assumptions of an ontological kind – assumptions which concern the very nature or essence of the social phenomena being investigated. Thus, the authors ask, is social reality external to individuals – imposing itself on their consciousness from without – or is it the product of individual consciousness? Is reality of an objective nature, or the result of individual cognition? Is it a given 'out there' in the world, or is it created by one's own mind? Is there a world which exists independent of the individual and which the researcher can observe, discovering relationships, regularities, causal explanations, and which can be tested empirically and repeatedly (i.e. under similar conditions) (cf. Pring, 2015, p. 64)? These questions spring directly from what philosophy terms the nominalist–realist debate. The former view holds that objects of thought are merely words and that there is no independently accessible thing constituting the meaning of a word. The realist position, however, contends that objects have an independent existence and are not dependent for it on the knower. The fact that I can see a dog is not simply because of my perception or cognition but because a dog exists independent of me.

The second set of assumptions identified by Burrell and Morgan are of an epistemological kind. These concern the very bases of knowledge – its nature and forms, how it can be acquired and how communicated to other human beings. How one aligns oneself in this particular debate profoundly affects how one will go about uncovering knowledge of social behaviour. The view that knowledge is hard, objective and tangible will demand of researchers an observer role, together with an allegiance to the methods of natural science; to see knowledge as personal, subjective and unique, however, imposes on researchers an involvement with their subjects and a rejection of the ways of the natural scientist. To subscribe to the former is to be positivist; to the latter, anti-positivist or post-positivist.

The third set of assumptions concern human nature and, in particular, the relationship between human beings and their environment. Since the human being is both its subject and object of study, the consequences for social science of assumptions of this kind are far-reaching. Two images of human beings emerge from such assumptions – the one portrays them as responding mechanically and deterministically to their environment, i.e. as products of the environment, controlled like puppets; the other, as initiators of their own actions with free will and creativity, producing their own environments. The difference is between *determinism* and *voluntarism* respectively (Burrell and Morgan, 1979), between *structure* and *agency*. Human action involves

some combination of these two, polarized here for the sake of conceptual clarity.

It follows from what we have said so far that the three sets of assumptions identified above have direct implications for the methodological concerns of researchers, since the contrasting ontologies, epistemologies and models of human beings will, in turn, suggest different research methods. Investigators adopting an objectivist (or positivist) approach to the social world and who treat it like the world of natural phenomena as being real and external to the individual will choose from a range of options such as surveys, experiments and the like. Others favouring the more subjectivist (or anti-positivist) approach and who view the social world as being of a much more personal and humanly created kind will select from a comparable range of recent and emerging techniques – accounts, participant observation, interpretive approaches and personal constructs, for example.

Where one subscribes to the view which treats the social world like the natural world – as if it were an external and objective reality – then scientific investigation will be directed at analysing the relationships and regularities between selected factors in that world. It will be concerned with identifying and defining elements and discovering ways in which their relationships can be expressed. Hence, methodological issues, of fundamental importance, are thus the concepts themselves, their measurement and the identification of underlying themes in a search for universal laws which explain and govern that which is being observed (Burrell and Morgan, 1979). An approach characterized by procedures and methods designed to discover general laws may be referred to as *nomothetic*. Here is not the place to debate whether social life is 'law-like' (i.e. can be explained by universal laws) in the same way as that mooted in the natural sciences (but see Kincaid, 2004) or whether social life is quintessentially different from the natural sciences such that 'law-like' accounts are simply a search for the impossible and untenable.

However, if one favours the alternative view of social reality which stresses the importance of the subjective experience of individuals in the creation of the social world, then the search for understanding focuses upon different issues and approaches them in different ways. The principal concern is with an *understanding* of the way in which individuals and social groups create, modify and interpret the world in which they find themselves. As Burrell and Morgan (1979) observe, emphasis here is placed on explanation and understanding of the unique and the particular individual cases (however defined: see Chapter 19 on case study, in which emphasis is placed on the denotation of what is the case: an individual, a group, a class, an institution etc.) rather than the general and the universal. In its emphasis on the particular and individual case, this approach to understanding individual (however defined) behaviour may be termed *idiographic*.

In this review of Burrell and Morgan's analysis of the ontological, epistemological, human and methodological assumptions underlying two ways of conceiving social reality, we have laid the foundations for a more extended study of the two contrasting perspectives evident in the practices of researchers investigating human behaviour and, by adoption, educational problems. Figure 1.1 summarizes these assumptions along a subjective/objective dimension. It identifies the four

A scheme for analysing assumptions about the nature of social science

The subjectivist approach to social science				The objectivist approach to social science
Nominalism	←	Ontology	→	Realism
Anti-positivism	←	Epistemology	→	Positivism
Voluntarism	←	Human nature	→	Determinism
Idiographic	←	Methodology	→	Nomothetic

FIGURE 1.1 The subjective-objective dimension

sets of assumptions by using terms we have adopted in the text and by which they are known in the literature of social philosophy.

Each of the two perspectives on the study of human behaviour outlined above has profound implications for research in classrooms and schools. The choice of problem, the formulation of questions to be answered, the characterization of students and teachers, methodological concerns, the kinds of data sought and their mode of treatment, all are influenced by the viewpoint held. Some idea of the considerable practical implications of the contrasting views can be gained by examining Table 1.1, which compares them with respect to a number of critical issues within a broadly societal and

TABLE 1.1 ALTERNATIVE BASES FOR INTERPRETING SOCIAL REALITY

	Conceptions of social reality	
Dimensions of comparison	*Objectivist*	*Subjectivist*
Philosophical basis	Realism: the world exists and is knowable as it really is. Organizations are real entities with a life of their own.	Idealism: the world exists but different people construe it in very different ways. Organizations are invented social reality.
The role of social science	Discovering the universal laws of society and human conduct within it.	Discovering how different people interpret the world in which they live.
Basic units of social reality	The collectivity: society or organizations.	Individuals acting singly or together.
Methods of understanding	Identifying conditions or relationships which permit the collectivity to exist. Conceiving what these conditions and relationships are.	Interpretation of the subjective meanings which individuals place upon their action. Discovering the subjective rules for such action.
Theory	A rational edifice built by scientists to explain human behaviour.	Sets of meanings which people use to make sense of their world and behaviour within it.
Research	Experimental or quasi-experimental validation of theory.	The search for meaningful relationships and the discovery of their consequences for action.
Methodology	Abstraction of reality, especially through mathematical models and quantitative analysis.	The representation of reality for purposes of comparison. Analysis of language and meaning.
Society	Ordered. Governed by a uniform set of values and made possible only by those values.	Conflicted. Governed by the values of people with access to power.
Organizations	Goal oriented. Independent of people. Instruments of order in society serving both society and the individual.	Dependent upon people and their goals. Instruments of power which some people control and can use to attain ends which seem good to them.
Organizational pathologies	Organizations get out of kilter with social values and individual needs.	Given diverse human ends, there is always conflict among people acting to pursue them.
Prescription for change	Change the structure of the organization to meet social values and individual needs.	Find out what values are embodied in organizational action and whose they are. Change the people or change their values if you can.

organizational framework. Implications of the two perspectives for educational research unfolds in the course of the text.

1.4 Paradigms

Educational research has absorbed several competing views of the social sciences – the scientific view and an interpretive view – and several others that we explore in this book, including critical theory and feminist theory. Some views hold that the social sciences are essentially the same as the natural sciences and are therefore concerned with discovering natural and universal laws regulating and determining individual and social behaviour. The interpretive view, however, while sharing the rigour of the natural sciences and the concern of social science to describe and explain human behaviour, emphasizes how people differ from inanimate natural phenomena and, indeed, from each other. These contending views – and also their corresponding reflections in educational research – stem in the first instance from different conceptions of social realities and of individual and social behaviour. We examine these in a little more detail.

Since the groundbreaking work of Kuhn (1962), approaches to methodology in research have been informed by discussions of 'paradigms' and communities of scholars. A paradigm is a way of looking at or researching phenomena, a world view, a view of what counts as accepted or correct scientific knowledge or way of working, an 'accepted model or pattern' (Kuhn, 1962, p. 23), a shared belief system or set of principles, the identity of a research community, a way of pursuing knowledge, consensus on what problems are to be investigated and how to investigate them, typical solutions to problems, and an understanding that is more acceptable than its rivals.

A notable example of this is the old paradigm that placed the Earth at the centre of the universe, only to be replaced by the Copernican heliocentric model, as evidence and explanation became more persuasive of the new paradigm. Importantly, one has to note that the old orthodoxy retained its value for generations because it was supported by respected and powerful scientists and, indeed, others (witness the attempts made by the Catholic Church to silence Galileo in his advocacy of the heliocentric model of the universe). Another example is where the Newtonian view of the mechanical universe has been replaced by the Einsteinian view of a relativistic, evolving universe. More recently still, the idea of a value-free, neutral, objective, positivist science has been replaced by a post-positivist, critical realist view of science with its hallmarks of conjecture and refutation (Popper, 1980) and with the ability for falsification being the distinguishing feature of science. Further, social science has recognized the importance of the (subjective) value systems of researchers, phenomenology, subjectivity, the need for reflexivity in research (discussed later in this book), the value of qualitative and mixed methods approaches to research, and the contribution of critical theory and feminist approaches to research methodologies and principles.

Paradigms are not simply methodologies (Hammersley, 2013, p. 15); they are ways of looking at the world, different assumptions about what the world is like and how we can understand or know about it. This raises the question of whether paradigms can live together, whether they are compatible or, since they constitute fundamentally different ways of looking at the world, they are incommensurate (which raises questions for mixed methods research – see Chapter 2). At issue here is the significance of regarding approaches to research as underpinned by different paradigms, an important characteristic of which is their incommensurability with each other (i.e. one cannot hold two distinct paradigms simultaneously as there are no common principles, standards or measures).

As more knowledge is acquired to challenge an existing paradigm, such that the original paradigm cannot explain a phenomenon as well as the new paradigm, there comes about a 'scientific revolution', a paradigm shift, in which the new paradigm replaces the old as the orthodoxy – the 'normal science' – of the day. Kuhn's (1962) notions of paradigms and paradigm shifts link here objects of study and communities of scholars, where the field of knowledge or paradigm is seen to be only as good as the evidence and the respect in which it is held by 'authorities'.

Part 1 sets out several paradigms of educational research and these are introduced in Chapters 1 to 3.

Social science research is marked by paradigmatic pluralism and multiple ways of construing paradigms. For example, Pring (2015) contrasts two paradigms (pp. 63–74). The first paradigm espouses the view that there is an objective reality which exists independent of the individual and comprises causally interacting elements which are available for observation; that different sciences (e.g. social, physical) can be used to define that reality once consensus has been reached on what that objective reality is; that the research is replicable and cumulative, i.e. a scientifically rooted body of knowledge can be gathered and checked for correspondence to the world as it is (the correspondence theory of truth) (pp. 63–4). Such a view resonates with Hammersley's (2013) summary of quantitative research which is characterized by hypothesis testing, numerical

data, 'procedural objectivity', generalization, the identification of 'systematic patterns of association' and the isolation and control of variables (pp. 10–11).

The second paradigm, by contrast, espouses the view that the world consists of ideas, i.e. a social construction, and that researchers are part of the world which they are researching, that meanings are negotiated between participants (including the researcher), that an objective test of truth is replaced by a consensus theory of truth, that ideas of the world do not exist independently of those who hold them (i.e. require a redefinition of 'objective' and 'subjective'), that multiple realities exist and that what is being researched is context-specific (Pring, 2015, pp. 65–6). Such a view accords with Hammersley's definition of qualitative research as that which uses less structured data, which emphasizes the central place of subjectivity in the research process and which studies 'a small number of naturally occurring cases in detail' using verbal rather than statistical analysis (Hammersley, 2013, p. 12).

However, Pring's (2015) point is not simply to set out these two paradigms, but to argue that they constitute a false dualism that should be rejected, as they artificially compel the researcher to make an either/or choice of paradigms and, thereby, misrepresent the world as multiply meaningful and both independent of and part of the researcher, not only a social construction. He argues (p. 69) that, just as an independent physical world must exist in order for researchers to construe it, the same can be said of the social world – there must be independent actors and social worlds in order for apperception and social construction of it to make sense.

Pring cautions against adopting a priori either a quantitative or qualitative view of the world as this massively over-simplifies the real world, which is complex and complicated. Rather, how we pursue the research depends on what the research is about, and this recognizes that social constructions vary from social group to social group and humans can be both the object and subject of research (2015, p. 73).

Pring is not alone in characterizing different paradigms of educational research. For example, Creswell (2013) notes four 'philosophical worldviews' (pp. 7ff.): post-positivism, constructivism, advocacy/participatory and pragmatism. These are discussed in Chapters 2 and 3. Here we note that the advocacy/participatory paradigm concerns the disempowered and marginalized, and it studies oppression and lack of voice; this brings it under the umbrella of critical approaches which we discuss in Chapter 3, including gender, race, ethnicity, disability, sexual orientation, socio-economic status and differentials of power that prop up inequality.

Lather (2004) sets out four paradigms: prediction (positivism); understanding (interpretive approaches); emancipatory (critical theoretical approaches); and deconstruction (post-structuralist). We discuss these in Chapters 1 to 3. Lukenchuk (2013) identifies six paradigms which, she notes, are not exhaustive (pp. 66ff.):

- Empirical-analytic (empiricist; scientific; concerned with prediction and control; quantitative; experimental; correlational; causal; explanatory; probabilistic; fallibilistic; concerned with warrants for knowledge claims; quantitative);
- Pragmatic (focus on 'what works'; trial and error; problem-centred; practical; experimental; action oriented; utility oriented; practitioner research; qualitative and quantitative);
- Interpretive (hermeneutic and existential understanding; meaning-making; phenomenological; qualitative; naturalistic; constructivist; interactionist; verstehen approaches; ethnographic; qualitative);
- Critical (ideology-critical; concerned with analysis of power and ideology; consciousness-raising; emancipatory and concerned with advocacy/participatory approaches; transformatory; politically oriented and activist; qualitative and quantitative);
- Post-structuralist (anti-foundation knowledge; deconstructionist; interpretation of life as discourse and texts; transformative; qualitative);
- Transcendental (asserts reason, intuition, mysticism, revelation as ways of knowing: mind, body, soul and spirit; life as directed by an 'internal moral compass'; foundational; qualitative).

This is not to say that paradigms necessarily *drive* the research, as research is driven by the purposes of the research. Indeed we can ask whether we need paradigmatic thinking at all in order to do research. Rather, it is to say that the purposes and nature of the research may be clarified by drawing on one or more of these paradigms; the paradigms can clarify and organize the thinking about the research. Further, it is not to say that these paradigms each have an undisputed coherence, unity or unproblematic singularity of conception. Rather, they are characterizations, ideal types, typifications and simplifications for ease of initial understanding, recognizing that this blurs the many variations that lie within each of them, and, indeed, may overlook the overlaps between them; each paradigm is not all of a single type and they are by no means mutually exclusive. To consider them as mutually exclusive is to prolong the unnecessary 'paradigm wars' to which Gage (1989) alluded so compellingly.

Because of its significance for the epistemological basis of social science and its consequences for educational research, we devote discussion in this chapter to the debate on positivism and anti-positivism/post-positivism, and on alternative paradigms and rationales for understanding educational research.

1.5 Positivism

Although positivism has been a recurrent theme in the history of western thought from the Ancient Greeks to the present, it is historically associated with the nineteenth-century French philosopher, Auguste Comte, who was the first thinker to use the word for a philosophical position (Beck, 1979) and who gave rise to sociology as a distinct discipline. His positivism turns to observation and reason as means of understanding behaviour, i.e. empirical observation and verification; explanation proceeds by way of scientific description. In his study of the history of the philosophy and methodology of science, Oldroyd (1986) says that, in this view, social phenomena could be researched in ways similar to natural, physical phenomena, i.e. generating laws and theories that could be investigated empirically.

Comte's position was to lead to a general doctrine of positivism which held that all genuine knowledge is based on sensory experience and can only be advanced by means of observation and experiment: the scientific method. Following in the empiricist tradition, it limited enquiry and belief to what can be firmly established and in thus abandoning metaphysical and speculative attempts to gain knowledge by reason alone, the movement developed a rigorous orientation to social facts and natural phenomena to be investigated empirically (Beck, 1979). Taking account of this, matters of values were out of court for the positivist, as they were not susceptible to observation evidence, i.e. there is a separation between facts and values.

With its emphasis on observational evidence and the scientific method, positivism accords significance to sensory experience (empiricism), observational description (e.g. ruling our inferences about actors' intentions, thoughts or attitudes), operationalism, 'methodical control', measurement, hypothesis testing and replicability through the specification of explicit and transparent procedures for conducting research (Hammersley, 2013, pp. 23–4). Hammersley notes that the terms 'positivism' and 'empiricism' are often regarded as synonymous with each other (p. 23), but to equate positivism simply with quantitative approaches is misguided, as qualitative data are equally well embraced within empiricism. Indeed he notes that ethnographers and discourse analysts rely on careful observational data (pp. 24–5).

Though the term positivism is used by philosophers and social scientists, a residual meaning derives from an acceptance of natural science as the paradigm of human knowledge (Duncan, 1968). This includes the following connected suppositions, identified by Giddens (1975). First, the methodological procedures of natural science may be directly applied to the social sciences. Positivism here implies a particular stance concerning the social scientist as an observer of social reality. Second, the end-product of investigations by social scientists can be formulated in terms parallel to those of natural science. This means that their analyses must be expressed in laws or law-like generalizations of the same kind that have been established in relation to natural phenomena. Positivism claims that science provides us with the clearest possible ideal of knowledge.

Where positivism is less successful, however, is in its application to the study of human behaviour, where the immense complexity of human nature and the elusive and intangible quality of social phenomena contrast strikingly with the order and regularity of the natural world. This point is apparent in the contexts of classrooms and schools where the problems of teaching, learning and human interaction present the positivistic researcher with a mammoth challenge.

We now look more closely at some of the features of the scientific method that is underpinned by positivism.

1.6 The assumptions and nature of science

We begin with an examination of the tenets of scientific faith: the kinds of assumptions held by scientists, often implicitly, as they go about their daily work. First, there is the assumption of *determinism*. This means simply that events have causes; that events are determined by other circumstances; and science proceeds on the belief that these causal links can eventually be uncovered and understood. Moreover, not only are events in the natural world determined by other circumstances, but there is regularity about the way in which they are determined: the universe does not behave capriciously. It is the ultimate aim of scientists to formulate laws to account for the happenings in the world, thus giving them a firm basis for prediction and control.

The second assumption is that of *empiricism*, which holds that certain kinds of reliable knowledge can only derive from experience. This is an example of foundationalism. In this case, to quote the philosopher John

Locke (1959): 'whence has it [the mind] all the materials of reason and knowledge? To this, I answer, in one word, from experience. In that all knowledge is founded; and from that it ultimately derives itself' (p. 26). Experience means sensory experience, and this contrasts with the rationalist epistemology in which reason rules supreme. In empiricism, experience alone provides the warrant for, or justification of, a knowledge claim, which is brought to the scientific community for acceptance. Such empiricism gives rise to the need for the operationalization of concepts, for example, creativity, intelligence, ability (Phillips and Burbules, 2000, p. 10), in order for them to be observable. Empiricism (and positivism) does not preclude non-experimental studies, nor does it prescribe only quantitative research.

In practice, empiricism means scientifically that the tenability of a theory or hypothesis depends on the nature of the empirical evidence for its support. 'Empirical' here means that which is verifiable by observation, direct experience and evidence, data-yielding proof or strong confirmation, in probability terms, of a theory or hypothesis in a research setting.

Mouly (1978) identifies five steps in the process of empirical science:

1. *Experience* – the starting point of scientific endeavour at the most elementary level;
2. *Classification* – the formal systematization of otherwise incomprehensible masses of data;
3. *Quantification* – a more sophisticated stage where precision of measurement allows more adequate analysis of phenomena by mathematical means;
4. *Discovery of relationships* – the identification and classification of functional relationships among phenomena;
5. *Approximation to the truth* – science proceeds by gradual approximation to the truth.

The third assumption underlying the work of the scientist is the principle of *parsimony*. The basic idea is that phenomena should be explained in the most economical way possible. As Einstein was known to remark, one should make matters as simple as possible, but no simpler! The first historical statement of the principle was by William of Occam when he said that explanatory principles (entities) should not be needlessly multiplied ('Occam's razor'), i.e. that it is preferable to account for a phenomenon by two concepts rather than three; that a simple theory is to be preferred to a complex one.

The final assumption, that of *generality*, played an important part in both the deductive and inductive methods of reasoning. Indeed, historically speaking, it was the problematic relationship between the concrete particular and the abstract general that was to result in two competing theories of knowledge – the rational and the empirical. Beginning with observations of the particular, scientists set out to generalize their findings to the world at large. This is because they are concerned ultimately with explanation. Of course, the concept of generality presents much less of a problem to natural scientists working chiefly with inanimate matter than to human scientists who, of necessity having to deal with samples of larger human populations, must exercise great caution when generalizing their findings to the particular parent populations.

We come now to the core question: What is science? Kerlinger (1970) points out that in the scientific world itself two broad views of science may be found: the *static* and the *dynamic*. The *static* view, which has particular appeal for laypeople, is that science is an activity that contributes systematized information to the world. The work of the scientist is to uncover new facts and add them to the existing corpus of knowledge. Science is thus seen as an accumulated body of

BOX 1.1 THE FUNCTIONS OF SCIENCE

1. Its problem-seeking, question-asking, hunch-encouraging, hypotheses-producing function.
2. Its testing, checking, certifying function; its trying out and testing of hypotheses; its repetition and checking of experiments; its piling up of facts.
3. Its organizing, theorizing, structuring function; its search for larger and larger generalizations.
4. Its history-collecting, scholarly function.
5. Its technological side; instruments, methods, techniques.
6. Its administrative, executive and organizational side.
7. Its publicizing and educational functions.
8. Its applications to human use.
9. Its appreciation, enjoyment, celebration and glorification.

Source: Maslow (1954)

findings, the emphasis being chiefly on the present state of knowledge and adding to it.[2] The *dynamic* view, by contrast, conceives science more as an activity, as something that scientists *do*. According to this conception it is important to have an accumulated body of knowledge of course, but what really matter most are the discoveries that scientists make. The emphasis here, then, is more on the heuristic nature of science.

Contrasting views exist on the functions of science. We give a composite summary of these in Box 1.1. For professional scientists, however, science is seen as a way of comprehending the world; as a means of explanation and understanding, of prediction and control. For them the ultimate aim of science is theory, and we discuss this in Chapter 4.

We look now in more detail at two such tools which play a crucial role in science – the concept and the hypothesis.

1.7 The tools of science

Concepts express generalizations from particulars – anger, achievement, alienation, velocity, intelligence, democracy. Examining these examples more closely, we see that each is a word representing an idea: more accurately, a concept is the relationship between the word (or symbol) and an idea or conception. Whoever we are and whatever we do, we all make use of concepts. Naturally, some are shared and used by all groups of people within the same culture – child, love, justice, for example; others, however, have a restricted currency and are used only by certain groups, specialists or members of professions – idioglossia, retroactive inhibition, anticipatory socialization.

Concepts enable us to impose some sort of meaning on the world; through them reality is given sense, order and coherence. They are the means by which we are able to come to terms with our experience. How we perceive the world, then, is highly dependent on the repertoire of concepts that we have. The more we have, the more sense data we can pick up and the surer will be our perceptual (and cognitive) grasp of whatever is 'out there'. If our perceptions of the world are determined by the concepts available to us, it follows that people with differing sets of concepts will tend to view the 'same' objective reality differently – a doctor diagnosing an illness will draw upon a vastly different range of concepts from, say, the restricted and perhaps simplistic notions of the layperson in that context.

So where is all this leading? Simply to this: social scientists have likewise developed, or appropriated by giving precise meaning to, a set of concepts which enable them to shape their perceptions of the world in a particular way, to represent that slice of reality which is their special study. And collectively, these concepts form part of their wider meaning system which permits them to give accounts of that reality, accounts which are rooted and validated in the direct experience of everyday life, for example, the concept of social class which offers researchers 'a rule, a grid, even though vague at times, to use in talking about certain sorts of experience that have to do with economic position, lifestyle, life-chances, and so on' (Hughes, 1976, p. 34).

There are two important points to stress when considering scientific concepts. The first is that they do not exist independently of us: they are our inventions, enabling us to acquire some understanding of nature. The second is that they are limited in number and in this way contrast with the infinite number of phenomena they are required to explain.

A second tool of great importance to the scientist is the *hypothesis*. It is from this that much research proceeds, especially where cause-and-effect or concomitant relationships are being investigated. The hypothesis has been defined by Kerlinger (1970) as a conjectural statement of the relations between two or more variables, or 'an educated guess', though it is unlike an educated guess in that it is often the result of considerable study, reflective thinking and observation. Medawar (1972) writes of the hypothesis and its function as being speculative and imaginative preconceptions or conjectures about what might be true, which are subject to criticism to see if they really are like the phenomenon in question. As he remarks, scientific reasoning is a dialogue between the 'imaginative and the critical', the 'possible and the actual', between 'what might be true and what is in fact the case' (Medawar, 1972, p. 22).

Kerlinger (1970) has identified two criteria for 'good' hypotheses. The first is that hypotheses are statements about the relations between variables; and second, that hypotheses carry clear implications for testing the stated relations. To these he adds two ancillary criteria: that hypotheses disclose compatibility with current knowledge; and that they are expressed as economically as possible. Thus if we conjecture that social class background determines academic achievement, we have a relationship between one variable, social class, and another, academic achievement. And since both can be measured, the primary criteria specified by Kerlinger can be met. Neither do they violate the ancillary criteria he proposed (see also Box 1.2).

Kerlinger further identifies four reasons for the importance of hypotheses as tools of research. First, they organize the efforts of researchers. The relationship expressed in the hypothesis indicates what they should do. They enable them to understand the problem

BOX 1.2 THE HYPOTHESIS

Once one has a hypothesis to work on, the scientist can move forward; the hypothesis will guide the researcher on the selection of some observations rather than others and will suggest experiments. Scientists soon learn by experience the characteristics of a good hypothesis. A hypothesis that is so loose as to accommodate *any* phenomenon tells us precisely nothing; the more phenomena it prohibits, the more informative it is.

A good hypothesis must also have *logical immediacy*, i.e. it must provide an explanation of whatever it is that needs to be explained and not an explanation of other phenomena. Logical immediacy in a hypothesis means that it can be tested by comparatively direct and practicable means. A large part of the *art of the soluble* is the art of devising hypotheses that can be tested by practicable experiments.

Source: Adapted from Medawar (1981)

with greater clarity and provide them with a framework for collecting, analysing and interpreting their data. Second, they are, in Kerlinger's words, the working instruments of theory. They can be deduced from theory or from other hypotheses. Third, they can be tested, empirically or experimentally, resulting in confirmation or rejection. And there is always the possibility that a hypothesis, once supported and established, may become a law. And fourth, hypotheses are powerful tools for the advancement of knowledge because, as Kerlinger explains, they enable us to get outside ourselves. Hypotheses and concepts play a crucial part in the scientific method and it is to this that we now turn our attention.

1.8 The scientific method

If the most distinctive feature of science is its empirical nature, the next most important characteristic is its set of procedures which show not only how findings have been arrived at, but are sufficiently clear for fellow-scientists to repeat them, i.e. to check them out with the same or other materials and thereby test the results. As Cuff and Payne (1979) say: 'A scientific approach necessarily involves standards and procedures for demonstrating the "empirical warrant" of its findings, showing the match or fit between its statements and what is happening or has happened in the world' (Cuff and Payne, 1979, p. 4). For convenience we will call these standards and procedures 'the scientific method', though this can be somewhat misleading, as the combination of the definite article, adjective and singular noun risks conjuring up a single invariant approach to problem solving. Yet there is much more to it than this. The term in fact cloaks a number of methods which vary in their degree of sophistication depending on their function and the particular stage of development a science has reached.

The scientific method initially involves systematic observation, moving to interconnecting ideas coherently and without internal contradictions (creating a scientific model), which is then tested by further observations (Capra and Luisi, 2014). Box 1.3 sets out the sequence of stages through which a science normally passes in its development or, perhaps more realistically, that are constantly present in its progress and on which scientists may draw depending on the kind of information they seek or the kind of problem confronting them.

BOX 1.3 STAGES IN THE DEVELOPMENT OF A SCIENCE

1. Definition of the science and identification of the phenomena that are to be subsumed under it.
2. Observational stage at which the relevant factors, variables or items are identified and labelled; and at which categories and taxonomies are developed.
3. Correlational research in which variables and parameters are related to one another and information is systematically integrated as theories begin to develop.
4. The systematic and controlled manipulation of variables to see if experiments will produce expected results, thus moving from correlation to causality.
5. The firm establishment of a body of theory as the outcomes of the earlier stages are accumulated. Depending on the nature of the phenomena under scrutiny, laws may be formulated and systematized.
6. The use of the established body of theory in the resolution of problems or as a source of further hypotheses.

Of particular interest in our efforts to elucidate the term 'scientific method' are stages 2, 3 and 4. Stage 2 is a relatively uncomplicated point at which the researcher is content to observe and record facts and possibly arrive at some system of classification. Much research in the field of education is conducted in this way, for example, surveys and case studies. Stage 3 establishes relationships between variables within a loose framework of inchoate theory. Stage 4 is the most sophisticated stage and often the one that many people equate exclusively with the scientific method. In order to arrive at causality, as distinct from mere measures of association, researchers here design experimental situations in which variables are manipulated to test their chosen hypotheses. This process moves from early, inchoate ideas, to more rigorous hypotheses, to empirical testing of those hypotheses, thence to confirmation or modification of the hypotheses (Kerlinger, 1970).

Hitchcock and Hughes (1995, p. 23) suggest an eight-stage model of the scientific method that echoes Kerlinger. This is represented in Box 1.4.

The elements the researchers fasten on to will naturally be suitable for scientific formulation; this means simply that they will possess quantitative aspects. Their principal working tool will be the hypothesis which, as we have seen, is a statement indicating a relationship (or its absence) between two or more of the chosen elements and stated in such a way as to carry clear implications for testing. Researchers then choose the most appropriate method and put their hypotheses to the test.

1.9 Criticisms of positivism and the scientific method

In spite of the scientific enterprise's proven success using positivism – especially in the field of natural science – its ontological and epistemological bases have been the focus of sustained and sometimes vehement criticism from some quarters. Beginning in the second half of the nineteenth century, the revolt against positivism occurred on a broad front. Essentially, it has been a reaction against the world picture projected by science which, it is contended, undermines life and mind. The precise target of the anti-positivists' attack has been science's mechanistic and reductionist view of nature which, by definition, regards life in measurable terms rather than inner experience, and excludes notions of choice, freedom, individuality and moral responsibility, regarding the universe as a living organism rather than as a machine (e.g. Nesfield-Cookson, 1987).

Here the putative objectivity of science is called into question, and objectivity is treated as problematic. Kettley (2012), for example, notes that objective knowledge is often treated as unproblematic and viewed through simplistic, unacceptably reductionist lenses in which empiricism is reduced to knowing through observation, positivism is viewed as Comte's rebuttal of metaphysics, that there is a unity between the scientific method and Durkheim's positivism, and realism is a synonym for undisputed existence (p. 71). However, he contends, objective knowledge is actually contested, subjective meanings affect or refract views of what are generally considered to be objective knowledge and objectivity (e.g. social facts) which do not necessarily reside in the phenomenon itself but in the subjective values of the researcher (p. 72), and that equating the scientific methods with positivism overlooks the important distinction between induction and deduction. Douglas (2004) notes that the very term 'objective' is fraught with definitional problems, and he gives several senses in which it is used, including, for example: manipulable, detached, procedural, value-neutral and value-free.

The point is well made: objectivity and objective knowledge are beset with problems, and researchers are well advised to avoid simple dichotomies or absolutist ideal types: objective or subjective, induction or deduction, quantitative or qualitative. Rather, there is no unified objectivist or subjectivist paradigm (Kettley,

BOX 1.4 AN EIGHT-STAGE MODEL OF THE SCIENTIFIC METHOD

Stage 1: Hypotheses, hunches and guesses
Stage 2: Experiment designed; samples taken; variables isolated
Stage 3: Correlations observed; patterns identified
Stage 4: Hypotheses formed to explain regularities
Stage 5: Explanations and predictions tested; falsifiability
Stage 6: Laws developed or disconfirmation (hypothesis rejected)
Stage 7: Generalizations made
Stage 8: New theories

2012, p. 76); objective reality is constructed subjectively; positivism is not a unified, singular, coherent tenet; hypothesis formation is a human act that derives in part from the subjective views of the researcher (and these subjective views can differ sharply); aggregated data do not override or negate the constructions and meanings accorded to a situation by individuals; and the assumption of linear relationships is frustrated by a non-linear world (pp. 76–7).

Another challenge to the claims of positivism came from Søren Kierkegaard, the Danish philosopher, one of the originators of existentialism. Kierkegaard was concerned with individuals and their need to fulfil themselves to the highest level of development. This realization of a person's potential was for him the meaning of existence which he saw as concrete and individual, unique and irreducible, not amenable to conceptualization (Beck, 1979). Features of the age in which we live – the ascendancy of scientific and technological progress – militate against the achievement of this end and contribute to the dehumanization of the individual. In his desire to free people from their illusions, the illusion Kierkegaard was most concerned about was that of objectivity. By this he meant the imposition of rules of behaviour and thought, and the making of a person into an observer set on discovering general laws governing human behaviour. The capacity for subjectivity, he argued, should be regained and retained. This he regarded as the ability to consider one's own relationship to whatever constitutes the focus of enquiry.

Also concerned with the dehumanizing effects of the social sciences is Ions (1977). While acknowledging that they can take much credit for throwing light in dark corners, he expresses serious concern at the way in which quantification and computation, assisted by statistical theory and method, are used. He argues that quantification is a form of collectivism, but that this runs the risk of depersonalization. His objection is not directed at quantification per se, but at quantification when it becomes an end in itself, replacing humane study which seeks to investigate and shed light on the human condition (Ions, 1977). This echoes Horkheimer's (1972) powerful critique of positivism as the mathematization of concepts about nature and of scientism – science's belief in itself as the only way of conducting research and explaining phenomena.

Another forceful critic of the objective consciousness has been Roszak (1970, 1972), who argues that science, in its pursuit of objectivity, is a form of alienation from our true selves and from nature. The justification for any intellectual activity lies in the effect it has on increasing our awareness and degree of consciousness, but this increase, some claim, has been retarded in our time by the excessive influence that the positivist paradigm has exerted on areas of our intellectual life. Holbrook (1977), for example, affording consciousness a central position in human existence and deeply concerned with what happens to it, condemns positivism and empiricism for their bankruptcy of the inner world, morality and subjectivity.

Hampden-Turner (1970) concludes that the social science view of human beings is a restricted image of humans when social scientists concentrate on the repetitive, predictable and invariant aspects of the person; on 'visible externalities' to the exclusion of the subjective world; and on the parts of the person in their endeavours to understand the whole.

Habermas (1972), in keeping with the Frankfurt School of critical theory (discussed in Chapter 3), provides a corrosive critique of positivism, arguing that the scientific mentality has been elevated to an almost unassailable position – almost to the level of a religion (scientism) – as being the only epistemology of the west. In this view all knowledge becomes equated with scientific knowledge. This neglects hermeneutic, aesthetic, critical, moral, creative and other forms of knowledge. It reduces behaviour to technicism.

Positivism's concern for control and, thereby, its appeal to the passivity of behaviourism and for instrumental reason is a serious danger to the more open-ended, creative, humanitarian aspects of social behaviour. Habermas (1972, 1974) and Horkheimer (1972) argue that scientism silences an important debate about values, informed opinion, moral judgements and beliefs. Scientific explanation seems to be the only means of explaining behaviour, and, for them, this seriously diminishes the very characteristics that make humans human. It makes for a society without conscience. Positivism is unable to answer many interesting or important areas of life (Habermas, 1972, p. 300), resonating with Wittgenstein's (1974) comment that when all possible scientific questions have been addressed, they have left untouched the main problems of life.

Other criticisms are commonly levelled at positivistic social science. One is that it fails to take account of our unique ability to interpret our experiences and represent them to ourselves. How we make sense of the social world resides in our distinctively human nature, and we have to take account of this in recognizing that the social world is not the same as an object of science (Pring, 2015, p. 115) (though Durkheim noted that there are 'social facts', i.e. those that transcend individuals' interpretations and constructions). We can, and do, construct theories about ourselves and our world,

and we act on these theories. In failing to recognize this, positivistic social science is said to ignore the profound differences between itself and the natural sciences. Social science, unlike natural science, stands in a subject–subject rather than a subject–object relation to its field of study, and works in a pre-interpreted world in the sense that the meanings that subjects hold are part of their construction of the world (Giddens, 1976).

The difficulty in which positivism finds itself is that it regards human behaviour as passive, essentially determined and controlled, thereby ignoring intention, individualism and freedom, i.e. as suffering from the same difficulties that inhere in behaviourism (see Chomsky's (1959) withering criticism). This problem with positivism also rehearses the familiar problem in social theory, namely, the tension between agency and structure (Layder, 1994): humans exercise agency – individual choice and intention – not necessarily in circumstances of their own choosing, but nevertheless they do not behave simply or deterministically like puppets.

Finally, the findings of positivistic social science are often said to be so banal and trivial that they are of little consequence to those for whom they are intended, namely, teachers, social workers, counsellors, managers and the like. The more effort, it seems, that researchers put into their scientific experimentation in the laboratory by restricting, simplifying and controlling variables, the more likely they are to end up with a stripped down, artificial, deterministic view of the world as if it were a laboratory.[3]

These are formidable criticisms; but what alternatives are proposed by the detractors of positivistic social science?

1.10 Post-positivism

The positivist view of the world is of an ordered, controllable, predictable, standardized, mechanistic, deterministic, stable, objective, rational, impersonal, largely inflexible, closed system whose study yields immutable, absolute, universal laws and patterns of behaviour (a 'grand narrative', a 'metanarrative') and which can be studied straightforwardly through the empirical, observational means of the scientific method. It suggests that there are laws of cause and effect, often of a linear nature (a specific cause produces a predictable effect, a small cause (stimulus) produces a small effect (response) and a large cause produces a large effect), which can be understood typically through the application of the scientific method as set out earlier in this chapter. Like a piece of clockwork, there is a place for everything and everything is in its place. It argues for an external and largely singular view of an objective reality (i.e. external to, and independent of, the researcher) that is susceptible to scientific discovery and laws. However, as Lukenchuk (2013) notes, positivism has been discarded as a useful scientific paradigm as it has failed to provide a 'logically unified system of theoretical statements grounded in the certainty of sense experience' (p. 16) and has been superseded by post-positivism.

Post-positivists challenge the positivist view of the world. Here, following Popper (1968, 1980), our knowledge of the world is not absolute but partial, conjectural, falsifiable, challengeable, provisional, probabilistic and changing. Whilst still embracing the scientific method and the acceptance of an objective world, it recognizes that there is no absolute truth, or, at least, not one which is discoverable by humans, but, rather, probabilistic knowledge only. Secure, once-and-for-all foundational knowledge and grand narratives of a singular objective reality, discoverable through empiricism, positivism, behaviourism and rationalism, are replaced by tentative speculation in which multiple perspectives, claims and warrants are brought forward by the researcher (Phillips and Burbules, 2000). The world is multilayered, able to tolerate multiple interpretations, and in which – depending on the particular view of post-positivism that is being embraced – there exist multiple external realities; knowledge is regarded as subjective rather than objective. In short, the values, biographies, perceptions, theories, environment and existing knowledge of researchers influence what is being observed, and this undermines the foundationalism of empiricism with its claims to neutral sensory experience and observation (Phillips and Burbules, 2000, p. 17). As mentioned earlier, theory is underdetermined by evidence, as the same evidence can support several different theories.

Post-positivists argue that facts and observations are theory-laden and value-laden (Feyerabend, 1975; Popper, 1980; Reichardt and Rallis, 1994), facts and theories are fallible, different theories may support specific observations/facts, and social facts, even ways of thinking and observing, are social constructions rather than objectively and universally true (Nisbett, 2005).

Imagine that a researcher observes a class lesson and notices one student winking at the teacher. Is this student being cheeky (a theory of deviant or challenging behaviour), a sign of understanding (a theory of cognition/recognition), a physical problem (Tourette's syndrome), a sign of stress or happiness (a theory of emotional behaviour), a sign of friendliness (a theory of interpersonal non-verbal behaviour), or what? The

observation on its own cannot tell us. There is a gap between an observed phenomenon and the explanation or theory of, or a hypothesis about, the phenomenon. As Phillips and Burbules (2000, pp. 18–19) remark, phenomena do not speak for themselves. This gap cannot be bridged by observed evidence alone, but needs help from outside that observed phenomenon, i.e. from non-sensory experience. What we see depends on our viewpoint. This is not to say that there is no correct answer or that multiple interpretations are acceptable (relativism), only that the observation alone is not sufficient to denote meaning.

Out goes foundational knowledge and in comes non-foundational, tentative, conjectural speculation and probabilistic, fallibilistic, imperfect, context-bound knowledge of multiple truths of a situation and multiple realities, whose validity has to be warranted whilst recognizing that such warrants may be overturned in light of future evidence. Here the separation of fact and value in positivism is unsustainable, and the foundationalism of empiricism is replaced by an admission that observation is theory-laden, and our values, perspectives, paradigms, conceptual schemes, even research communities determine what we focus on, how we research, what we deem to be important, what counts as knowledge, what research 'shows', how we interpret research findings and what constitutes 'good' research.

Post-positivism argues for the continuing existence of an objective reality, i.e. it rejects relativism, but it adopts a pluralist view of multiple, coexisting realities rather than a single reality. Imagine that two people are observing a classroom; one sits at the back of the room, and the other at the front. What they see may differ, but it is still the same classroom. Multiple views are not the same as relativism; multiple truths can coexist. There is an objective reality: the classroom, but there are different views of this, i.e. 'truth' is not simply what one of the observers takes it to be, and one frame of reference may differ from another. This raises the issue of bias and value-neutrality in educational research, which we discuss in Chapter 3.

Post-positivism recognizes that we know the world only probabilistically and imperfectly. Whilst not rejecting the value of the scientific method (e.g. experimentation), it argues for the reformulation of the strength of theories and claims made from the scientific method, namely, that their strengths are contingent on their ability to withstand 'severe tests' of their falsifiability and that their discoveries are subject to future falsification in the light of new evidence. Seen in this light, the gap between natural sciences and social science evaporates. In the post-positivist view of science, characterized by the theory-laden nature of observations, the underdetermination of theory by empirical evidence, the importance of the community of scholars in validating warrants for knowledge, the tentative, conjectural nature of conclusions, and the multiple nature of reality and 'truths', the researcher in the natural sciences is in no more or less a privileged position than the social science researcher.

1.11 Alternatives to positivistic and post-positivist social science: naturalistic and interpretive approaches

Although opponents of positivism within social science subscribe to a variety of schools of thought, each with its own different epistemological viewpoint, they are united by their common rejection of the belief that human behaviour is governed by general, universal laws and characterized by underlying regularities. Moreover, they would agree that the social world can only be understood from the standpoint of the individuals who are part of the ongoing action being investigated and that their model of a person is an autonomous one, not the version favoured by positivist researchers. Such a view is allied to constructivism (Creswell, 2013) and to interpretive approaches to social science (discussed below).

In rejecting the viewpoint of the detached, objective observer – a mandatory feature of traditional research – anti-positivists and post-positivists would argue that individuals' behaviour can only be understood by the researcher sharing their frame of reference: understanding of individuals' interpretations of the world around them has to come from the inside, not the outside. Social science is thus seen as a subjective rather than an objective undertaking, as a means of dealing with the direct experience of people in specific contexts, where social scientists understand, explain and demystify social reality through the eyes of different participants; the participants themselves define the social reality (Beck, 1979). This is not to say that understanding subjective meanings is the only route for the researcher. Rather it is both a question of emphasis and a recognition that there are external matters that impinge on subjective meaning-making and, indeed, that what constitutes 'subjectivity' is open to question and to multiple interpretations and consequences, rather than being a unified, coherent singularity (Kettley, 2012, pp. 78–9). Subjective meanings may be as empirically testable as objective statements.

The anti-positivist/post-positivist movement has many hues, for example, postmodernism, post-structuralism

and Wittgenstein's work on language games. These have influenced areas of social science such as psychology, social psychology and sociology. In the case of psychology, for instance, a school of humanistic psychology has emerged alongside the coexisting behaviouristic and psychoanalytic schools. Arising as a response to the challenge to combat the growing feelings of dehumanization which characterize many social and cultural milieux, it sets out to study and understand the person as a *whole* (Buhler and Allen, 1972). Humanistic psychologists present a model of people that is positive, active and purposive, and at the same time stresses their own involvement with the life experience itself. They do not stand apart, introspective, hypothesizing. Their interest is directed at the intentional and creative aspects of the human being. The perspective adopted by humanistic psychologists is naturally reflected in their methodology. They are dedicated to studying the individual in preference to the group, and consequently prefer idiographic approaches to nomothetic ones. The implications of the movement's philosophy for education have been drawn by Carl Rogers (1942, 1945, 1969).

Comparable developments within social psychology may be perceived in the 'science of persons' movement. It is argued here that we must use ourselves as a key to our understanding of others and, conversely, our understanding of others as a way of finding out about ourselves, an anthropomorphic model of people. Since anthropomorphism means, literally, the attribution of human form and personality, the implied criticism is that social psychology as traditionally conceived has singularly failed, so far, to model people as they really are, and that social science should treat people as capable of monitoring and arranging their own actions, exercising their agency (Harré and Secord, 1972).

Social psychology's task is to understand people in the light of this anthropomorphic model. Proponents of this 'science of persons' approach place great store on the systematic and painstaking analysis of social episodes, i.e. behaviour in context. In Box 1.5 we give an example of such an episode taken from a classroom study. Note how the particular incident would appear on an interaction analysis coding sheet of a researcher employing a positivistic approach. Note, too, how this slice of classroom life can only be understood by knowledge of the specific organizational background and context in which it is embedded.

BOX 1.5 A CLASSROOM EPISODE

Walker and Adelman describe an incident in the following manner:

> In one lesson the teacher was listening to the boys read through short essays that they had written for homework on the subject of 'Prisons'. After one boy, Wilson, had finished reading out his rather obviously skimped piece of work the teacher sighed and said, rather crossly:
>
> T: Wilson, we'll have to put you away if you don't change your ways, and do your homework. Is that all you've done?
> P: Strawberries, strawberries. (Laughter)

Now at first glance this is meaningless. An observer coding with Flanders Interaction Analysis Categories (FIAC) would write down:

'7' (teacher criticizes) followed by a,
'4' (teacher asks question) followed by a,
'9' (pupil irritation) and finally a,
'10' (silence or confusion) to describe the laughter.

Such a string of codings, however reliable and valid, would not help anyone to *understand* why such an interruption was funny. Human curiosity makes us want to know *why* everyone laughs – and so, I would argue, the social scientist needs to know too. Walker and Adelman asked subsequently why 'strawberries' was a stimulus to laughter and were told that the teacher frequently said the pupils' work was 'like strawberries – good as far as it goes, but it doesn't last nearly long enough'. Here a casual comment made in the past has become an integral part of the shared meaning system of the class. It can only be comprehended by seeing the relationship as developing over time.

Source: Adapted from Delamont (1976)

The approach to analysing social episodes in terms of the 'actors' themselves is known as the 'ethogenic method'.[4] Unlike positivistic social psychology which ignores or presumes its subjects' interpretations of situations, ethogenic social psychology concentrates on the ways in which persons construe their social world. By probing their accounts of their actions, it endeavours to come up with an understanding of what those persons were doing in the particular episode.

As an alternative to positivist approaches, naturalistic, qualitative, interpretive approaches of various hue possess particular distinguishing features:

- people are deliberate and creative in their actions, they act intentionally and make meanings in and through their activities (Blumer, 1969);
- people actively construct their social world – they are not the 'cultural dopes' or passive dolls of positivism (Becker, 1970; Garfinkel, 1967);
- situations are fluid and changing rather than fixed and static; events and behaviour evolve over time and are richly affected by context – they are 'situated activities';
- events and individuals are unique and largely non-generalizable;
- a view that the social world should be studied in its natural state, without the intervention of, or manipulation by, the researcher (Hammersley and Atkinson, 1983);
- fidelity to the phenomena being studied is fundamental;
- people interpret events, contexts and situations, and act on the bases of those events (echoing Thomas's (1928) famous dictum that if people define their situations as real then they are real in their consequences – if I believe there is a mouse under the table, I will act as though there is a mouse under the table, whether there is or not (Morrison, 1998));
- there are multiple interpretations of, and perspectives on, single events and situations;
- reality is multilayered and complex;
- many events are not reducible to simplistic interpretation, hence 'thick descriptions' (Geertz, 1973) are essential rather than reductionism; that is to say, thick descriptions representing the complexity of situations are preferable to simplistic ones;
- researchers need to examine situations through the eyes of participants rather than the researcher.

The anti-positivist/post-positivist movement in sociology is represented by three schools of thought – phenomenology, ethnomethodology and symbolic interactionism. A common thread running through the three schools is a concern with phenomena, that is, the things we directly apprehend through our senses as we go about our daily lives, together with a consequent emphasis on qualitative as opposed to quantitative methodology. The differences between them and the significant roles each phenomenon plays in educational research are such as to warrant a more extended consideration of them in the discussion below.

1.12 A question of terminology: the normative and interpretive paradigms

So far we have introduced and used a variety of terms to describe the numerous branches and schools of thought embraced by the positivist and anti-positivist viewpoints. As a matter of convenience and as an aid to communication, we clarify at this point two generic terms conventionally used to describe these two perspectives and the categories subsumed under each, particularly as they refer to social psychology and sociology. The terms in question are 'normative' and 'interpretive'. The normative paradigm (or model) contains two major orienting ideas (Douglas, 1973): first, that human behaviour is essentially rule-governed; and second, that it should be investigated by the methods of natural science. The interpretive paradigm, in contrast to its normative counterpart, is characterized by a concern for the individual. Whereas normative studies are positivist, theories constructed within the context of the interpretive paradigm tend to be anti-positivist. As we have seen, the central endeavour in the context of the interpretive paradigm is to understand the subjective world of human experience. To retain the integrity of the phenomena being investigated, efforts are made to get inside the person and to understand from within. The imposition of external form and structure is resisted, since this reflects the viewpoint of the observer as opposed to that of the actor directly involved.

Two further differences between the two paradigms may be identified here: the first concerns the concepts of 'behaviour' and 'action'; the second, the different conceptions of 'theory'. A key concept within the normative paradigm, 'behaviour' refers to responses either to external environmental stimuli (e.g. another person, or the demands of society) or to internal stimuli (e.g. hunger, or the need to achieve). In either case, the cause of the behaviour lies in the past. Interpretive approaches, on the other hand, focus on action. This may be thought of as behaviour-with-meaning; it is intentional behaviour, and as such, future oriented. Actions are only meaningful to us insofar as we are able to ascertain the intentions of actors to share their

experiences. A large number of our everyday interactions with one another rely on such shared experiences.

As regards theory (see also Chapter 4), normative researchers try to devise general theories of human behaviour and to validate them through the use of research methodologies which, some believe, push them further and further from the experience and understanding of the everyday world and into a world of abstraction. For them, the basic reality is the collectivity; it is external to the actor and manifest in society, its institutions and its organizations. The role of theory is to say how reality hangs together in these forms or how it might be changed so as to be more effective. The researcher's ultimate aim is to establish a comprehensive 'rational edifice', a universal theory, to account for human and social behaviour.

But what of the interpretive researchers? They begin with individuals and set out to understand their interpretations of the world around them. Indeed they use approaches such as '*verstehen*' ('understanding') and hermeneutic (uncovering and interpreting meanings) to try to see the social world through the eyes of the participants, rather than as an outsider. Here is a view which states that, unlike natural scientists, social scientists recognize that human behaviour is intentional, that people interpret situations through their own eyes and act on those interpretations and that the research has to take cognizance of this. People make sense of the world in their own terms, and such interpretation takes place in socio-cultural, socio-temporal and socio-spatial contexts (cf. Marshall and Rossman, 2016). In turn this requires researchers to suspend or forgo their own assumptions about people, cultures and contexts in favour of looking at a situation and its context in its own terms (cf. Hammersley, 2013, p. 27), to set aside the search for universal statements or causal laws, i.e. to adopt idiographic rather than the nomothetic research of the positivists. The nature of research, then, is exploratory in nature, to investigate the interpretations of the situation made by the participants themselves, to understand their attitudes, behaviours and interactions.

In interpretive research, theory is emergent and arises from particular situations; it is 'grounded' in data generated by the research (Glaser and Strauss, 1967) (see Chapter 37). Theory should not precede research but follow it. Investigators work directly with experience and understanding to build their theory on them. The data thus yielded will include the meanings and purposes of those people who are their source. Further, the theory so generated must make sense to those to whom it applies. The aim of scientific investigation for the interpretive researcher is to understand how this reality goes on at one time and in one place and compare it with what goes on in different times and places. Thus theory becomes sets of meanings which yield insight and understanding of people's behaviour. These theories are likely to be as diverse as the meanings and understandings that they seek to explain. From an interpretive perspective, the hope of a universal theory which characterizes the normative outlook gives way to multifaceted images of human behaviour as varied as the situations and contexts supporting them.

1.13 Phenomenology, ethnomethodology, symbolic interactionism and constructionism

There are many variants of qualitative, naturalistic, interpretive approaches (Hitchcock and Hughes, 1995). Marshall and Rossman (2016) identify several such 'genres' (pp. 17–41). Under 'major genres' they include those which: (a) focus on culture and society (e.g. ethnographic approaches); (b) focus on the lived experiences of individuals (phenomenological approaches); (c) focus on texts and talking (sociolinguistic approaches); (d) use grounded theory approaches; and (e) use case studies. Under 'critical genres' they include: (a) critical ethnography and autoethnography; (b) critical discourse analysis; (c) action research and participatory action research; (d) queer theory; (e) critical race theory; (f) feminist theory; (g) cultural studies; and (h) internet/virtual ethnography. We discuss critical theories in Chapter 3. Here we focus on four significant 'traditions' in the interpretive style of research – phenomenology, ethnomethodology, symbolic interactionism and constructionism.

Phenomenology

In its broadest meaning, phenomenology is a theoretical point of view that advocates the study of direct experience taken at face value and which sees behaviour as determined by the phenomena of experience rather than by external, objective and physically described reality (English and English, 1958). Although phenomenologists differ among themselves on particular issues, there is fairly general agreement on the following points identified by Curtis (1978), Hammersley (2013) and Marshall and Rossman (2016), which can be taken as distinguishing features of their philosophical viewpoint:

- A belief in the importance, and even the primacy, of subjective consciousness;
- The importance of documenting and describing immediate experiences;

- The significance of understanding how and why participants' knowledge of a situation comes to be what it is;
- The social and cultural situatedness of actions and interactions, together with participants' interpretations of a situation;
- An understanding of consciousness as active, as meaning bestowing;
- A claim that there are certain essential structures to consciousness of which we gain direct knowledge by a certain kind of reflection. Exactly what these structures are is a point about which phenomenologists differ.

Various strands of development may be traced in the phenomenological movement: we briefly examine two of them – the transcendental phenomenology of Husserl; and existential phenomenology, of which Schutz is perhaps the most characteristic representative.

Husserl, regarded by many as the founder of phenomenology, was concerned with investigating the source of the foundation of science and with questioning the common-sense, 'taken-for-granted' assumptions of everyday life (see Burrell and Morgan, 1979). To do this, he set about opening up a new direction in the analysis of consciousness. His catchphrase was 'back to the things!' which for him meant finding out how things appear directly to us rather than through the media of cultural and symbolic structures. In other words, we are asked to look beyond the details of everyday life to the essences underlying them. To do this, Husserl exhorts us to 'put the world in brackets' or free ourselves from our usual ways of perceiving the world. What is left over from this reduction is our consciousness, of which there are three elements – the 'I' who thinks, the mental acts of this thinking subject, and the intentional objects of these mental acts. His was a call to overcome the subjective–objective divide. The aim, then, of this method of *epoché*, as Husserl called it, is the dismembering of the constitution of objects in such a way as to free us from all preconceptions about the world.

Schutz was concerned with relating Husserl's ideas to the issues of sociology and to the scientific study of social behaviour. Of central concern to him was the problem of understanding the meaning structure of the world of everyday life. He sought the origins of meaning in the 'stream of consciousness' – basically an unbroken stream of lived experiences which have no meaning in themselves. One can only impute meaning to them retrospectively, by the process of turning back on oneself and looking at what has been going on. In other words, meaning can be accounted for here by the concept of reflexivity. For Schutz, the attribution of meaning reflexively is dependent on the people identifying the purpose or goal they seek (Burrell and Morgan, 1979).

According to Schutz, the way we understand the behaviour of others is dependent on a process of typification by means of which the observer makes use of concepts resembling 'ideal types' to make sense of what people do. These concepts are derived from our experience of everyday life and it is through them, claims Schutz, that we classify and organize our everyday world. In this respect he adhered to principles of empiricism. As Burrell and Morgan observe, we learn these typifications through our biographical locations and social contexts. Our knowledge of the everyday world inheres in social order and itself is socially ordered.

The fund of everyday knowledge by means of which we are able to typify other people's behaviour and come to terms with social reality varies from situation to situation. We thus live in a world of multiple realities, and social actors move within and between these, abiding by the rules of the game for each of these worlds.

Ethnomethodology

Like phenomenology, ethnomethodology is concerned with the world of everyday life, studying participants' circumstances, thoughts and commonplace daily lives as worthy of empirical study (Garfinkel, 1967, p. vii). Garfinkel maintains that students of the social world must doubt the reality of that world; and that in failing to view human behaviour more sceptically, sociologists have created an ordered social reality that bears little relationship to the real thing. He thereby challenges the basic sociological concept of order.

Ethnomethodology, then, is concerned with how people make sense of their everyday world. More especially, it is directed at the mechanisms by which participants achieve and sustain interaction in a social encounter – the assumptions they make, the conventions they utilize, and the practices they adopt. Ethnomethodology thus seeks to understand social accomplishments in their own terms; it is concerned to understand them from within (Burrell and Morgan, 1979).

In identifying the 'taken-for-granted' assumptions characterizing a social situation and the ways in which the people involved make their activities rationally accountable, ethnomethodologists use notions of 'indexicality' and 'reflexivity'. Indexicality refers to the ways in which actions and statements are related to the social contexts producing them, and to the way

their meanings are shared by the participants but not necessarily stated explicitly. Indexical expressions are thus the designations imputed to a particular social occasion by the participants in order to locate the event in the sphere of reality. Reflexivity, on the other hand, refers to the way in which all accounts of social settings – descriptions, analyses, criticisms etc. – and the social settings occasioning them, are mutually interdependent.

One can distinguish between two types of ethnomethodologists: *linguistic* and *situational*. *Linguistic* ethnomethodologists focus upon the use of language and the ways in which conversations in everyday life are structured. Their analyses make much use of the unstated 'taken-for-granted' meanings, the use of indexical expressions and the way in which conversations convey much more than is actually said. *Situational* ethnomethodologists cast their view over a wider range of social activity and seek to understand the ways in which people negotiate the social contexts in which they find themselves. They are concerned to understand how people make sense of and order their environment. As part of their empirical method, ethnomethodologists may consciously and deliberately disrupt or question the ordered 'taken-for-granted' elements in everyday situations in order to reveal the underlying processes at work.

The substance of ethnomethodology thus largely comprises a set of specific techniques and approaches to be used in studying what Garfinkel has described as the 'awesome indexicality' of everyday life. It is geared to empirical study, and the stress which its practitioners place upon the uniqueness of the situation encountered projects its essentially relativist standpoint. A commitment to the development of methodology and fieldwork has occupied first place in the interests of its adherents, so that related issues of ontology, epistemology and the nature of human beings have received less attention than perhaps they deserve.

Symbolic interactionism

Essentially, the notion of symbolic interactionism derives from the work of Mead (1934). Although subsequently to be associated with such noted researchers as Blumer, Hughes, Becker and Goffman, the term does not represent a unified perspective in that it does not embrace a common set of assumptions and concepts accepted by all who subscribe to the approach. Here, however, it is possible to identify three basic postulates. These have been set out by Woods (1979) as follows. First, human beings act towards things on the basis of the meanings they have for them. Humans inhabit two different worlds: the 'natural' world wherein they are organisms of drives and instincts and where the external world exists independently of them, and the social world where the existence of symbols, like language, enables them to give meaning to objects. This attribution of meanings, this interpreting, is what makes them distinctively human and social. Interactionists therefore focus on the world of subjective meanings and the symbols by which they are produced and represented. This means not making any prior assumptions about what is going on in an institution, and taking seriously, indeed giving priority to, inmates' own accounts. Thus, if students appear preoccupied for too much of the time – 'being bored', 'having a laugh' etc. – the interactionist is keen to explore the properties and dimensions of these processes.

Second, this attribution of meaning to objects through symbols is a continuous process. Action is not simply a consequence of psychological attributes such as drives, attitudes or personalities, or determined by external social facts such as social structure or roles, but results from a continuous process of meaning attribution which is always emerging, in a state of flux and subject to change. The individual constructs, modifies, pieces together, weighs up the pros and cons, and bargains.

Third, this process takes place in a social context. Individuals align their actions to those of others. They do this by 'taking the role of the other', by making indications to themselves about others' likely responses. They construct how others wish to or might act in certain circumstances, and how they themselves might act. They might try to 'manage' the impressions others have of them, put on a 'performance', try to influence others' 'definition of the situation'.

Instead of focusing on the individual, then, and his or her personality characteristics, or on how the social structure or social situation causes individual behaviour, symbolic interactionists direct their attention at the nature of interaction, the dynamic activities taking place between people. In focusing on the interaction itself as a unit of study, the symbolic interactionist creates a more active image of the human being and rejects the image of the passive, determined organism. Individuals interact; societies are made up of interacting individuals. People are constantly undergoing change in interaction and society is changing through interaction. Interaction implies human beings acting in relation to each other, taking each other into account, acting, perceiving, interpreting, acting again. Hence, a more dynamic and active human being emerges rather than an actor merely responding to others. Woods (1983, pp. 15–16) summarizes key emphases of symbolic interaction thus:

- individuals as constructors of their own actions;
- the various components of the self and how they interact; the indications made to self, meanings attributed, interpretive mechanisms, definitions of the situation; in short, the world of subjective meanings, and the symbols by which they are produced and represented;
- the process of negotiation, by which meanings are continually being constructed;
- the social context in which they occur and whence they derive;
- by taking the 'role of the other' – a dynamic concept involving the construction of how others wish to or might act in a certain circumstance, and how individuals themselves might act – individuals align their actions to those of others.

Constructionism

In constructionism (also termed constructivism), in contrast to the argument that external objects and factors determine, shape, impress, print or fix themselves onto passive recipients (i.e. are 'givens' in society or individuals), people actively and agentically seek out, select and construct their own views, worlds and learning, and these processes are rooted in socio-cultural contexts and interactions. In other words, cognition is generative and active rather than receptive and passive respectively. Through such active cognition and deliberate perception we come to understand ourselves and how this affects the worlds we inhabit and the way in which we interact with the objects and people in them.

Hammersley (2013) notes that constructionism requires researchers to focus on the processes that lead to the construction, constitution and character given to independent objects and the relationships between them (pp. 35–6), i.e. how people collectively construct their social worlds (e.g. through discourse analysis) (p. 36). He gives an example of replacing the definition of a person as 'intelligent' with an examination of the 'discursive practices' which led to the construction of that person being intelligent and how this affects how that person operates in socio-cultural and institutional contexts (p. 36).

Social constructionism holds that individuals seek to make meaning of their social lives and that the researcher has to examine the situation in question through the multiple lenses of the individuals involved, to obtain their definition of the situation, to see how they make sense of their situation and to focus on interactions, contexts, environments and biographies. Indeed social constructionism emphasizes the social nature of learning, arguing that it is only through social interaction and communication that certain types of learning occur and certain views of the world are constructed.

A characteristic common to the phenomenological, ethnomethodological, symbolic interactionist and constructionist perspectives, which makes them attractive to the educational researcher, is the way they fit naturally to the kind of concentrated action found in classrooms and schools. Yet another shared characteristic is the manner in which they are able to preserve the integrity of the situation in which they are employed. Here the influence of the researcher in structuring, analysing and interpreting the situation is present to a much smaller degree than would be the case with a more traditionally oriented research approach.

1.14 Criticisms of the naturalistic and interpretive approaches

Critics have wasted little time in pointing out what they regard as weaknesses in these newer qualitative perspectives. They argue that while it is undeniable that our understanding of the actions of our fellow-beings necessarily requires knowledge of their intentions, this, surely, cannot be said to constitute *the* purpose of a social science. As Rex observed:

> Whilst patterns of social reactions and institutions may be the product of the actors' definitions of the situations there is also the possibility that those actors might be falsely conscious and that sociologists have an obligation to seek an objective perspective which is not necessarily that of any of the participating actors at all.… We need not be confined purely and simply to that … social reality which is made available to us by participant actors themselves.
>
> (Rex, 1974)

While these more recent perspectives have presented models of people that are more in keeping with common experience, some argue that anti-positivists/post-positivists have gone too far in abandoning scientific procedures of verification and in giving up hope of discovering useful generalizations about behaviour. Are there not dangers in rejecting the approach of physics in favour of methods more akin to literature, biography and journalism? Some specific criticisms of the methodologies are well directed, for example Argyle (1978) questions whether, if carefully controlled interviews such as those used in social surveys are inaccurate, then the less controlled interviews carry even greater risks of inaccuracy. Indeed Bernstein (1974) suggests that subjective reports may be incomplete and misleading.

I may believe that the teacher does not like me, and, therefore, act as though the teacher does not like me (a self-fulfilling prophecy), but, in fact, all the time the teacher actually does like me; my perception is wrong.

Bernstein's criticism is directed at the overriding concern of phenomenologists and ethnomethodologists with the meanings of situations and the ways in which these meanings are negotiated by the actors involved. What is overlooked about such negotiated meanings, observes Bernstein, is that the very process whereby one interprets and defines a situation is itself a product of the circumstances in which one is placed. One important factor in such circumstances that must be considered is the power of others to impose their own definitions of situations upon participants. Doctors' consulting rooms and headteachers' studies are locations in which inequalities in power are regularly imposed upon unequal participants. The ability of certain individuals, groups, classes and authorities to persuade others to accept their definitions of situations demonstrates that while – as ethnomethodologists insist – social structure is a consequence of the ways in which we perceive social relations, it is clearly more than this.

Conceiving of social structure as external to ourselves helps us include its self-evident effects upon our daily lives into our understanding of the social behaviour going on about us. Here is rehearsed the tension between agency and structure of social theorists (Layder, 1994); the danger of interactionist and interpretive approaches is their relative neglect of the power of external – structural – forces to shape behaviour and events. There is a risk in interpretive approaches that they become hermetically sealed from the world outside the participants' theatre of activity – they put artificial boundaries around subjects' behaviour. Just as positivistic theories can be criticized for their macro-sociological persuasion, so interpretive and qualitative theories can be criticized for their narrowly micro-sociological perspectives.

1.15 Postmodernist and post-structuralist perspectives

It is not only post-positivists who challenge the modernist, positivist conception of the world. For modernists the world is available to be studied objectively and, by using scientific methods, to arrive at secure, rigorous, scientific, discipline-based explanations of observed phenomena – 'grand narratives' which are redolent of the Enlightenment project of providing foundationalist and absolute knowledge. Postmodernism challenges each of these. Whilst it is perhaps invidious to try to characterize postmodernists (as they would argue against any singular or all-embracing definitions), in a seminal text Jameson (1991) argues that postmodernism does have several distinguishing hallmarks, including, for example:

- the absence of 'grand narratives' (metanarratives) and grand designs, laws and patterns of behaviour (thereby, ironically, eclipsing the status of their own narrative);
- the valorization of discontinuity, difference, diversity, pluralism, variety, uniqueness, subjectivity, distinctiveness and individuality;
- the importance of the local, the individual and the particular;
- the 'utter forgetfulness of the past' and the 'autoreferentiality' of the present (Jameson, 1991, p. 42);
- the importance of temporality and context in understanding phenomena: meanings are rooted in time, space, cultures, societies and are not universal across these;
- the celebration of depthlessness, multiple realities (and, as Jameson argues, multiple superficialities) and the rectitude of individual interpretations and meanings rather than an appeal to a singular or universal rationalism;
- relativism rather than absolutism in deciding what constitutes worthwhile knowledge, research and their findings;
- the view of knowledge as a human, social construct;
- multiple, sometimes contradictory, yet co-existent interpretations of the world, in which the researcher's interpretation is only one out of several possible interpretations, i.e. the equal value of different interpretations and the reduction in the authority of the researcher, yet, simultaneously, the privileging of some interpretations of the world to the neglect of others (i.e. the nexus between knowledge and power, a feature of critical theory, discussed in Chapter 3);
- the recognition that researchers are part of the world that they are researching;
- the emancipatory potential of according value to individual views, values, perspectives and interpretations (see Chapter 3).

Pring (2015) adds to this the point that postmodernism is characterized by a revolt against thought control and cultural control, by an assertion of multiple forms of cultural expression, an abandonment of certainty, a replacement of 'authority' (as in 'authoritative') by multiple voices and negotiated meanings, and a blurring of artificial boundaries (disciplines) of knowledge, a questioning of received wisdoms and a recognition of

fallibilism, all of which he sees as the function of the 'perennial philosophical tradition' and not one given birth to by postmodernism (pp. 134–7). In one sense postmodernism supports the interpretive paradigm set out earlier in this chapter. In another sense it supports complexity theory as discussed below, and in a third sense it supports critical theory as set out in Chapter 3. Postmodernism has a chameleon-like nature in this respect.

Post-structuralism, like postmodernism, has many different interpretations (we will not discuss here the interpretation that relates to semiology). Here we take a necessarily selective interpretation, to focus on those features that are relevant to the foundations and conduct of educational research. Here post-structuralism can be regarded as a counter to those structural-functionalists who adopt a systems view of society (e.g. Marxism, or functionalist anthropologists such as Lévi-Strauss) or behaviour as a set of interrelated parts which, in law-like fashion, pattern themselves and fit together neatly into a fixed view of the world and its operations and in which individual behaviour is largely determined by given, structural features of society (e.g. social class, position in society, role in society). In post-structuralist approaches, data (e.g. conversations, observations) and even artefacts can be regarded as texts (Burman and Parker, 1993), as discourses that are constructed and performed through discourses (see Chapter 35), open to different meaning and interpretations (Francis, 2010, p. 327).

Post-structuralists (e.g. Foucault, Derrida) argue that individual agency has prominence; individuals are not simply puppets of a given system; people are diverse and different, indeed they may carry contradictions and tensions within themselves (e.g. in terms of class, ethnicity, gender, employment, social group, family membership and tasks, and so on); they are not simply the decentred bearers of given roles. Individuals have views of themselves, and one task of the researcher is to locate research findings within the views of the self that the participants hold, and to identify the meanings which the participants accord to phenomena. Hence not only do the multiple perspectives of the participants have to be discerned, but also those of the researchers, the audiences of the research and the readers of research. The task of the research is to 'deconstruct', to expose, the different meanings, layers of meanings and privileging of meanings inherent in a phenomenon or piece of research. There is no single, 'essential' meaning, but many, and one task of research is to understand how meanings and knowledge are produced, legitimized and used. (This links post-structuralism to critical theory, though some critical theorists, e.g. Habermas (1987), argue against critical theory's affinity to postmodernism or post-structuralism.)

One can detect affinities between post-positivism, postmodernism and post-structuralism in underpinning interpretive and qualitative approaches to educational research, complexity theory and critical theory, and the significance given to individual and subjective accounts in the research process, along with reflexivity on the part of the researcher. (That said, many post-positivists, postmodernists and post-structuralists would reject such a simple affinity, or even the links between their views and, for example, phenomenology and interpretivism. We do not explore this here.) One can suggest that post-positivism, postmodernism and post-structuralism argue for multiple interpretations of a phenomenon to be provided, to accord legitimacy to individual voices in research, and to abandon the search for deterministic, simple cause-and-effect laws of behaviour and action.

1.16 Subjectivity and objectivity in educational research

The preceding overview has alluded to the sympathies between some paradigms and objectivity in research and other paradigms and subjectivity in research. To make such an exclusive separation is a chimera, a false dichotomy. With regard to objectivity, to say, for instance, that objectivity inheres in positivist and post-positivist approaches overlooks not only the several interpretations of positivism and post-positivism but what it means to be subjective. Objectivity is refracted through the researcher's eyes and the generation, construction and testing of hypotheses draw on personal understandings and formulations. In other words, objectivity cannot escape some subjective roots. Taken to an extreme, it leads to a rejection of the idea that the researcher can ever be objective, just as there is a rejection of the idea that there is an objective reality or 'truth' about a phenomenon (Hammersley, 2011, p. 89). Objectivity here is defined as intersubjectivity (as opposed to subjectivity), reliability and freedom from bias (Risjord, 2014, p. 22). Risjord illustrates the difference between intersubjectivity and subjectivity thus (p. 23): I feel hungry (subjective) so I eat a sandwich (intersubjective, in that it can be seen by an observer, i.e. is open to critical scrutiny).

On the other hand, subjectivity cannot turn its back on what is 'out there' in terms of overriding the social, societal and institutional social facts, which have an existence independent of the participant. Subjectivity cannot lay claim to being a privileged discourse without risking relativism.

Subjectivity and objectivity are frequently placed at the poles of different continua (cf. Hammersley, 2011, p. 90), for example:

Subjective		*Objective*
Internal	… … … … . .	External
Private	… … … … . .	Public
Positivist	… … … … . .	Interpretive
Idiographic	… … … … . .	Nomothetic
Judgement	… … … … . .	Technical application (e.g. of statistics)
Individual	… … … … . .	Shared
Personal	… … … … . .	Impersonal
Particular	… … … … . .	General
Relative	… … … … . .	Absolute
Opinion	… … … … . .	Proof
Experimental	… … … … . .	Interactionist
Biased	… … … … . .	Bias-free
Unobservable	… … … … . .	Observable
Idiosyncratic	… … … … . .	Regular
Uncertain	… … … … . .	Certain
Unpredictable	… … … … . .	Predictable
Unreliable	… … … … . .	Reliable
Imprecise	… … … … . .	Explicit
Questionable	… … … … . .	Conclusive
Unverifiable	… … … … . .	Checkable
Prone to error	… … … … . .	Secure
Complex	… … … … . .	Straightforward
Opaque	… … … … . .	Transparent

Source: Adapted from Barr Greenfield (1975)

However, this creates false dichotomies, and look how easily one can create biases in the pejorative terms used: many of the items in the left-hand column are presented as the shabby, less respectable end of research, whilst the right-hand column seems much more clean and respectable. This can overlook the risk of bias and errors that researchers might commit in working in the right-hand column and the authenticity, correctness and truth of the left-hand column. Both subjective and objective views have to face judgements of plausibility, validity, reliability, meaningfulness and credibility.

However, more fundamentally, as Hammersley (2011) remarks, we depend on personal knowledge and judgement in making meaning of phenomena and data, be those data numbers, words, pictures or sounds. We rely on our senses in making observations. Following objective procedures requires a personal commitment. We rely on our judgement in raising hypotheses, making inferences and drawing conclusions. However, simply amassing subjective data from participants does not ensure that the data are true or reliable, but stating objective procedures does not ensure identical practices, not least as, in the social world, researchers – consciously or not – adjust their practices to the situation and the people who are participating in the research; standardizing practice has to extend to participants.

Medical research is a good example here: whilst there might be an objective, standardized procedure for patients taking medicine in a randomized controlled trial, that does not guarantee that patients will follow it: they might refuse to take the medicine, forget to take it, take it at the wrong time of day, take some but not all of it, take the wrong dose (too little or too much), misread the instructions, and so on. Intention does not match actuality.

The claims we make from knowledge, be they from the left-hand or right-hand columns here, do not constitute absolute truth: the same data can, and do, sustain multiple interpretations, claims and conclusions. Further, is it really possible or desirable to set aside one's own biography, values and assumptions, however reflexive one might be? Reflexivity is not the same as objectivity. Is it not the case, anyway, that knowledge, particularly of the social world, is a socio-temporal construction rather than the clean world of the objectivist, and to pretend otherwise is simply naive or deceitful (Hammersley, 2011, p. 96)? Or is this giving in to the relativists and the postmodernists, in the knowledge that relativism is, by its own definition, only relative, and that the postmodernists cannot lay claim to their views as having any status at all as to do so would be to acknowledge that metanarratives exist – a claim which postmodernists proscribe as an article of faith.

Hammersley (2011) is clear that errors may stem from the researcher's own social or individual characteristics and their influence on their research, but that it is unnecessary and, indeed, undesirable to assume that the researcher can stand out completely from his or her social and individual characteristics. Further, error does not automatically follow from an acknowledgement of the researcher's own social and individual characteristics.

The task, then, is to protect the research from negative effects of subjectivity (2011, p. 101), though Hammersley acknowledges that what constitutes 'error' is not always clear. However, he offers researchers some advice here, cautioning them to be on their guard against preconceptions, prior assumptions, preferences and biases that are 'external to the pursuit of knowledge' (p. 102), i.e. which are goals that are separate

from the research itself. Objectivity, in this case, means adhering to the 'epistemic virtue' of keeping *only* to the canons and requirements of the research itself, setting aside any extraneous personal convictions or subordinating the research to any other goals outside the research (p. 103). Given this, objectivity and the suppression of personal, subjective beliefs, values, commitments or agendas have a key role to play in educational research. The objective reliability of the research does not depend on the political, valuative or moral motivations of the researcher (cf. Risjord, 2014, p. 23).

Similarly, value-neutrality in educational and social science research leaves unsaid any comment on what *ought* or *ought not* be done; that is for policy makers. Rather, educational research confines itself to facts; that is, the scientific enterprise. Saying that teachers should not assault students is an evaluative statement and not a matter for social science research, as it does not rest on empirical data alone, though reporting incidents of assault and its effects surely is a matter for research.

Whether researchers should have a 'committed' position is a matter that we return to in Chapter 3 on critical theory, which explicitly disavows value-free positions, and argues for partisan positions in research as contributing to the greater good of an emancipated society in freeing itself from that ideology which conceals oppression and unjust subordination and power differentials of social groups, and which transforms society to equality, democracy and social justice. Fact and value reunite.

1.17 The paradigm of complexity theory

An emerging paradigm in educational research is that of complexity theory (Medd, 2002; Morrison, 2002a, 2008; Radford, 2006, 2007, 2008; Kuhn, 2007; Byrne and Callaghan, 2014; Boulton *et al*., 2015), as schools can be regarded as 'complex adaptive systems' (Kaufmann, 1995). Complexity theory looks at the world in ways which break with simple cause-and-effect models, simple determinism and linear predictability (Morrison, 2008) and a dissection/atomistic approach to understanding phenomena (Radford, 2007, 2008; Byrne and Callaghan, 2014), replacing them with organic, non-linear and holistic approaches (Santonus, 1998, p. 3). Relations within interconnected, dynamic and changing networks are the order of the day (Wheatley, 1999, p. 10), and there is a 'multiplicity of simultaneously interacting variables' (Radford, 2008, p. 510). Here key terms are feedback, recursion, emergence, connectedness and self-organization. Out go the simplistic views of linear causality (Radford, 2007; Morrison, 2009; Byrne and Callaghan, 2014; Boulton *et al*., 2015), the ability to predict, control and manipulate, to apply reductive techniques to research, and in come uncertainty, networks and connection, holism self-organization, emergence over time through feedback and the relationships of the internal and external environments, and survival and development through adaptation and change.

In complexity theory, a self-organizing system is autocatalytic and possesses its own unique characteristics and identity (Kelly and Allison, 1999, p. 28) which enable it to perpetuate and renew itself over time – it creates the conditions for its own survival. This takes place through engagement with others in a system (Byrne and Callaghan, 2014; Boulton *et al*., 2015). The system is aware of its own identity and core properties, and is self-regenerating (able to sustain that identity even though aspects of the system may change, e.g. staff turnover in a school).

Through feedback, recursion, perturbance, autocatalysis, connectedness and self-organization, higher levels of complexity and differentiated, new forms of life, behaviour and systems arise from lower levels of complexity and existing forms. These complex forms derive from often comparatively simple sets of rules – local rules and behaviours generating emergent complex global order and diversity (Waldrop, 1992, pp. 16–17; Lewin, 1993, p. 38). General laws of emergent order can govern adaptive, dynamical processes (Waldrop, 1992, p. 86; Kauffman, 1995, p. 27).

The interaction of individuals feeds into the wider environment which, in turn, influences the individual units of the network; they co-evolve, shaping each other (Stewart, 2001), and co-evolution requires connection, cooperation and competition: competition to force development and cooperation for mutual survival. The behaviour of a complex system as a whole, formed from its several elements, is greater than the sum of the parts (Byrne and Callaghan, 2014; Boulton *et al*., 2015).

Feedback occurs between the interacting elements of the system. Negative feedback is regulatory (Marion, 1999, p. 75), for example learning that one has failed a test. Positive feedback brings increasing returns and uses information to change, grow and develop (Wheatley, 1999, p. 78); it amplifies small changes (Stacey, 1992, p. 53). Once a child has begun to read she is gripped by reading, she reads more and learns at an exponential rate.

Connectedness, a key feature of complexity theory, exists everywhere. In a rainforest ants eat leaves, birds eat ants and leave droppings, which fertilize the soil for

growing trees and leaves for the ants (Lewin, 1993, p. 86). In schools, children are linked to families, teachers, peers, societies and groups; teachers are linked to other teachers, support agencies (e.g. psychological and social services), policy-making bodies, funding bodies, the legislature, and so on. The child (indeed the school) is not an island, but is connected externally and internally in several ways. Disturb one element and the species or system must adapt or die; the message is ruthless.

Emergence is the partner of *self-organization*. Systems possess the ability for self-organization, which is not according to an a priori grand design – a cosmological argument – nor a teleological argument; complexity is neither. Further, self-organization emerges, it is internally generated; it is the opposite of external control. As Kauffman (1995) suggests, order comes for free and replaces control. Order is not imposed; it emerges; in this way it differs from control. Self-organized order emerges of itself as the result of the interaction between the organism and its environment, and new structures emerge that could not have been predicted; that emerged system is, itself, complex and cannot be reduced to those parts that gave rise to the system. As Davis and Sumara (2005, p. 313) write: 'phenomena have to be studied at their level of emergence', i.e. at their present overall state, not in terms of the elements present in the pre-metamorphosed state.

Stacey (2000) suggests that a system can only evolve, and evolve spontaneously, where there is diversity and deviance (p. 399) – a salutary message for command-and-control teachers who exact compliance from their pupils. The future is largely unpredictable. At the point of 'self-organized criticality' (Bak, 1996), a tipping point, the effects of a single event are likely to be very large, breaking the linearity of Newtonian reasoning wherein small causes produce small effects; the straw that breaks the camel's back.

Complexity theories argue against the linear, deterministic, patterned, universalizable, stable, atomized, modernistic, objective, mechanist, controlled, closed systems of law-like behaviour which may be operating in the laboratory but which do not operate in the social world of education. These features of complexity theories seriously undermine the value of experiments and positivist research in education (e.g. Waldrop, 1992; Lewin, 1993).

Complexity theory replaces these with an emphasis on networks, linkages, holism, feedback, relationships and interactivity in context (Byrne and Callaghan, 2014), emergence, dynamical systems, self-organization and an open system (rather than the closed world of the experimental laboratory). Even if one could conduct an experiment, its applicability to ongoing, emerging, interactive, relational, open situations, in practice, is limited (Morrison, 2001). It is misconceived to hold variables constant in a dynamical, evolving, fluid, open situation. What is measured is history.

Complexity theory challenges randomized controlled trials – the 'gold standard' of research. Classical experimental methods, abiding by the need for replicability and predictability, may not be particularly fruitful since, in complex phenomena, results are never clearly replicable or predictable: As Heraclitus noted, we never jump into the same river twice. Complexity theory suggests that educational research should concern itself with: (a) how multivalency and non-linearity feature in education; (b) how voluntarism and determinism, intentionality, agency and structure, life-world and system, divergence and convergence interact in learning (Morrison, 2002a, 2005); (c) how to both use, but transcend, simple causality in understanding the processes of education (Morrison, 2012); (d) how viewing a system holistically, as having its own ecology of multiple interacting elements, is more powerful than an atomized approach. Complexity theory suggests that phenomena must be looked at holistically; to atomize phenomena into measurable variables and then to focus only on certain of these is to miss synergy, the dynamic interaction of several parts (Morrison, 2008) and the significance of the whole. Measurement, however acute, may tell us little of value about a phenomenon; one can measure every observable variable of a person to an infinitesimal degree, but his/her nature, what makes him/her who he or she is, eludes atomization and measurement.

These should merge, so that in complexity theory the unit of analysis becomes a web, network or ecosystem (Capra, 1996, p. 301; Morrison, 2012), focused on, and arising from, a specific topic or centre of interest (a 'strange attractor'). Individuals, families, students, classes, schools, communities and societies exist in symbiosis; complexity theory tells us that their relationships are necessary, not contingent, and analytic, not synthetic. This is a challenging prospect for educational research, and complexity offers considerable leverage into understanding societal, community, individual and institutional change theory (Radford, 2006; Morrison, 2008); it provides the nexus between macro- and micro-research in understanding and promoting change.

In addressing holism, complexity theory suggests the need for case study methodology, narrative approaches, action research and participatory forms of research, premised in many ways on interactionist, qualitative accounts, i.e. looking at situations through the eyes of as many participants or stakeholders as

possible (e.g. Byrne and Callaghan, 2014; Boulton *et al*., 2015). This enables multiple causality, multiple perspectives and multiple effects to be charted (Morrison, 2012). Self-organization, a key feature of complexity theory, argues for participatory, collaborative and multi-perspectival approaches to educational research. This is not to deny 'outsider' research; it is to suggest that, if it is conducted, outsider research has to take in as many perspectives as possible.

In educational research terms, complexity theory stands against methodologies based on linear views of causality, arguing for multiple causality, multi-directional causes and effects and networks of causes (Morrison, 2012) at a host of different levels and in a range of diverse ways. No longer can one be certain that a simple cause brings a simple or single effect, or that a single effect is the result of a single cause, or that the location of causes will be in single fields only, or that the location of effects will be in a limited number of fields (Morrison, 2009, 2012). Researching causality becomes a search for networked, multi-causality and multi-stranded causality (Morrison, 2012).

Complexity theory not only questions the values of positivist research and experimentation, but it also underlines the importance of educational research to catch the deliberate, intentional, agentic actions of participants and to adopt interactionist and constructivist perspectives. (In this respect it has sympathies, perhaps, with posthumanism, though it is a very different animal from posthumanism.) Kuhn (2007, pp. 172–3) sets out a series of axioms for complexity-based research: (a) reality is dynamic, emergent and self-organizing, requiring multiple perspectives to be addressed (see also Medd, 2002); (b) the relationship between the knower and the known is, itself, dynamic, emergent and self-organizing; (c) hypotheses for research must relate to time and context (cf. Medd, 2002; Radford, 2006); (d) it is impossible to distinguish cause from effect, as entities are mutually shaping and influencing (co-evolution); (d) inquiry is not value-free.

Addressing complexity theory's argument for self-organization, the call is for the teacher-as-researcher movement to be celebrated, and complexity theory suggests that research in education could concern itself with the symbiosis of internal and external researchers and research partnerships. Just as complexity theory suggests that there are multiple views of reality, so this accords not only with the need to catch several perspectives on a situation (using multi-methods), but resonates with those tenets of critical research which argue for different voices, views and interpretations to be heard, incorporated and understood respectively. Heterogeneity is the watchword.

Complexity theory provides not only a powerful challenge to conventional approaches to educational research, but it suggests both a substantive agenda and also a set of methodologies, arguing for methodological, paradigmatic and theoretical pluralism. For example, Byrne and Callaghan (2014) and Boulton *et al*. (2015) suggest that research should study the processes of emergence over time and critical incidents in evolving situations. In addressing holism, complexity theory suggests the need for case study methodology, qualitative research and participatory, multi-perspectival and collaborative (self-organized), partnership-based forms of research, premised on interactionist, qualitative and interpretive accounts (e.g. Lewin and Regine, 2000).

1.18 Conclusion

This chapter has argued that planning and conducting educational research cannot follow simple recipes but is a complex, deliberative and iterative process in which ontological and epistemological matters have to be considered and in which many different kinds of understanding feature. In addressing this, the chapter has introduced several paradigms and their possible contribution to educational research, including: positivism, post-positivism, post-structuralism, postmodernism and complexity theory. It has commented on different views of social reality and a range of approaches to understanding that reality: deductive and inductive; empirical and rationalist; nomothetic and idiographic; subjective and objective; the scientific method; and alternatives in naturalistic, interpretive, phenomenological, interactionist and constructionist approaches.

The argument through the chapter has suggested that foundationalism and the quest for absolute knowledge in educational research is questionable. In this it has indicated the expanding range of approaches, of which, for example, postmodernism, post-structuralism and complexity theory are examples. Complexity theory challenges conceptions of simple cause-and-effect, experimental approaches to research and it advocates attention to context and holism in educational research.

In recognizing the many and expanding number of paradigms and approaches to educational research, the chapter has argued for methodological, paradigmatic and theoretical pluralism, indeed mixed methods (Chapter 2). These set the ground for the many approaches, designs, methodologies and methods set out in the remainder of the book. Simple recipe-following is out, and deliberation, fitness for purpose and fitness of purpose are key watchwords here.

The companion website to the book provides additional material and PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: www.routledge.com/cw/cohen.

Notes

1 We are not here recommending, nor would we wish to encourage, exclusive dependence on rationally derived and scientifically provable knowledge for the conduct of education – even if this were possible. There is a rich fund of traditional and cultural wisdom in teaching (as in other spheres of life) which we would ignore to our detriment. What we are suggesting, however, is that total dependence on the latter has tended in the past to lead to an impasse, and that for further development and greater understanding to be achieved education must needs resort to the methods of science and research.

2 A classic statement opposing this particular view of science is that of Kuhn (1962), *The Structure of Scientific Revolutions*. Kuhn's book, acknowledged as an intellectual tour de force, makes the point that science is not the systematic accumulation of knowledge as presented in textbooks; that it is a far less rational exercise than generally imagined. In effect, 'it is a series of peaceful interludes punctuated by intellectually violent revolutions … in each of which one conceptual world view is replaced by another'.

3 The formulation of scientific method outlined earlier has come in for strong and sustained criticism. Mishler (1990), for example, describes it as a 'storybook image of science', out of tune with the actual practices of working scientists who turn out to resemble craftspersons rather than logicians. By craftspersons, Mishler is at pains to stress that competence depends upon 'apprenticeship training, continued practice and experienced-based, contextual knowledge of the specific methods applicable to a phenomenon of interest rather than an abstract "logic of discovery" and application of formal "rules" '. The knowledge base of scientific research, Mishler contends, is largely tacit and unexplicated; moreover, scientists learn it through a process of socialization into a 'particular form of life'. The discovery, testing and validation of findings is embedded in cultural and linguistic practices and experimental scientists proceed in pragmatic ways, learning from their errors and failures, adapting procedures to their local contexts, making decisions on the basis of their accumulated experiences. See, for example, Mishler (1990).

4 Investigating social episodes involves analysing the accounts of what is happening from the points of view of the actors and the participant spectator(s)/investigator(s). This is said to yield three main kinds of interlocking material: images of the self and others, definitions of situations, and rules for the proper development of the action. See Harré (1976).

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. In addition there is further information on complexity theory. These resources can be found online at **www.routledge.com/cw/cohen**.

Mixed methods research

CHAPTER 2

This chapter introduces:

- definitions of mixed methods research
- why use mixed methods research
- the foundations of mixed methods research
- paradigms and the commensurability problem in mixed methods research
- working with mixed methods approaches
- mixed methods designs and data
- reliability and validity in mixed methods research
- mixed methods research questions
- sampling in mixed methods research
- mixed methods data analysis
- timing and writing up the data analysis in mixed methods research
- stages in mixed methods research

2.1 Introduction

When we look at a phenomenon, do we suddenly don a quantitative hat, or a qualitative hat? Surely not. In viewing our world we naturally integrate rather than separate; we use all the means and data at our disposal to understand a situation. We use mixed methods to find out about something. So it can be in educational research. Mixed methods research (MMR) is not new (Denscombe, 2014, p. 159), but its new-found ascendancy and prominence, and indeed its title, have captured the world (cf. de Lisle, 2011). Claims made for MMR are not modest. The rise of MMR has been meteoric to the extent that it has been called the 'third methodological movement' (Johnson *et al*., 2007; Teddlie and Tashakkori, 2009), the 'third research paradigm' (Johnson and Onwuegbuzie, 2004; Johnson *et al*., 2007, p. 112; Denscombe, 2008) and the 'third path' (Gorard and Taylor, 2004), whilst Fetters and Freshwater (2015) suggest that the synergy of quantitative plus qualitative offers more than the individual components ('1 + 1 = 3' (p. 116)).

The 'paradigm wars' (Gage, 1989), in which one stood by one's allegiances to quantitative or qualitative methodologies, and which sanctioned the rise of qualitative methods and the partial eclipse of solely numerical methods (Denzin, 2008, p. 316), have given way to MMR (Gorard and Taylor, 2004; Gorard and Smith, 2006; Teddlie and Tashakkori, 2009). This recognizes that there is a need for greater rapprochement and less confrontational approaches to be adopted between different research paradigms (Denzin, 2008, p. 322), greater convergence between the two (Brannen, 2005), and a greater dialogue to be engaged between them and their proponents.

The placement of this chapter on MMR after the opening chapter in this book is deliberate, to acknowledge that, for many writers, MMR has its own paradigm, its own foundational views on social reality and research, its own ontology and epistemology, its own axiologies and methodologies. MMR already has a major place in research. It constitutes an approach, a methodology and a view of designs and methods (which we also set out in this chapter for the sake of fidelity to the principle of pragmatism that underlines MMR as well as for the sake of coherence and practical implications). The argument that we raise in this chapter is that, by virtue of its theoretical roots in pragmatism, its ontology and epistemology, its axiological premises, it is well located in Part 1. We also recognize that the later parts of this chapter could also sit comfortably in Parts 2 and 3, but this would be to fragment unnecessarily the discussion of MMR and lose the coherence to which MMR stakes an important claim.

The attention given to MMR is evidenced in the *Journal of Mixed Methods Research*, the *International Journal of Multiple Research Approaches*, an exponential increase in the number of key texts in the field and the launching of the Mixed Methods International Research Association (http://mmira.wildapricot.org).

MMR recognizes, and works with, the fact that the world is not exclusively quantitative or quantitative; it is not an either/or world, but a mixed world, even though the researcher may find that the research has a predominant disposition to, or requirement for, numbers or qualitative data. We see the world in multiple ways, some of which may or may not agree with each other. MMR encourages us not only to look at the world in different ways but to share those multiple, different

views in making sense of the world, discussing our views and values in it.

MMR not only relates to data collection, but concerns philosophical bases of research, paradigms which guide research and assumptions which inform the design and conduct of research. Creswell and Plano Clark (2011) observe that MMR brings together quantitative and qualitative data in a single research study or series of research studies (p. 5), the intention of which is to give a greater understanding of the topic or problem in question than either a quantitative or qualitative approach on its own would provide.

MMR focuses on collecting, analysing and mixing both quantitative and qualitative data in a single study or series of studies. Its central premise is that the use of quantitative and qualitative approaches, in combination, provides a better understanding of research problems and questions than either approach on its own. This is, in part, because research problems are not exclusively quantitative or qualitative, hence using only one kind of data (quantitative or qualitative), one methodology, one paradigm, one way of looking at the problem or one way of conducting the research, may not do justice to the issue in question (cf. Creswell and Plano Clark, 2011, p. 10; Creswell, 2012, p. 535). Further, a piece of research may have more than one phase, and MMR may take place both within and across phases. However, MMR is not only about data types; its reach extends much further, into ways of viewing the world, ontologies, epistemologies, axiologies, methodologies and a range of other areas which are introduced in this chapter.

2.2 What is mixed methods research?

Mixed methods research defies simple or single definitions, as the following references indicate.

Creswell and Plano Clark (2011, p. 4) offer an introductory definition in suggesting that MMR typifies research undertaken by one or more researchers which combines various elements of both quantitative and qualitative approaches (e.g. with regard to perspectives, data collection and data analysis) to research, together with the nature of the inferences made from the research (p. 4), the purposes of which are to give a richer and more reliable understanding (broader and deeper) of a phenomenon than a single approach would yield. Leech and Onwuegbuzie (2009, p. 265) suggest that conducting MMR involves data collection (both quantitative and qualitative), analysis and interpretation of studies that, singly or together, address a particular phenomenon.

However, MMR is not confined simply to methods, nor to methodology; rather it has a much wider embrace. MMR has many different definitions (Tashakkori and Teddlie, 2003). Johnson *et al*. (2007, pp. 119–21) give nineteen definitions that vary according to what is being mixed, where and when the mixing takes place, the breadth and scope of the mixing, the reasons for the mixing, and the orientation of the research. Greene (2008, p. 20) suggests that a mixed method way of thinking recognizes that there are many legitimate approaches to social research and that, as a corollary, a single approach on its own will only yield a partial understanding of the phenomenon being investigated.

As an example of its definitional pluralism, Tashakkori and Teddlie (2003) indicate that varieties of meanings of MMR lie in six major domains: (a) basic definitions; (b) utility of MMR; (c) paradigmatic foundations of MMR; (d) design issues; (e) drawing inferences; and (f) logistical issues in conducting MMR. Teddlie and Tashakkori (2006, 2009) set out seven dimensions in organizing different views of MMR:

- the number of methodological approaches used;
- the number of strands or phases in the research;
- the type of implementation process in the research;
- the stage(s) at which the integration of approaches occur(s);
- the priority given to one or more methodological approaches (e.g. quantitative over qualitative or vice versa, or of equal emphasis;
- the purpose and function of the research study;
- the theoretical perspective(s) in the research.

Creswell and Tashakkori (2007) set out four different realms of MMR which address what is being mixed: (a) methods (quantitative and qualitative methods for the research and data types); (b) methodologies (mixed methods as a distinct methodology that integrates world views, research questions, methods, inferences and conclusions); (c) paradigms (philosophical foundations and world views of, and underpinning, MMR); and (d) practice (mixed methods procedures in research). Clearly MMR operates at all stages and levels of research.

Greene (2008, pp. 8–10) organized discussion of MMR into four domains:

- philosophical assumptions and stances (assumptions about ontology – the nature of the world – and epistemology – how we understand and research the world, and the warrants we use in validating our understanding);

- inquiry logics (e.g. purposes and research questions, designs, methodologies of research, sampling, data collection and analysis, reporting and writing);
- guidelines for practice (how to mix methods in empirical research and in the study of phenomena);
- socio-political commitment (what and whose interests, purposes and political stances are being served).

Hesse-Biber and Johnson (2013) note that MMR applies to different paradigms, axiologies, stakeholders, levels of analysis (micro, meso, macro) and research cultures and practices (p. 103), recognizing that it is the research question that is central and critical in the design of the MMR and that research problems often require plural methodologies, cross-disciplinary approaches and multiple philosophical perspectives.

A mixed methods approach can apply to all the stages and areas of research: philosophical foundations and paradigms; ontologies, epistemologies, axiologies; methodology, research questions and design; instrumentation, sampling, validity, reliability, data collection; data analysis and interpretation; reporting; and outcomes and uses of the research (cf. Creswell and Tashakkori, 2007; Bergman, 2011a). This echoes Yin (2006, p. 42), who argues that the stronger the mix of methods and their integration at all stages, the stronger the benefit of mixed methods approaches (p. 46).

Clearly, even at the definitional and scoping stages, challenges are raised concerning what MMR is, how it can be conceptualized and organized, what it comprises and how it is conducted.

2.3 Why use mixed methods research?

It is claimed that MMR enables a more comprehensive and complete understanding of phenomena to be obtained than single methods approaches and answers complex research questions more meaningfully, combining particularity with generality, 'patterned regularity' with 'contextual complexity', insider *and* outsider perspectives (*emic* and *etic* research), focusing on the whole *and* its constituent parts, and the causes of effects (discussed in Chapter 6). Creswell and Plano Clark (2011) note that MMR can yield insights into, and explanations of, the processes at work in a phenomenon and the multiple views of the phenomenon (p. 61), thereby increasing the usefulness and credibility of the results found, indeed affording the opportunity for unexpected results to be found.

Denscombe (2014, p. 147) suggests that MMR can provide a more complete picture of the phenomenon under study than would be yielded by a single approach, thereby overcoming the weaknesses and biases of single approaches (the benefits of 'complementarity' and 'completeness' (Creswell and Plano Clark, 2011, p. 61)). Denscombe (2014) also suggests that MMR can increase the accuracy of data and reliability through triangulation, reduce bias in the research, provide a 'practical, problem-driven approach to research' (p. 160) and enable compensation between strengths and weaknesses of research strategies.

Day and Sammons (2008) indicate how a mixed method approach can provide more nuanced and authentic accounts (than single methods approaches) of the complexities of phenomena under investigation. Greene (2005, p. 207) argues for a mixed methods approach that welcomes multiple methodological traditions, as these catch diversity and difference and are 'anchored in values of tolerance, acceptance, respect' and democracy (p. 208). Mertens (2007) and Greene (2008) argue that, in seeking social justice, MMR operates in a 'transformative paradigm' (see Chapter 3).

Care has to be taken to separate 'complementarity' from 'supplementarity' in MMR. Whilst 'complementarity' suggests that one method may make up for the shortcomings of another, 'supplementary' is simply additive (cf. Bergman, 2011a), and, in itself, is not a sufficient justification for MMR, as any addition would meet this requirement. The researcher has to decide whether one method is being used to complement or supplement the research. If it is the former, then what is absent that the complementarity must rectify, and if it is the latter, what is being added or supplemented that renders it important for such addition or supplementation to be included? Further, unless the research question or problem unequivocally requires MMR, it is for the researcher to demonstrate that MMR in principle is preferable to a mono-method approach (p. 274).

In considering whether or not to employ MMR, and in addressing fitness for purpose, researchers can ask:

- What is gained/lost by looking/not looking at the world in mixed ways, i.e. using/not using MMR in terms of philosophical foundations, paradigms, ontologies, epistemologies, axiologies, methodologies, designs, research questions, sampling, data types, instrumentation, data analysis, data interpretation, drawing conclusions and reporting?
- What does researching objectively and subjectively, scientifically and interpretively, quantitatively and qualitatively, by numbers and by qualitative approaches, tell us?

- What is it about a piece of research that requires MMR, such that not to use MMR is to diminish the quality, validity, reliability and utility of the research?

2.4 The foundations of mixed methods research

Paradigms and pragmatism

Mixed methods research has several foundations (cf. de Lisle, 2011, pp. 91–2). For example, quantitative approaches may have their roots in positivism, post-positivism and the scientific paradigm. Qualitative methods may have their roots in the interpretive paradigm. Transformative approaches may appeal to critical theory with its political and ideological agenda of empowerment, emancipation, equality and social justice. The foundations of MMR have multiple allegiances, and these allegiances determine and embrace world views (what the world is like and how to look at the world), ontologies (views of reality), epistemologies (ways of understanding, knowing about and researching that reality) and axiologies (values and value systems, e.g. value-free or value-laden research). These are brought together in different ways in different paradigms.

A paradigm, following Kuhn (1962), defines 'the set of practices that define a scientific discipline at any particular period of time' (p. 175): what is to be observed and scrutinized; the kinds of research questions to be asked and problems to be investigated; how to structure such research questions; what predictions can be made by the primary theory in that discipline; the ways of working; and how to interpret results. A paradigm embodies the values and beliefs of a group (in Kuhn's case it was scientists), such that one set of views and beliefs may be incommensurable with another, abiding by different philosophical assumptions, ontologies, epistemologies and axiologies. Mertens (2012) suggests that paradigms are 'philosophical frameworks that delineate assumptions about ethics, reality, knowledge, and systematic inquiry' (p. 256). Paradigms include how we look at the world, the conceptual frameworks in which we work in understanding the world, the community of scholars who are working within that framework and who define what counts as worthwhile knowledge and appropriate methodology in it, how we research the world, what the key concepts are, what counts as relevant knowledge and how we validate and consider that knowledge.

Given that a 'paradigm' embraces a 'world view', to define a paradigm in terms of quantitative, qualitative or mixed methods is misleading, as these refer largely or only to kinds of data (Biesta, 2010a), and a paradigm has a much wider embrace than this which includes a world view, an epistemological stance, shared beliefs and model examples (Freshwater and Cahill, 2013, p. 50). MMR concerns not only mixing data but mixing paradigms, ontologies, epistemologies and axiologies in order to give a fair, rounded picture of the phenomenon under investigation.

Creswell and Plano Clark (2011, p. 40) identify four paradigms or world views (see also Chapter 1):

- Post-positivism (quantitative research), in which emphasis is placed on the identification of causality and its effects, focusing on variables and their manipulation (e.g. isolation and control of variables in a reductionist world), careful observation and measurement, and hypothesis testing in a world characterized by a singular view of reality and in which the researcher imposes the research on the phenomenon (i.e. top-down).
- Constructivism (qualitative research), in which the objective of the research is to understand a phenomenon as it is seen and interpreted by the participants themselves, individually (e.g. Piagetian constructivism) or socially (e.g. Vygotskyian constructivism) in a world characterized by a multiple view of reality and in which the researcher works with the world as it is construed by its participants (i.e. bottom-up).
- Participatory/transformative (qualitative research), in which the research has a deliberate agenda of seeking to improve the situation of its participants, focusing, thereby, on issues of: agentic control of one's life; power, empowerment, social justice, marginalization and oppression; voice and action, all in a world characterized by a political, negotiated view of reality and in which the researcher works collaboratively with participants to improve the life situation of disempowered groups and individuals.
- Pragmatism (quantitative and qualitative), in which the research focuses on framing and answering the research question or problem, which is eclectic in its designs, methods of data collection and analysis, driven by fitness for purpose and employing quantitative and qualitative data as relevant, i.e. as long as they 'work' – succeed – in answering the research question or problem, and in which the researcher employs both inductive and deductive reasoning to investigate the multiple, plural views of the problem and the research question.

Mertens (2012) identifies three paradigms in MMR: 'dialectical pluralism', lodged between constructivism and post-positivism (p. 256); 'pragmatism' and the

'transformative' paradigm (p. 256). She argues that these paradigms in MMR have 'different sets of philosophical assumptions' (p. 256), though it is questionable where the incommensurability question is actually answered here, as incommensurability does not evaporate by making different data types available in a single piece of research. This rehearses the differences between mixing data, methods and world views in MMR.

Morgan (2007) argues against the use of the term 'paradigm' in MMR, suggesting its replacement by 'approach', particularly in his advocacy of the pragmatic approach. In MMR, methodological pluralism is the order of the day as this enables errors in single approaches to be identified and rectified (Johnson *et al*., 2007, p. 116). It also enables meanings in data to be probed, corroborated and triangulated, rich(er) data to be gathered and new modes of thinking to emerge where paradoxes between two individual data sources are found (p. 115; Sechrest and Sidana, 1995). For example, one can adopt a constructivist approach in developing a research problem or question, and then adopt a pragmatic, post-positivist or transformative paradigm for investigating it (Flick *et al.*, 2012). At issue here is whether commencing in one paradigm frames a research question or problem in a way that would be different if one had commenced in a different paradigm. A paradigm affects how we think about a problem or issue (Mertens and Hesse-Biber, 2012).

Much MMR works beyond quantitative and qualitative exclusivity or affiliation, and instead operates in a 'pragmatist paradigm' (Onwuegbuzie and Leech, 2005; Ercikan and Roth, 2006; Johnson *et al*., 2007, p. 113; Teddlie and Tashakkori, 2009, p. 4; Gorard, 2012, p. 8) which draws on, and integrates, both numeric and narrative approaches and data, quantitative and qualitative methods where relevant, to meet the needs of the research rather than the allegiances or preferences of the researcher, and in order to answer research questions fully. Whereas post-positivist approaches are premised on scientific, objectivist ontologies (how we construe reality) and epistemologies (how we understand, come to know about or research reality), and whereas interpretive approaches are premised on humanistic and existential ontologies and epistemologies, by contrast, MMR is premised on pragmatist ontologies and epistemologies.

Quantitative approaches are not all of one kind, and neither are all qualitative approaches. In this respect, Onwuegbuzie and Leech (2005, p. 377) argue that not all quantitative approaches are positivist and not all qualitative approaches are hermeneutic. For example, quantitative approaches can catch opinions, perceptions, probabilistic causality and process approaches (e.g. structured observation), and qualitative approaches can feature in experiments, identifying causality, surveys and patterns of, and trends in, data (e.g. Miles and Huberman, 1984, 1994).

Onwuegbuzie and Leech (2005, p. 376) argue that MMR recognizes similarities between different philosophies and epistemologies (in quantitative and qualitative traditions), rather than the differences that keep them apart, and that there are far more similarities than differences between the two approaches, as both use observational data, both describe data, and construct explanations and speculations about the reasons why observed outcomes are as they are (p. 379). Both concern corroboration and elaboration; both complement each other and identify important conflicts, where they arise, between findings from the two kinds of data (cf. Brannen, 2005, p. 176).

Hammersley (2013) suggests that the terms 'quantitative research' and 'qualitative research' are no longer useful categories (p. 99), as there are major variants of each, and he suggests, rather, that in conducting research it is preferable to use a range of strategies that lend themselves to 'research practice' (p. 99). Methodological puritanism should give way to methodological pragmatism in addressing research questions (cf. Caracelli and Greene, 1993; Greene, 2008; Creswell, 2009).

A commonly given basis of MMR is pragmatism. This is loosely interpreted to be 'what works', i.e. if the methods of research and the data collected – be they numerical or qualitative – address the research purposes, problems or questions then they are acceptable. In other words, the research is driven by the research question. Biesta (2012) contrasts a pragmatic approach with a principled approach (p. 147), though this is contestable, as pragmatism is no less a principle or a philosophical position than, say, post-positivism or constructivism. The principle underpinning pragmatism is that thought should lead to action, to prediction and problem solving.

Pragmatists such as James, Peirce and Dewey consider thought to be an instrument or tool for accurate prediction, problem solving and action, i.e. philosophy is not merely a contemplative exercise but is judged by its practical outcomes, success in practice, ability to solve problems and the everyday use-value of philosophizing. What is 'true' and what is valuable is 'what works'. As Ulysse and Lukenchuk (2013, p. 18) remark, in pragmatism one is less concerned with the truth or falsehood of an idea and more concerned with whether the idea can make a difference (they quote William James's comment that pragmatism concerns its 'cash value'). Similarly they note that Peirce's

pragmatism concerned less a theory of truth and more whether a solution can be found to a problem.

Pragmatism is essentially practical rather than idealistic; it is 'practice-driven' (Denscombe, 2008, p. 280). It argues that there may be both singular and multiple versions of the truth and reality, sometimes subjective and sometimes objective, sometimes scientific and sometimes humanistic. It is a matter-of-fact approach to life, oriented to the solution of practical problems in the practical world. It prefers utility, practical consequences, outcomes and heurism over the pursuit of a single, particular kind of accuracy in representing 'reality'. Rather than engaging in the debate over qualitative or quantitative affiliations, it gets straight down to the business of judging research by whether it has found out what the researcher want to know, regardless of whether the data and methodologies are quantitative or qualitative (Feilzer, 2010, p. 14).

In pragmatism, what something 'means' is manifested in its practical, observable consequences and success in practices, with its links to experience, rather than, for example, abstract theory with little practical import, or ideology, or dogmatic adherence to a particular value system or epistemology. Theories are to be judged by their practical utility rather than being ends in themselves; they are instruments for coping with, understanding and living with 'reality'. Hence a 'good' theory pulls its weight in its practical utility; values and beliefs denote rules for action.

Working in this vein argues against any privileged, distinctive method of enquiry; 'what works' is what helps us to understand, research and solve a problem. Our frames of reference, conceptual schemes, categories for understanding the world, are not immutable or eternal, but are our creations, our artefacts, useful insofar as they solve practical problems. Which frameworks, categories, theories, conceptual schemes and ways of viewing a problem we use are decided by their practical utility and applicability in solving a particular problem. Knowledge and action are closely connected and mutually informing.

Clearly pragmatism is no less value-based than other 'principles'; it is simply that its values differ from others. Pragmatism adopts a methodologically eclectic, pluralist approach to research, drawing on positivist, post-positivist and interpretive epistemologies based on the criteria of fitness for purpose and applicability, and regarding 'reality' as both objective and socially constructed (Johnson and Onwuegbuzie, 2004). No longer is one a slave to methodological loyalty and a particular academic community or social context (Oakley, 1999). Denscombe (2008) argues for the mixed methods paradigm to be defined in terms of a new 'community of practice' of those like-minded researchers who adopt the principles of MMR; regarding MMR in terms of a 'community of practice' respects the pragmatic underpinning of this approach.

Pragmatism suggests that 'what works' to answer the research questions is the most useful approach to the investigation, be it a combination of experiments, case studies, surveys or whatever, as such combinations enhance the quality of the research (e.g. Suter, 2005). Indeed Chatterji (2004) argues that mixed methods are unavoidable if one wishes to discover 'what works'. Pragmatism is not an 'anything goes', sloppy, unprincipled approach; it has its own standards of rigour, and these are that the research must answer the research questions and 'deliver' useful, practicable, reliable and valid answers to questions put by the research.

Paradigms and the commensurability problem in mixed methods research

Mixed methods research has to grapple with the issue of 'commensurability': is it possible to mix methods which have distinct and incompatible roots and views of the world, and how we should research and understand it, what should we look for and look at, and how should we make sense of the world?

Whether paradigms are or are not incommensurable, whether they can coexist alongside each other or can be integrated, is an immense open, philosophical question. Bergman (2011a, 2011b) comments that the recourse to pragmatism is no solution to, or resolution of, the incompatibility problem; it still exists and will continue to exist as it is illogical to try to seek coherence of such incoherence in a single research design (2011a, p. 101) (see also Denzin, 2012), even if it 'works' in practice. Hammersley (2013) argues that quantitative and qualitative approaches are irreconcilable as their rationales are very different (p. 97), such that mixing quantitative and qualitative methods means, in effect, 'abandoning key assumptions' of qualitative research (p. 97). Indeed Borge (2012, p. 15) notes that there are times when, rather than trying to mix methods, it may be helpful to have different specialisms and division of labour in quantitative and qualitative terms: we need specialists to give us expert advice on particular aspects of a phenomenon.

Biesta (2012, p. 148) identifies seven levels of 'mixing', and he raises challenging questions for those working with MMR:

1 '*Ontologies*', questioning whether and how it is possible combine different ontologies (e.g. views of the nature of reality).

2 '*Epistemologies*', questioning whether and how it is possible to combine different epistemologies (ways of knowing).
3 '*Research purposes*', questioning whether and how it is possible to combine the wish to have research which seeks causal explanations with that which seeks understanding and interpretation.
4 '*Practical orientation*', questioning whether and how it is possible for research to be directed both towards producing 'solutions, techniques and technologies' (p. 148) and towards developing 'critical understanding'.
5 '*Designs*', questioning whether and how it is possible to combine interventionist designs, such as experiments, with non-interventionist designs, such as naturalistic research.
6 '*Data*', questioning whether and how it is possible to combine text and numbers.
7 '*Methods*', questioning whether and how it is possible to combine different methods of collecting and/or analysing data.

Biesta's view goes to the heart of the dilemma of MMR, questioning whether a piece of research can genuinely 'mix' different elements (as in mixing water and milk to form a new liquid) or simply combine them but keep them separate (as in combining the separate pieces of a jigsaw to make a complete picture). We return to 'commensurability' and incommensurability later in this chapter.

Bergman (2011a) notes that even the term 'mixing' is inappropriate because one cannot mix that which cannot be mixed, and he argues that MMR designs are unable to bridge incompatible ontological, epistemological and axiological positions (p. 273). How, he asks, can one combine a subjectivist foundation with an objectivist one, or research that separates the researcher from the research with that which binds them together? He argues that more suitable terms than 'mixed' might be 'blended', 'meshed' and 'combined' (p. 272). Similarly Creswell and Plano Clark (2011, p. 277) comment that mixed methods differ from multi-methods, in that multi-methods do not necessarily imply that they will be mixed. In terms of educational research this suggests the need to identify the benefits of each approach (e.g. quantitative and qualitative) in terms of the overall research purpose, problem or question.

Consider the analogy: was it possible for scientists to work in two distinct paradigms – the geocentric view which put the Earth at the centre of the universe (a Ptolemaic model) or a heliocentric view with the sun at the centre (the Copernican view)? Surely these two are fundamentally incompatible? Applying this analogy to MMR calls into question whether, in fact, it is fitting to call MMR a paradigm at all. For example, in what sense can I combine an atheistic view of the world with a theistic view of the world and then call this a new paradigm? The two have fundamentally different and irreconcilable starting positions, rationales, values, foundations and ways of looking at the world, and to bring them together under a convenient label of a 'paradigm' is a misnomer; it does not 'mix' them at all, it just puts them side by side and draws on each as appropriate in answering a research question or problem. In this instance we have two paradigms, not one. Maybe MMR is just a convenient shorthand for something that we understand but which has different and incompatible premises, and which is not actually a single paradigm, or, more generously, is a paradigm based on compatibility – each party living in comfort alongside the other – rather than mixing, i.e. a marriage rather than a metamorphosis into a single organism.

Putting together quantitative and qualitative designs and data may be difficult, as the two may be incommensurate in terms of the paradigms, ontologies, epistemologies, methodologies, axiologies, data types, etc. The analogy may be made with trying to mix oil and water, which stay separate, rather than milk and water, which mix. Recognizing such differences may not be a problem as, together, complementarily, they can yield a complete picture of the phenomenon in question. Oil and water may not mix but they give more than oil alone or water alone.

Further, neither is quantitative nor qualitative research all of one type. For example, not all quantitative research is large scale and not all qualitative research is small scale (cf. Miles and Huberman, 1984, 1994). 'Quantitative' and 'qualitative' are umbrella terms, each covering a multitude of research types. Hence, in designing MMR, specificity is necessary about what kind of research is planned with respect to the quantitative and qualitative elements.

In relation to the issues of the incommensurability of paradigms (Howe, 1988; Denzin, 2008; Creswell, 2009, p. 102; Trifonas, 2009, p. 297), MMR argues for their compatibility, or at least their ability to live alongside each other and to work together to solve a research problem. These same authors suggest the power of integrating different approaches, ways of viewing a problem, and types of data in conducting research, induction and deduction in answering research questions, in strengthening the inferences that can be made from research and data and in generating theory. Indeed Reams and Twale (2008, p. 133) argue that mixed methods are necessary and important in addressing information and perspectives, and that they 'increase

corroboration of the data, and render less biased and more accurate conclusions'. Maybe that leaves behind the problem of whether MMR constitutes a paradigm, whether quantitative and qualitative approaches can be brought into a single overarching paradigm, or whether each is incommensurable with the other. In other words, whether or not we recognize commensurability and incommensurability actually doesn't matter that much, if at all, in the 'real world' of practical utility in MMR.

Researchers need not become mired in the paradigm debate; as long as we know what we are dealing with in MMR then this may suffice. Mertens and Hesse-Biber (2012) suggest it is time to move beyond the commensurability/incommensurability question (p. 75). We still have not resolved the incompatibility thesis, but that does not mean that we are unable to move forward in MMR (Bergman, 2011b) or to conduct MMR research.

2.5 Working with mixed methods approaches

There are no blueprints for how to work with MMR; each piece of research is unique and the researcher has to decide how to design and implement the research, based on its own purposes, foci, merits and characteristics. What follows, then, are considerations in coming to these decisions in terms of design issues, research questions, sampling, data collection and analysis, and writing up the data analysis. We leave behind the issue of paradigms and their commensurability, and move to planning 'what works', as this accords with the pragmatic roots of MMR.

Mixed methods research designs and data

A research design is the plan for, and foundations of, approaching, operationalizing and investigating the research problem or issue; setting out the approach, theory/ies and methodology/ies to be employed; the types of data required, how they will be collected (instrumentation) and from whom (the population and/or sample); how the data will be analysed, interpreted and reported; the warrants to be adduced to defend the conclusions drawn and the degree of trust that can be placed in the validity and reliability of each element of the research; and the sequence of the research.

In MMR the kinds and methods of research and its several stages or phases are driven by the research questions or research problem, with 'fitness for purpose' as a guiding principle. There must be a clear matching of the research question to the research problem and to the methods used for answering that research inquiry. For MMR this means providing a reasoned and reasonable justification for mixing whatever elements of the research design are, indeed, to be mixed (e.g. world views, views of reality, paradigms, rationales, theories, methodologies and approaches, data types and instrumentation, sampling, data analysis, interpretation and reporting, types of validity and reliability), stages and phases of the research, conclusions, outcomes and consequences of the research.

In approaching MMR designs, key decisions have to be taken on several issues (cf. Teddlie and Tashakkori, 2009, p. 141; Creswell and Plano Clark, 2011, pp. 64–7):

- Why used a mixed methods approach? What will a mixed methods approach provide that a non-mixed methods approach does not?
- What, actually, will be mixed, and why, for example, paradigms, ontologies, epistemologies, theories and theoretical frameworks, designs, research purposes and questions, methodologies, populations and samples, data types, data-collection instruments and their contents, data analysis, interpretation and reporting?
- Why, where, at what level(s), in what areas and how will this 'mixing' occur, how will it be done, adhering to what principles, procedures and processes?
- When, where, why and how will the designs and data be mixed, merged, integrated, connected, adhering to what principles, procedures and processes, and how will the quantitative designs and data relate to qualitative designs and data, and vice versa? How and why will one design be embedded in another?
- What methodologies will be used, where, when, why and how?
- How many strands, levels, stages and phases will there be in the research, and where, how and why do quantitative and qualitative approaches feature in these? What will be the relative priority accorded to the quantitative and qualitative strands, for example, will they have equal priority/importance, will one take priority over the other, and, if so, at which stages or phases of the research, and why?
- What will be the level and type of interaction between the quantitative and qualitative strands of the research, for example, will they be independent, separate, integrated, combined, parallel, interactive?
- What will be the timing and/or sequence of the quantitative and qualitative strands in the research, for example, will they be concurrent/parallel and/or sequential in a time sequence within and between phases, and why?
- What ethical issues does MMR present?

Teddlie and Tashakkori (2009) suggest different designs in MMR. '*Parallel mixed designs*' (p. 26) (also termed 'concurrent designs') are those in which both qualitative and quantitative approaches run simultaneously but independently in addressing research questions, akin to the familiar notion of triangulation of method, theory, methodologies, investigators, perspectives and data, discussed later in this book. '*Sequential mixed designs*' (p. 26) are those in which one or other of quantitative and qualitative approaches run one after the other, as the research requires, and in which one strand of the research or research approach determines the subsequent strand or approach and in which the major findings from all strands are subsequently synthesized. '*Quasi-mixed designs*' (p. 142) are those in which both quantitative and qualitative data are gathered but which are not integrated in answering a particular research question, i.e. quantitative data might answer one research question and qualitative data another research question, even though both research questions are included in the same piece of research. '*Conversion mixed designs*' (p. 151) are those in which data are transformed (qualitative to quantitative and vice versa, e.g. in a parallel mixed design) (the issues of quantitizing qualitative research and qualitizing quantitative research are discussed below). '*Multilevel mixed designs*' (in parallel or sequential research designs) (p. 151) (also termed 'hierarchical' research designs) are those where different types of data (both quantitative and qualitative) are integrated and/or used at different levels of the research (e.g. student, class, school, district, region), for instance numerical data may be used at one level (students) and qualitative data used at another level (school). '*Fully integrated mixed designs*' (p. 151) are those in which mixed methods are used at each and all stages (perhaps iteratively: where one stage influences the next) and levels of the research.

Creswell and Plano Clark (2011) identify six MMR designs in which timing and sequence feature strongly. They contend that there must be a valid warrant or justification for the sequence and design chosen, and note that samples and sample sizes may vary with each kind of data and at different stages of the research. Their *convergent parallel design* (pp. 69–79) has both quantitative and qualitative data which are collected independently and in parallel with each other, and then they converge, yielding triangulation of data and offering complementary data on the question, problem, issue or topic in question. Quantitative and qualitative data are collected and analysed separately and then put together, for example they may be compared and contrasted, looking for similarity, difference and complementarity. The overall, combined or integrated results are reported.

In an *explanatory sequential design* (pp. 82–4), quantitative data are usually collected first, followed by qualitative data to explain the quantitative data. It is important for the researcher to identify which parts of the quantitative data need to be explained and how they can be explained (and with which sample(s)).

Their *exploratory sequential design* (pp. 86–7) reverses the sequence of data collection in the explanatory sequential design; qualitative data are usually collected first (typically with a small sample), with quantitative data from a larger sample used to generalize the findings.

Their *embedded design* (pp. 90–2) recognizes that each research question requires both quantitative and qualitative data, and qualitative data may be added to, embedded in or supplemented by quantitative data (e.g. in an experiment) or vice versa (e.g. a case study) in this design. In the former (the experiment), the qualitative data may be used to explain and interpret the quantitative data, whilst in the latter (the case study) the quantitative data may provide additional, more generalized data on the case (e.g. frequencies). The authors note that one type of data tends to have priority over another in this design: for example, qualitative data may be embedded within a largely quantitative study or quantitative data may feature within a mainly qualitative study. The authors also note that quantitative and qualitative data tend to be kept separate. It is important to decide when, and in what sequence, to collect the data: for example, concurrently and/or sequentially. In discussing an embedded design, Creswell and Plano Clark introduce a widely used notation:

QUAN = Quantitative data which have priority over qualitative data
Quan = Quantitative data which are subordinate to qualitative data
QUAL = Qualitative data which have priority over quantitative data
Qual = Qualitative data which are subordinate to quantitative data

They also introduce other symbols in outlining notation in designs (pp. 108–10):

+ (the methods – quantitative and qualitative – occur simultaneously);
() (one method is embedded within another);
→ (a linear sequence, where one stage informs the next or is kept separate);
→← (the methods are used recursively);

[] (mixed methods operate within a single study or a series of studies);
= (the outcome of the mixing).

For example, a case study may be characterized as '(QUAL and Quan)', whereas an experiment may be characterized as '(QUAN and Qual)'. The authors indicate the sequence of the quantitative/qualitative methodology, data collection and analysis by a simple arrow (→). We outline some conceptual MMR designs using these (Figure 2.1).

In their *transformative design* (pp. 96–7), as in critical theory, there is an explicitly political or ideological, social intention or agenda, to advance the social justice for the group or groups under study. In this collaborative, participatory type of research, the authors suggest

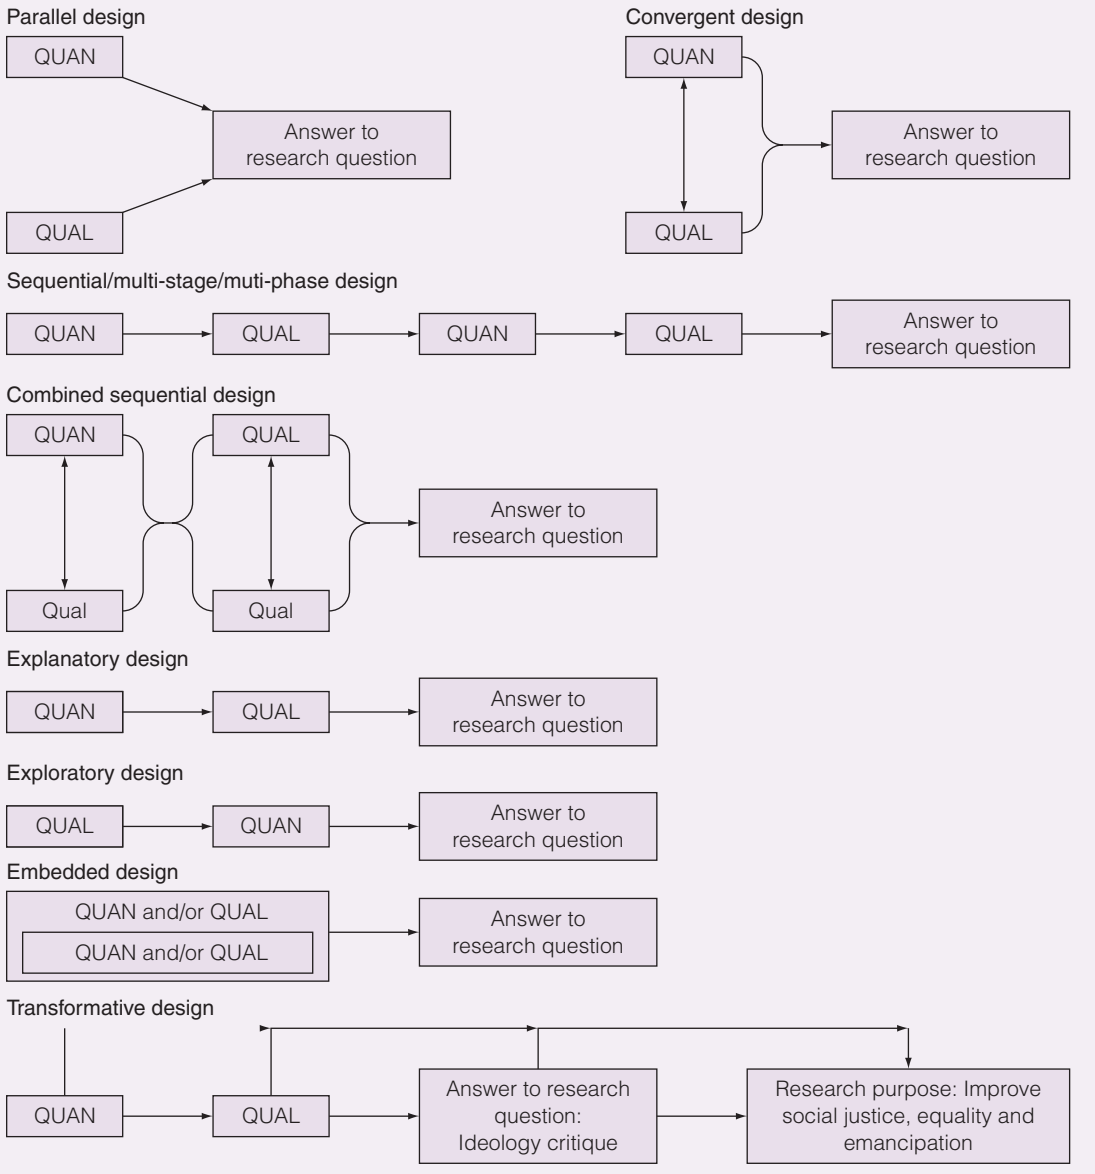

FIGURE 2.1 Mixed methods research typologies

that quantitative data precede qualitative data. However, in this design it is less the data types and sequence that are important as the overall purpose of the research, i.e. the research has a political/ideological agenda (whether this is the legitimate concern of researchers is another matter, for example Hammersley (2014, chapter 3) questions whether researchers should concern themselves with what uses are made of their data and, rather, should concentrate on ensuring that their research is conducted rigorously and without bias). As we argue in Chapter 3, the methodologies of research in the critical theory approaches are ideology critique and action research (Carr and Kemmis, 1986).

Finally, in their *multi-phase design* (Creswell and Plano Clark, 2011, pp. 100–11) the quantitative and qualitative data can be concurrent and/or sequential, depending on the phase of the research in which they are being used. At issue here is the need to identify the key phases of the research as it unfolds, and then decide which kind of data are needed in each phase. The point here is that the progress of the research is incremental and cumulative: one phase builds on, and is informed and influenced by, the preceding phase in addressing the overall purposes of the research. Hence the decision of which kinds of data are required at each stage is an iterative one, and it is important that each phase of the research is connected clearly. The authors comment that this kind of research is often characterized as a series of 'mini-studies' leading towards the overall answer to the research question or problem.

These are suggested models; clearly there are very many variants on these designs, as there may be enormous variety of: timing; number of stages/phases; sequence; data types in the sequence and within each stage; the priority/weights given to data types; interaction/independence of data (de Lisle (2011) provides a useful summary of these). It is for each research study to plan its own design. Even though mixed methods may be used, in some research the numerical approach may predominate – with its own sampling implications – whilst in others qualitative data may predominate, with an emphasis on purposive and non-probability sampling (cf. Teddlie and Yu, 2007, p. 85).

The designs set out above are not exhaustive, nor are they discrete, nor do they indicate the levels (other than data) at which the quantitative and qualitative aspects operate (e.g. paradigms; world views; ontologies; epistemologies; axiologies; methodologies; instrumentation; sampling; data types, collection, analysis, interpretation, reporting etc.). There is no single methodological approach in MMR (Hesse-Biber and Johnson, 2013). Rather, the typologies set out above are ideal types and typifications for the sake of heuristic clarity, designed to alert researchers to different kinds of MMR. It is for each research study to plan its own design. The design types set out above identify key issues to be addressed (e.g. Ivankova *et al*., 2006, pp. 9–11; Greene, 2008, pp. 14–17):

- *The paradigm dimension*: which paradigms are operating in the research, and why? For example, Creswell and Plano Clark (2011) align post-positivism with quantitative research, constructivism with qualitative research, transformative research with the transformative design, and pragmatism with those designs which are directed to answering the research question or problem regardless of which data types are used. This is not to argue that research is, or must be, paradigm-driven; rather it is to say that different kinds of design may be present within an overall study, and that the logic of each design type should be integrated into the overall logic of the entire study.
- *The methodology dimension*: which methodologies/approaches will be used (e.g. survey; experiment; case study; ethnography, interpretive and interactionist approaches; action research; historical study), which will impact on the research design, sampling, instrumentation, data analysis, ethics?
- *The time dimension*: when and where will the quantitative and qualitative elements be present in the study – in what sequence and/or concurrence or simultaneity? Should the quantitative and qualitative data be analysed together or separately?
- *The priority dimension*: which and what has priority (if any), where and when – quantitative and qualitative (e.g. paradigms, methodologies, data types, data analysis)?
- *The relationship dimension*: will the research types and data types be independent, interactive, complementary, additional to each other? What are the relationships between different types of data at different points in the research, both within-phase/within-stage and cross-phase/cross-stage?
- *Integration*: where and when – at which stages – and why do the integration of quantitative and qualitative methods and data occur?
- *Independence, the obverse of integration*: where, when and why will methods and data be kept concurrent, separate, interactive or independent?
- *Differentiation*: will mixed methods and data be used to address the same issue or different issues?
- *Matching*: which kinds of data are required for which stages of the research?
- *Issues in question*: around what issues do the mixed methods occur, for example, at the levels of

constructs, variables, research questions, purposes of the research?
- *Transformative intention*: does the research have an explicitly political agenda?
- *Scope*: does the mixing of methods occur within a single study or across more than one study in a set of coordinated studies within a single programme of research?
- *Strands*: how many different strands are mixed in the study (Greene, 2008, p. 14)?

In reality, the cleanness of the designs set out above may not catch the reality of conducting research, which, in many cases, is characterized by multiple iterations, modifications and emergence rather than a pre-figured design. Indeed Creswell and Plano Clark (2011, p. 105) note that designs may be fixed from the very beginning or may emerge as the study unfolds. For example, there is no golden rule which states that such-and-such a design or data type should precede or succeed another or that data can only be analysed or mixed at such-and-such a point or points in time; the decision is taken on fitness for research purpose and fitness for research question. We present different designs in Figure 2.1.

Kettley (2012) questions the usefulness of delineating an unending host of different designs of MMR at all, deeming such attempts to be 'unproductive labour' (p. 85). This is uncharitable, as such delineation can stimulate and clarify, without shackling, the deliberative process needed in deciding what is to be the appropriate design for a given piece of research. Typologies have heuristic value, and, indeed may indicate the relative importance of the quantitative or qualitative elements (Denscombe, 2014, p. 151). Pluralism and fitness for purpose, rather than slavish adherence to a single pre-fixed design, are the order of the day. Indeed research designs may change and emerge over the course of a study; the process is an emergent part of a dynamical system. Each design is different and must be decided by the research in hand.

There must be a defensible reason for mixing data types. For example, qualitative data may be used to develop instruments (e.g. a pre-pilot); to understand the context of research and the participants in it; to validate the quantitative data; to understand participants' views of the research and what is being studied; to gain feedback on an intervention; to identify the effects and impact of an intervention and its unanticipated effects and risks; to understand the processes of an intervention and the changes in participants over time; to identify intervening factors; to explain cause and effect; to explain, understand and triangulate the quantitative data.

On the other hand, quantitative data may be used for generalizing the outcomes of research or an intervention; providing 'hard' data; measuring effects of an intervention; refining data-collection instruments (e.g. removing unreliable items or items which too strongly correlate with other items); gaining an overall picture and patterns of response; identifying, measuring and modelling correlations and relationships, differences, key underlying factors; and suggesting cause and effect.

The mixed methods researcher has the same battery of instruments available for data collection as for mono-methods research. These are set out in the several chapters of this book. Of concern here are the implications of the 'mixed' nature of MMR for mixing data. Whilst this is taken up in the prior discussion of MMR designs, at issue here is whether, how and where to mix data, the warrants that attach to each, and ensuring the validity and reliability of the resultant mix. Underpinning this is the point that a genuine 'mix' means fidelity not only to the different nature and warrants of quantitative and qualitative data but also to the fact that both types must be demonstrably relevant to answering a given research question and must be fit for purpose.

Timing is an important dimension of the research design in respect of data types in MMR. Qualitative data may be useful *before* an experiment/trial commences, for example for: ensuring that the research meets a need; instrument development; gaining informed consent; understanding more about the participants; and gaining baseline data. This differs from the use of qualitative data *during* an experiment/trial, which here may be for: data validation and triangulation; impact analysis; gaining participants' perceptions of and opinions on what is occurring; understanding what is happening and why; identifying resource needs; identifying emerging issues and factors affecting the process. In turn, this differs from the use of qualitative data *after* an experiment/trial, which may be to gain participants' perceptions of and opinions and feedback on what had happened; to determine outcomes, effects and impact; to suggest explanations of or reasons for what had happened; and to compare before-and-after situations.

MMR addresses both the 'what' (numerical and quantitative data) and 'how or why' (qualitative) types of research questions. This is particularly important if the intention of the researcher is really to understand different explanations of outcomes. For example, let us say that the researcher has found that a hundred people decide that schools are like prisons. This might be an interesting finding in itself, but it might be that forty of the respondents thought they were like prisons because

they restricted students' freedom and had very harsh, controlling discipline. Twenty respondents might say that schools were like prisons because they were overcrowded; fifteen might say that schools were like prisons because the food was awful; ten might say that schools were like prisons because there was a lot of violence and bullying; ten might say schools were like prisons because they were 'total institutions' (Goffman, 1968); and another five might say that schools were like prisons because students had an easy life as long as they obeyed the rules. Here the reasons given for the simple statistic are very different from each other, and it is here that qualitative data can shed a lot of useful light on a simple statistic.

Reliability and validity in mixed methods research

Including quantitative and qualitative data may offer greater *reliability*. Within quantitative and qualitative approaches this includes a range of elements (see Chapter 14): for example, respondent validation, credibility of results, replicability, equivalence, stability, internal consistency and Cronbach alphas, dependability, credibility, accuracy, fidelity to context etc. These ensure reliability *within* each approach (quantitative and qualitative). Further, reliability-as-triangulation includes *between methods* approaches: for example, instruments, data types, researchers, time, participants, perspectives (people and approaches: objective and subjective, inductive and deductive (Morgan, 2007; Torrance, 2012); theories; methodologies; paradigms; axiologies; designs). Denscombe (2014, pp. 154–5) suggests that triangulation can be: (a) *methodological* (between methods), enabling researchers to study a phenomenon from a variety of perspectives and using dissimilar methods; (b) *methodological* (within methods), i.e. those methods which are similar to each other; (c) *data triangulation* (using contrasting sources of information, e.g. from different people, at different times, in different locations); (d) *investigator* (different researchers); and (e) *theory* (different theoretical positions).

Combining quantitative and qualitative data may also strengthen the *validity* of the research and the inferences that can be drawn from it in: the rigour of the design and its fitness for purpose in meeting the research purposes and research questions; methodological rigour; consistency of findings and conclusions with the evidence presented; defensible and credible inferences drawn; and the quality of the synthesis of data.

Validity *within* an approach is required, and Chapter 14 addresses this. Validity in quantitative and qualitative approaches have their own canons of rigour. In ensuring validity *between* approaches, Teddlie and Tashakkori (2009) argue that 'meta-inferences' assess the extent and degree to which the sets of inferences from quantitative and qualitative approaches are credible (cf. Ivankova, 2013), and that credible research requires such meta-inferences to be addressed and to be legitimate. Validity in MMR requires: designs that are appropriate for the research questions, methodologies and sampling; consistency with all the components of the study; procedures employed for analysing data to be appropriate to answer the research questions; and the different strands or elements of the MMR to be connected appropriately (Ivankova, 2013).

Ivankova (2013, p. 48) sets out a three-step process of validation of meta-inferences in MMR which employ a QUAN → QUAL design:

Step 1: Using a systematic process for selecting which participants to include in a qualitative follow-up;
Step 2: Elaborating, following up on and probing unexpected results from the quantitative data and their analysis;
Step 3: Observing and reporting on interactions between quantitative and qualitative strands of the study.

At issue here is the point that reliability and validity within each element/stage/data type of the research must be complemented by reliability and validity when combining the different elements/stages/data types of the research. We refer the reader here to Chapter 14, which includes more discussion of reliability and validity in mixed methods research.

Mixed methods research questions

In MMR the research is driven by the research questions (which require both quantitative and qualitative data to answer them). Greene (2008, p. 13) comments that methodology follows from the purposes and questions in the research rather than vice versa, and that different kinds of MMR designs follow from different kinds of research purposes: for example, hypothesis testing, understanding, explanation, democratization (see the discussion of critical theory in Chapter 3). Such purposes can adopt probability and non-probability samples (see Chapter 12), multiple instruments for data collection, and a range of data analysis methods, both numerical and qualitative.

In considering whether to adopt an MMR study, it is important for researchers to look at the research question or problem and ask themselves whether a single method on its own is appropriate or sufficient to answer

or address this respectively. If the answer is 'yes', then why consider MMR? If the answer is 'no', then what is needed from the quantitative and qualitative elements in order to answer the question or problem, and where should they be mixed or kept separate?

Tashakkori and Creswell (2007, p. 207) write that 'a strong mixed methods study starts with a strong mixed methods research question', and they suggest that such a question could ask 'what and how' or 'what and why' (p. 207), i.e. the research question, rather than requiring *only* numerical or qualitative data, is a 'hybrid' (p. 208). The research question, in fact, might be broken down into separate sub-questions, each of which could be either quantitative or qualitative, as in 'parallel' or concurrent mixed methods designs (see above) or in 'sequential mixed designs' (see above), but which converge into a combined, integrated answer to the research question (see also Chapter 10). Bryman (2007a, p. 13) goes further, to suggest not only that qualitative and quantitative data must be mutually informing, but that the research design itself has to be set up in a way that ensures that integration will take place, i.e. so that it is not biased to, say, a numerical survey.

Such research questions could be, for example: 'What are the problems of staff turnover in inner city schools, and why do they occur?' Here qualitative data might provide an indication of the problems and a range of reasons for these, whilst numerical data might provide an indication of the extent of the problems. Here qualitative data subsequently might be 'quantitized' into the numbers of responses expressing given reasons, or the quantitative data subsequently might be 'qualitized' in a narrative case study.

Sampling in mixed methods research

The material here does not rehearse the chapter on sampling, and readers are referred to Chapter 12. Here we confine ourselves to issues of sampling in MMR. Teddlie and Yu (2007) and Teddlie and Tashakkori (2009, pp. 180–1) indicate that it is commonplace for MMR to use more than one kind of sample (probability, non-probability) and to use samples of different sizes, scope and types (cases: people; materials: written, oral observational; other elements in social situations: locations, times, events etc.) within the same piece of research.

In MMR, sampling in quantitative approaches should address issues and criteria that are relevant to such quantitative approaches: for example, sampling strategy, probability and non-probability sampling, sample size calculation (with references to confidence intervals, confidence levels, sampling error and statistical power), choice of sample, representativeness, and access to the sample. In other words, sampling in quantitative approaches should abide by the canons of sampling principles for quantitative studies. This is not to say naively that samples in quantitative approaches should be large; they may be large, small and/or variable, depending on fitness for purpose, research questions and research design.

Similarly, qualitative approaches should abide by the canons of sampling in qualitative research, which address similar issues as quantitative approaches but have different decisions made on, or answers given to, those issues, for example on sampling strategy, purposive sampling, representativeness, access, size. This is not to say naively that samples in qualitative research should be small; they may be small, large and/or variable.

However, given the specifically *mixed* nature of MMR, consideration should be given to the implications of this for sampling, for example:

- What sampling strategies will be used for which elements of the research and will the same or different samples be used in both the quantitative and qualitative elements, for example, to ensure 'carry-through' and consistency of people, as having different samples may bring inconsistencies and undue divergence (Ivankova, 2013, p. 42)?
- Will the qualitative sample be drawn from the sample used in the quantitative element (i.e. some 'carry-through' of the sample, with the qualitative sample becoming, in effect, a sample of the quantitative sample), and will the qualitative sample include, but add to, the sample used in the quantitative element? If the qualitative sample is drawn from the quantitative sample, i.e. a sample of the sample, how will the qualitative sample be chosen?
- Will the quantitative sample be drawn from the sample used in the qualitative element (i.e. some 'carry-through' of the sample, with the quantitative sample becoming, in effect, a sample of the qualitative sample), and will the quantitative sample include, but add to, the sample used in the qualitative element? If the quantitative sample is drawn from the qualitative sample, i.e. a sample of the sample, how will the quantitative sample be chosen?
- At what point in the research will the samples be drawn, i.e. when will you decide whom the sample will comprise?
- Will the samples for the quantitative and qualitative elements be of the same or different sizes?
- Will the same or different samples be used for the same research question(s) and issues under study?

In some MMR studies it may be possible to decide the exact members of the sample(s) in advance of commencing the entire research, whereas in others it may be that choosing members of the sample may not be possible until a particular stage of the research has taken place. However, this does not mean that the *principles* for the sampling at different stages or for different elements of the research may not be decided in advance, only that the actual members for every stage of element may be unknown in advance.

For example, it may be that an initial quantitative survey in an MMR study may yield 'average' responses together with outliers, and that the qualitative element of the same overall study is designed to conduct follow-up interviews with some respondents whose responses were 'average' and others whose responses were outliers, i.e. to include in the qualitative sample members whose responses to the quantitative survey showed maximum variation. We do not know in advance who they will be, but we know the *principle* on which the qualitative sample will be selected.

An example of this is given by Ivankova (2013). She reports an MMR study of an online research methods training course which commenced with a quantitative survey (N = 119), and, following the statistical analysis of the numerical data, a sample of those from the quantitative survey was drawn for follow-up qualitative telephone interviews (N = 13). The sample for the qualitative interviews was purposive, chosen to be able to help the explanation and elaboration of the quantitative data (including unexpected results), and was based on the principles of seeking to reduce potential bias and socially desirable responses.

As another example, an MMR study might commence with a small-scale qualitative, exploratory set of interviews which raise issues to be included in a larger-scale quantitative survey which will require a random stratified sample, stratified according to characteristics that emerge in the initial interviews. Again, we do not know in advance who will be targeted for inclusion in the quantitative survey, but we know the *principle* on which the quantitative sample will be selected.

A major decision will concern whether to have entirely independent samples in the quantitative and qualitative approaches – different members in each sample – or whether to have any overlap of members. Decisions on this matter may depend on fitness for purpose. For example, Monteiro and Morrison (2014) report a study of undergraduate collaborative blended learning in which an initial large-scale survey was conducted on a population of students in one university, followed by a targeted quasi-experiment with a sample of students from one year-group of this population, gathering both quantitative and qualitative data from a purposive sample drawn from high-, medium- and low-performing students, using classroom observations, learning logs and interviews. This 'carry-through' of students for the quantitative and qualitative elements of the research enabled comparisons to be made between the survey data and the qualitative data, using the large-scale survey as a context in which the quasi-experiment was embedded.

Teddlie and Tashakkori (2009, pp. 185–91) provide a useful overview of different mixed methods sampling (see also Chapter 12). This includes *parallel mixed methods sampling*, *sequential mixed methods sampling*, *multilevel mixed methods sampling*, *stratified purposive sampling*, *purposeful random sampling* and *nested sampling designs*. Each of these, with examples, is addressed in Chapter 12, and we refer readers to that chapter. In the same chapter we note that the sampling strategy should derive logically from the research questions or hypotheses being investigated/tested. It should also be faithful to the assumptions on which the sampling strategies are based (e.g. random allocation, even distributions of characteristics in the population etc.). Each sample should generate sufficient qualitative and quantitative data in order to answer the research questions and enable clear inferences to be drawn from both the numerical and qualitative data. Sampling, of course, must abide by ethical principles and be practicable and efficient. Researchers should also consider whether the data will enable generalizability of the results to be addressed and to whom the results are generalizable. Further, the sampling should be reported at a level of detail that will enable other researchers to understand it and perhaps use it in the future.

Mixed methods data analysis

It is a truism to say that analysing quantitative and qualitative data must be faithful to the canons of quantitative and qualitative analysis respectively, and these are addressed in different chapters of this book (Part 5). These operate when treating quantitative and qualitative data separately. However, MMR asks for the integration of, and connection between, quantitative and qualitative data.

Quantitative and qualitative data can be analysed separately and independently, as, for example, in parallel or sequential designs (e.g. quantitative to qualitative or vice versa), and they can also be mutually informing. For example, Ivankova (2013) reports how, after she had conducted her quantitative data analysis and then proceeded to her qualitative data analysis, her qualitative data analysis suggested that she needed to go back and conduct further statistical analysis of her numerical

data. The process of data analysis in MMR is iterative, not necessarily a once-and-for-all event for each element or stage of the research. The researcher will need to decide:

- the purposes of data analysis both during and after the research process;
- which tools to use for analysis (e.g. numbers, words, graphics), what kind of analysis is most suitable for what kinds of data, what to look for in different kinds of data (e.g. do the different kinds of data focus on the same issue or different issues?), how to present different kinds of data analysis (e.g. in prose, tables, graphics), how to analyse the quantitative and qualitative data (see Part 5), and how to apply 'constant comparison' (see Chapter 37) to compare them, looking for similarities, differences, contrasts, additions, refinements, extensions, contradictions, mutual reinforcements, supplements, complements etc.;
- whether and why to analyse quantitative and qualitative data separately, independently or together, i.e. what, if any, is the relationship between the data types and their analysis?;
- the sequence and timing of the data analysis: when to analyse each kind of data, whether, why – and, if appropriate, how – to use the analysis of one kind of data to inform subsequent data collection and analysis and whether, when, where, why and how to relate, connect, merge and/or integrate data and data types;
- whether, where, how and why to quantitize qualitative data and to qualitize quantitative data, how to combine, compare and represent different types of data in answering a research question (e.g. analyse quantitative data and then qualitative data, or vice versa, and then draw key messages/themes from them together);
- which data in the data analysis have greater priority, and why, and how to represent and address this;
- what to do if the results from the analysis of one kind of data contradict, support, refine, qualify, extend those of another kind of data, what to do if re-analysis of earlier data is required, and what to do if inadequate, insufficient or weak data are found;
- how to combine data if they derive from different sampling strategies and different, unequal sample sizes, types and people.

Some kinds of research require 'progressive focusing' (Parlett and Hamilton, 1976), in which a study commences with a broad field of view and analyses data on this broad picture in order to identify key features. These features are then investigated further, in closer detail, moving from a wide view to a much narrower, focused set of issues. In MMR, for example, this lends itself to the analysis of large-scale quantitative data identifying patterns and key features, similarities and differences, which are then explored, for example in focus groups, observational data or semi-structured qualitative interviews. The point here is that one set of data analysis both precedes and informs what comes next.

MMR can combine data types (numerical and qualitative) in answering research questions and also convert data (Bazeley, 2006, p. 66). Caracelli and Greene (1993) suggest four strategies for integrating and converting data in MMR (see also Creswell and Plano Clark, 2011, p. 213): (a) data transformation (discussed below); (b) typology development (where classifications from one set or type of data are applied to the other set or type of data); (c) extreme case analysis (where outliers found in one set of data are explored using different data and methods); and (d) data consolidation/merging (where new variables are created by merging data).

'Data conversion' ('transformation') (Teddlie and Tashakkori, 2009, p. 27) is where qualitative data are 'quantitized' (converted into numbers, typically nominal or ordinal; see Chapter 38) (e.g. Miles and Huberman, 1994). This can be done, for example, by giving frequency counts of certain responses, codes, data or themes in order to establish regularities or peculiarities, or rating scales of intensity of those responses, data, codes or themes (Sandelowski *et al*., 2009, p. 210; Teddlie and Tashakkori, 2009, p. 269). Software can also assist the researcher in providing frequency counts of qualitative data (e.g. Bazeley, 2006). 'Data conversion' can also take place where numerical data are 'qualitized' (converted into narratives and then analysed using qualitative data analysis processes).

It is misguided to imagine that different types of data can somehow be truly mixed, as if their different nature simply disappears. MMR recognizes that data are different, but that is not the issue. Rather, the issue is how they can be combined, related and merged. In this, the answer is both simple and difficult: be guided by the research question. It is the logic of the research question that impacts on the data analysis. In answering the research question, both quantitative and qualitative data might be adduced, each calls on its own warrants and claims to validity and reliability. The differences are intrinsic; oil is not water, and that is the beauty of each of them, but that does not mean we cannot draw on both in addressing an issue.

Timing and writing up the data analysis in mixed methods research

Bryman (2007a, p. 8) indicates a signal feature of MMR that distinguishes it from the simple usage of quantitative and qualitative research separately within a single piece of research; here mixed methods researchers write up their research in 'such a way that the quantitative and qualitative components are mutually illuminating'. This criterion of 'mutually illuminating' not only argues for the fully integrated mixed design but it also calls for research purposes and questions to *require* such integration, i.e. that the research question cannot be answered sufficiently by drawing only on one or the other of quantitative or qualitative methods, but that it requires both types of data.

The researcher is faced with several decisions in writing up the data analysis: for example, when to conduct and/or write up the data analysis (e.g. during or after the research, at the end of each stage or phase of the research in a sequential study); how to organize the presentation/write-up to answer each research question (e.g. by sample and sub-sample, individuals, theme, topic, research question, instrument, data type, stage/phase of the research etc.; see Part 5); whether one data type or stage of the research influences another data type or stage of the research (e.g. do the findings from quantitative data influence the qualitative data at that stage, or are they kept independent; whether the findings from one stage (e.g. quantitative stage) influence what happens in the next, qualitative stage); and how to organize the write-up of the data analysis in each stage or phase.

A major question here is whether one stage of the research influences the subsequent stage, even if, within each stage, mixed methods are being used. For example, in an explanatory design the quantitative data might suggest areas that the subsequent qualitative data should explain; in an exploratory design the qualitative data might suggest areas to be explored in the subsequent quantitative data. In these instances the timing of the data analysis is critical, as it is impossible to proceed to the next stage until the preceding data analysis is completed.

In a *parallel design*, with quantitative and qualitative data kept separate until the point of convergence, it would seem appropriate to organize the writing-up of the data analysis by the research question. But then the researcher has to decide, when writing up the data analysis in answering the research question, whether to present the data analysis separately by data type (e.g. qualitative and quantitative), or by different themes in answering the research question (with relevant quantitative and qualitative data integrated in addressing each theme), or by sample/sub-sample or instrument.

In a *sequential design* (e.g. quantitative followed by qualitative) it might be more appropriate to organize the data analysis and write-up first by stage/phase of the research and then draw this all together at the end of the data analysis to answer the research question. At each phase the researcher faces a similar set of decisions as in a parallel design, i.e. how to organize the write-up of the data analysis: by sample and sub-sample, individuals, theme, topic, research question, instrument or data type.

In an *explanatory sequential design* the qualitative data collection may come after the quantitative data. Here, for clarity, it may be useful to follow the same sequence in presenting the data analysis, with the quantitative data preceding the qualitative data, followed by a section which draws together the two data types in answering the research question. In an exploratory sequential design the sequence is reversed, with the quantitative data collection coming after the qualitative data. Here, for clarity, it may be useful to follow the same sequence in presenting the data analysis, with the qualitative data preceding the quantitative data, followed by a section which draws together the two data types in answering the research question.

In an *embedded design* one kind of data is subordinate to, or embedded within, another major data type. In this situation the main data may be presented first, with the supplementary data ensuing. It may be that the write-up of the data analysis takes the form of a case study, in which the quantitative and qualitative data are integrated in a narrative that 'tells the story' of the case. This latter can also apply to transformative designs.

The above designs are only typologies. As mentioned earlier, there are no blueprints for how and when to conduct and write up the data analysis. Each piece of research suggests its own most suitable designs, and these may be iterative and emergent, with several stages which move from quantitative to qualitative data and vice versa and their consequent own suitable ways of presenting the data analysis and the timing of these. Fitness for purpose is complemented by the need for clarity, relevance and ease in understanding the data and how they answer the research question. Indeed, in many cases the text of the write-up is exactly that – a text – in which both numbers and words appear as appropriate.

Consider, for example, a case study of an intervention to improve school attendance. Here overall school figures on attendance and absence may be addressed at

the start of, or even before, the intervention. Quantitative and qualitative data may give rise to the research (e.g. frequency of absence from school), leading to qualitative and quantitative data from analysis of records, followed by analysis of further quantitative data, followed by exploratory interviews, followed by re-analysis of qualitative and qualitative data, and so on. Each stage of the research is driven by the data analysis at the preceding stage, and the researcher in this MMR design has to decide when is the appropriate time to conduct and use the data analysis. The logic of each stage of the design and the research question decides where, when and how to combine the quantitative and qualitative data, and indeed the overall write-up of the research may be a narrative which draws freely on both numbers and words.

2.6 Stages in mixed methods research

Creswell (2012, pp. 554–7) sets out a seven-step process in MMR planning and conduct:

Step 1: Determine whether a mixed methods study is practicable and feasible.
Step 2: Set out the rationale for mixing methods (justify the use of MMR and justify the model of MMR being used).
Step 3: Set out the data-collection strategy (consider the priority, sequence and kinds of qualitative and quantitative data required).
Step 4: Develop quantitative, qualitative and mixed methods questions.
Step 5: Collect quantitative and qualitative data.
Step 6: Analyse data separately, concurrently or both.
Step 7: Write the report as a one- or two-phase or a multi-phase study.

However, this overlooks a more exact indication of what is to be mixed. Hence we suggest a twelve-step process:

Step 1: Decide the purpose of the research.
Step 2: Decide the nature of the phenomenon or problem that you wish to research, such that MMR is the most appropriate approach.
Step 3: Decide the research questions, ensuring that they can only be answered fully by the provision and analysis of mixed data.
Step 4: Decide what is to be 'mixed' in the MMR: ontologies (views of reality); paradigms (world views, lenses through which to define the problem and how to consider the research, and commensurate ways of working in the research); epistemologies; axiologies; theories and theoretical frameworks; research designs; methodologies and approaches; data types; data-collection instruments and methods; sampling; data; data analysis, interpretation and reporting; types of validity, validation and reliability.
Step 5: Decide the stages and phases of the research, where the 'mixing' will occur in these stages/phases and which kinds of methodologies and data are pre-eminent at each stage or phase.
Step 6: Decide the data collection (quantitative and qualitative and their interrelations), what (kind of) data are required from whom, when and at what stage(s) and phase(s).
Step 7: Design the data-collection instruments and the sampling.
Step 8: Collect the data.
Step 9: Plan the data analysis including: the function of the data analysis (e.g. formative, summative, an ongoing record), which data have priority, when and where, the timing (e.g. ongoing, at the end of each phase, at the end of the entire project) and sequence of data analysis.
Step 10: Conduct the data analysis, being clear on which data, from whom, and when the data and their analysis will be mixed, related, kept separate, interactive, when the analysis will commence overall and by stage or phase.
Step 11: Decide how to organize and write the research report, for example, by phase, by data types, where to integrate data types, where to comment on the points in Step (4).
Step 12: Write the research report.

Clearly in a multi-phase research design several of these steps will be repeated, or the sequence altered (e.g. Step 9 may precede Step 8).

As can be seen here, the research question (Step 3), though it may drive the MMR, is itself the consequence of prior considerations (Steps 1 and 2), and MMR must be able to justify itself in terms of addressing these prior considerations. As Biesta (2012, p. 149) remarks, the research question, far from being the first step in the research, is itself the operationalized consequence of the research purposes and problems.

2.7 Conclusion

This chapter has suggested that MMR constitutes an important way of looking at the social and educational

world that is informed by a pragmatic paradigm of practicality in answering research purposes and research question – 'what works' in planning, conducting and reporting the research – which rests on a range of ontological, epistemological and axiological foundations. For many years pragmatism has emerged as a prevailing principle to guide researchers. In order to give coherence to the discussion, the chapter then moved from the material on paradigms, principles, ontologies and epistemologies, to a practical account of its implications for the practice of research, thereby embodying the 'practicality' spirit of pragmatism that underpins MMR. In this spirit the chapter discussed matters of research designs, research questions, sampling, methodologies, reliability and validity, data types, data collection and analysis, and reporting.

The chapter also raised some challenges for MMR, for example, whether it really constitutes a new paradigm and how it addresses the problem of commensurability and incommensurability of the paradigmatic roots that underpin quantitative and qualitative research. Further, on the one hand, the advocates of MMR hail it as an important approach that is rooted in pragmatism, which: (a) yields real answers to real questions; (b) is useful in the real world; (c) avoids mistaken allegiance to either quantitative or qualitative approaches on their own; (d) enables rich data to be gathered which address the triangulation that has been advocated in research for many years; (e) respects the mixed, messy real world; and (f) increases validity and reliability; in short, that 'delivers' 'what works'. MMR possesses the flexibility in usage that reflects the changing and integrated nature of the world and the phenomenon under study. Further, it draws on a variety of ways of working and methodologies of enquiry, ontology, epistemology and values. It is a way of thinking, in which researchers see the world as integrated and in which they have to approach research from a standpoint of integrated purposes and research questions. As has been argued in this chapter, MMR enters into all stages of the research process: (a) philosophical foundations, paradigms, ontologies, world views, epistemologies and axiologies; (b) research purposes and research questions; (c) research design, methodology, sampling, data types, instrumentation and data collection, validity and reliability; (d) data analysis; (e) data interpretation; (f) conclusions and reporting results.

On the other hand, MMR has been taking place for years, before it was given the cachet of a new paradigm; it is not unusual for different methods to be used at different stages of a piece of research or even at the same stage, or with different samples within a single piece of research. It does not really have the novelty that seems to be claimed for it. Further, underneath MMR are still existing quantitative and qualitative paradigms, and they are different in world views, ontologies, epistemologies and axiologies, so to mix them by bringing them under a single sobriquet of 'mixed methods research' may be a disingenuous sleight of hand. There is also the matter of the perceptions which reveal underlying sympathies to paradigms and/or views of combining research types: imagine that we mix water with wine; is the liquid which results from such mixing 'fortified water' or 'diluted wine' – strengthened or weakened?

Giddings (2006), Giddings and Grant (2007) and Hesse-Biber (2010) question whether there is suppressed, or covert, support for positivism or quantitative approaches residing within MMR. Further, can one call a paradigm new simply because it brings together two previous paradigms and makes a case for thinking in a mixed method way of answering research questions by different types of data? The jury is still out, though this book underlines the importance of combining methods where necessary and relevant in planning and doing research, and we return to MMR throughout the book, as an indication of its importance.

Denscombe (2014, p. 161) notes that MMR might entail increasing the time costs of the research and will require researchers who are skilled in more than one method. One can add to his point that there is an additional skill required in being able to combine methods. Further, MMR might give rise to problems if data from different methods do not corroborate each other, requiring the researcher to explore why this might be (de Lisle (2011, p. 106) notes that qualitative findings might provide contradictory rather than complementary data). MMR might misinterpret the philosophy of pragmatism to be expediency rather than principled action (e.g. 'anything goes') (Denscombe, 2014, p. 161).

In a wide-ranging review, Creswell (2011) identifies eleven key controversies in MMR:

1. What actually MMR is in a context of shifting and widening definitions of MMR (method, methodology, orientation, philosophy, world view, a way of seeing).
2. The usefulness of quantitative and qualitative descriptors (i.e. that the binary nature of these two terms does not hold in practice and is unnecessarily limiting).
3. Whether MMR is as new as some of its claimants might propose.

4 What really drives the interest in MMR (including the interests of funding agencies).
5 The relevance and usefulness of debates on paradigms and whether they can actually be mixed.
6 The putative privileging of post-positivism in MMR, and the consequent diminishing status of qualitative approaches, for example, in 'embedded' designs.
7 Whether there is a 'fixed discourse' in mixed methods, who controls it and whether mixed methods is becoming a new metanarrative.
8 Whether MMR should adopt a 'bilingual language' for its terms, i.e. whether a language should move beyond the vocabulary which might favour quantitative or qualitative approaches to a new, non-partisan glossary of terms.
9 The usefulness of a plethora of designs and typologies, which become confusing and betray the complexity of the phenomena under study.
10 Whether MMR is 'misappropriating' designs and methodologies from other fields of, and approaches to, research, and whether MMR might be 'a subordinate procedure within ethnography' (p. 280).
11 What the added value of MMR is, i.e. what it offers by way of understanding a research issue better than either quantitative or qualitative approaches alone offer.

These suggest that, though MMR has been around for decades, there are still many questions to be answered. Hesse-Biber and Johnson (2013) suggest that MMR still has 'gaps and opportunities', including, for example: ethical issues and team approaches in MMR; 'retooling' 'methods and traditions' whose origins lie in quantitative or qualitative research to bring them into MMR; implications of web-based developments; and big data and analytics for MMR.

Whilst there is a powerful case for MMR, the argument here has been that the researcher has to decide whether and how to use MMR, and that these decisions must be driven by fitness for purpose.

The companion website to the book provides PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: www.routledge.com/cw/cohen.

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Critical educational research

CHAPTER 3

This chapter sets out key features of critical theory as they apply to educational research, and then it links these to:

- critical theory and critical educational research
- participatory action research
- feminist theory
- value-neutrality in educational research

It recognizes that other approaches can be included under the umbrella of critical theory (e.g. post-colonial theory, queer theory), and, whilst the chapter includes a note on these, it does not develop them. Indeed critical theory embraces a range of other theories, for example, critical race theory, critical pedagogy, critical disability theory.

3.1 Critical theory and critical educational research

Positivist and interpretive paradigms are essentially concerned with understanding phenomena through two different lenses. Positivism strives for objectivity, measurability, predictability, controllability, patterning, the construction of laws and rules of behaviour, and the ascription of causality; interpretive paradigms strive to understand and interpret the world in terms of its actors. In the former, observed phenomena are important; in the latter, meanings and interpretations are paramount. Giddens (1976) describes this latter as a 'double hermeneutic', where people strive to interpret and operate in an already interpreted world; researchers have their own values, views and interpretations, and these affect their research, and, indeed, that which they are researching is a world in which other people act on their own interpretations and views.

It was suggested in Chapter 2 that mixed methods research has an affinity with equity, social justice and a 'transformative paradigm' (Mertens, 2007), and it is to this that we turn now. This paradigm of *critical educational research* regards the two previous paradigms of positivism and interpretivism as presenting incomplete accounts of social behaviour when they neglect the political and ideological contexts of educational research. Positivistic and interpretive paradigms are seen as preoccupied with technical and hermeneutic knowledge respectively (Grundy, 1987; Gage, 1989). The paradigm of critical educational research is influenced by the early work of Habermas and, to a lesser extent, his predecessors in the Frankfurt School, most notably Adorno, Marcuse, Horkheimer and Fromm. Here the expressed intention is deliberately political – the emancipation of individuals and groups in an egalitarian society.

Critical theory is explicitly prescriptive and normative, entailing a view of what behaviour in a social democracy *should* entail (Fay, 1987; Morrison, 1995a). Its intention is not merely to give an account of society and behaviour but to realize a society that is based on equality and democracy for all its members. Its purpose is not merely to understand situations and phenomena but to change them. In particular it seeks to emancipate the disempowered, to redress inequality and to promote individual freedoms within a democratic society. In doing so it focuses not only on individuals and groups, but also on society and its institutions and social arrangements, and it uses both evaluative and descriptive concepts (Hammersley, 2013, p. 30) such as exploitation, empowerment, class division, emancipation, justice, interests and suchlike, with the intention of bringing about specific political aims: equality, social justice, democracy, freedom from oppression and exploitation, and the transformation of society to an emancipated democracy within which people are empowered to take control over their own lives and life choices.

In this enterprise, critical theory identifies the 'false' or 'fragmented' consciousness (Eagleton, 1991) that has brought an individual or social group to relative powerlessness or, indeed, to power, and it questions the legitimacy of this. It holds up to the lights of legitimacy and equality issues of repression, voice, ideology, power, participation, representation, inclusion and interests. It argues that much behaviour (including research behaviour) is the outcome of particular illegitimate, dominatory and repressive factors, illegitimate in

the sense that they do not operate in the general interest – one person's or group's freedom and power is bought at the price of another's freedom and power. Hence critical theory seeks to uncover the *interests* at work in particular situations and to interrogate the legitimacy of those interests, identifying the extent to which they are legitimate in their service of equality and democracy. Its intention is *transformative*: to change society and individuals to social democracy. In this respect the purpose of critical educational research is intensely practical and political, to bring about a more just, egalitarian society in which individual and collective freedoms are practised, and to eradicate the exercise and effects of illegitimate power. The pedigree of critical theory in Marxism is not difficult to discern. For critical theorists, researchers can no longer claim neutrality and ideological or political innocence.

Critical theory and critical educational research have their substantive agenda: for example, examining and interrogating the relationships between school and society; how schools perpetuate or reduce inequality; the social construction of knowledge and curricula, who defines worthwhile knowledge; what ideological interests schools serve and how this reproduces inequality in society; how power is produced and reproduced through education; whose interests are served by education and how legitimate these are (e.g. rich, white, middle-class males rather than poor, non-white females); how different groups in society fare (e.g. by social class, gender, race, physical features, ethnicity, disability, sexuality) and how political goals might be achieved; in other words, the emancipation of all social groups regardless of social class, gender, race, physical features, ethnicity, disability, sexuality etc. Researchers, then, have an obligation to promote certain political views and to achieve certain political goals.

The significance of critical theory for research is immense, for it suggests that much social research is comparatively trivial in that it *accepts* rather than *questions* given agendas for research, compounded by the funding for research, which underlines the political dimension of research sponsorship (discussed later) (e.g. Norris, 1990). Critical theorists would argue that the positivist and interpretive paradigms are essentially technicist, seeking to understand and render more efficient an existing situation, rather than to question or transform it.

Critical approaches recognize that peoples, social groups, institutions and societies operate on the basis of 'interests' which are allied to ideologies and values. Habermas's early work (1972) offers a useful tripartite conceptualization of 'interests'. He suggests that knowledge – and hence research knowledge – serves different interests. Interests, he argues, are socially constructed, and are 'knowledge-constitutive', because they shape and determine what counts as the objects and types of knowledge. Interests have an ideological function (Morrison, 1995a), for example, a 'technical interest' (discussed below) can have the effect of keeping the empowered in their empowered position and the disempowered in their powerlessness, reinforcing and perpetuating the status quo. An 'emancipatory interest' (discussed below) threatens the status quo. In this view, knowledge – and research knowledge – is not neutral (see also Mannheim, 1936). What counts as worthwhile knowledge is determined by the social and positional power of the advocates of that knowledge. The link here between objects of study and communities of scholars echoes Kuhn's (1962) notions of paradigms and paradigm shifts, discussed in Chapters 1 and 2. Knowledge and definitions of knowledge reflect the interests of the community of scholars who operate in particular paradigms. Habermas (1972) constructs the definition of worthwhile knowledge and modes of understanding around three cognitive interests:

i prediction and control;
ii understanding and interpretation;
iii emancipation and freedom.

He names these the '*technical*', '*practical*' and '*emancipatory*' interests respectively. The technical interest characterizes the scientific, positivist method, with its emphasis on laws, rules, prediction and control of behaviour, with passive research objects: instrumental knowledge. The practical interest, an attenuation of the positivism of the scientific method, is exemplified in the hermeneutic, interpretive methodologies outlined in qualitative approaches. Here research methodologies seek to clarify, understand and interpret the communications of 'speaking and acting subjects' (Habermas, 1974, p. 8).

Hermeneutics focuses on interaction and language; it seeks to understand situations through the eyes of the participants, echoing the *verstehen* approaches of Weber (Ringer, 1997) and premised on the view that reality is socially constructed (Berger and Luckmann, 1967). Indeed Habermas (1988, p. 12) suggests that sociology must understand social facts in their cultural significance and as socially determined. Hermeneutics involves recapturing the *meanings of* interacting others, recovering and reconstructing the *intentions* of the other actors in a situation. Such an enterprise involves the analysis of *meaning in a social context* (Held, 1980). Gadamer (1975, p. 273) argues that the hermeneutic sciences (e.g. qualitative approaches) involve

the *fusion of horizons* between participants. Meanings rather than phenomena take on significance here.

The emancipatory interest subsumes the previous two paradigms; it requires them but goes beyond them (Habermas, 1972, p. 211). It is concerned with *praxis* – action that is informed by reflection with the aim of emancipation. The twin intentions of this interest are to expose the operation of power and to bring about social justice, as domination and repression act to prevent the full existential realization of individual and social freedoms (Habermas, 1979, p. 14). The task of this knowledge-constitutive interest, indeed of critical theory itself, is to restore to consciousness those suppressed, repressed and submerged determinants of unfree behaviour with a view to their dissolution (Habermas, 1984, pp. 194–5). This is a transformative agenda, concerned to move from oppression and inequality in society to the bringing about of social justice, equity and equality. These concern fairness in the egalitarian distribution of opportunities for, uptake of, processes in, participation in and outcomes of education and its impact on society, together with distributive justice, social justice and equality.

Mertens (2007, p. 213) argues that a transformative paradigm enters into every stage of the research process, because it concerns an interrogation of power. A transformative paradigm, she avers (pp. 216, 224), has several 'basic beliefs':

- Ontology (the nature of reality or of a phenomenon): politics and interests shape multiple beliefs and values, as these beliefs and values are socially constructed, privileging some views of reality and under-representing others;
- Epistemology (how we come to know these multiple realities): influenced by communities of practice which define what counts as acceptable ways of knowing, and affecting the relationships between the researcher and the communities who are being researched, such that partnerships are formed that are based on equality of power and esteem;
- Methodology (how we research complex, multiple realities): influenced by communities of practice which define what counts as acceptable ways of researching, and in which mixed methods can feature, as they enable a qualitative dialogue to be established between the participants in the research;
- Axiology (principles and meanings in conducting research, and the ethics that govern these): beneficence, respect and the promotion of social justice (see Chapter 7).

Mertens (p. 220) argues for mixed methods in a transformative paradigm (discussed later), as they reduce the privileging of powerful voices in society, and she suggests that participatory action research is a necessary, if not sufficient, element of a transformative paradigm, as it involves people as equals.

From Habermas's early work we conceptualize three research styles: the scientific, positivist style; the interpretive style; and the emancipatory, ideology critical style. Not only does critical theory have its own research agenda, but it also has its own research methodologies, in particular ideology critique and action research. The three methodologies, then, aligned to Habermas's knowledge-constitutive interests, are set out in Table 3.1.

With regard to ideology critique, a particular reading of ideology is being adopted here, as the 'suppression of generalizable interests' (Habermas, 1976, p. 113), where systems, groups and individuals operate in

TABLE 3.1 HABERMAS'S KNOWLEDGE-CONSTITUTIVE INTERESTS AND THE NATURE OF RESEARCH

Interest	*Methodology*	*Characteristics*
Technical interest	Scientific testing and proof	Scientific methodology; positivist (e.g. surveys, experiments); hypothesis testing; quantitative.
Practical interest	Hermeneutic; interpretive, understanding	Interactionist; phenomenological; humanistic; ethnographic; existential; anthropological; naturalistic; narratives; qualitative.
Emancipatory interest	Ideology critique	Political agenda, interrogation of power, transformative potential: people gaining control over their own lives; concern for social justice and freedom from oppression and from the suppression of generalizable interests; research to change society and to promote democracy.

rationally indefensible ways because their power to act relies on the disempowering of other groups, i.e. their principles of behaviour cannot be generalized.

Ideology – the values and practices emanating from particular dominant groups – is the means by which powerful groups promote and legitimate their particular – sectoral – interests at the expense of disempowered groups. Ideology critique exposes the operation of ideology in many spheres of education, the working out of vested interests under the mantle of the general good. The task of ideology critique is to uncover the vested interests at work that may be occurring consciously or subliminally, revealing to participants how they may be acting to perpetuate a system which keeps them either empowered or disempowered (Geuss, 1981), i.e. which suppresses a 'generalizable interest'. Explanations for situations might be other than those 'natural', taken for granted, explanations that the participants might offer or accept. Situations are not natural but problematic (Carr and Kemmis, 1986). They are the outcomes or processes wherein interests and powers are protected and suppressed; one task of ideology critique is to expose this (Grundy, 1987). The interests at work are uncovered by ideology critique, which, itself, is premised on reflective practice (Morrison, 1995a, 1995b, 1996a). Habermas (1972, p. 230) suggests that ideology critique through reflective practice can be addressed in four stages:

Stage 1: a description and interpretation of the existing situation – a hermeneutic exercise that identifies and attempts to make sense of the current situation (echoing the *verstehen* approaches of the interpretive paradigm).

Stage 2: a presentation of the reasons that brought the existing situation to the form that it takes – the causes and purposes of a situation and an evaluation of their legitimacy, involving an analysis of interests and ideologies at work in a situation, their power and legitimacy (both in micro- and macro-sociological terms). Habermas's early work (1972) likens this to psychoanalysis as a means for bringing into the consciousness of 'patients' those repressed, distorted and oppressive conditions, experiences and factors that have prevented them from having a full, complete and accurate understanding of their conditions, situations and behaviour, and that, on such exposure and examination, will be liberating and emancipatory. Critique here reveals to individuals and groups how their views and practices might be ideological distortions that, in their effects, perpetuate a social order or situation that works against their democratic freedoms, interests and empowerment (see also Carr and Kemmis, 1986, pp. 138–9).

Stage 3: an agenda for altering the situation – in order for moves to an egalitarian society to be furthered (the 'transformative paradigm' mentioned earlier).

Stage 4: an evaluation of the achievement of the situation in practice.

In the world of education, Habermas's stages are paralleled by Smyth (1989), who also denotes a four-stage process: *description* (what am I doing?); *information* (what does it mean?); *confrontation* (how did I come to be like this?); and *reconstruction* (how might I do things differently?). Ideology critique here has both a reflective, theoretical side and a practical side to it; without reflection it is blind and without practice it is empty.

As ideology is not mere theory but impacts directly on practice (Eagleton, 1991), there is a strongly practical methodology implied by critical theory, which articulates with action research (Callawaert, 1999). Action research (see Chapter 22), as its name suggests, is about research that impacts on, and focuses on, practice. In its espousal of practitioner research, for example, teachers in schools, participant observers and curriculum developers, action research recognizes the significance of *contexts* for practice – locational, ideological, historical, managerial, social. Further, it accords power to those who are operating in those contexts, for they are both the engines of research and of practice. The claim is made that action research is strongly empowering and emancipatory in that it gives practitioners a 'voice' (Carr and Kemmis, 1986; Grundy, 1987), participation in decision making and control over their environment and professional lives. Whether the strength of the claims for empowerment are as strong as their proponents would hold is another matter, for action research might be relatively powerless in the face of mandated changes in education and might be more concerned with intervening in existing practice to ensure that mandated change is addressed efficiently and effectively.

3.2 Criticisms of approaches from critical theory

Morrison (1995a) suggests that critical theory, because it has a practical intent to transform and empower, can – and should – be examined and perhaps tested empirically. For example, critical theory claims to be empowering; that is a testable proposition. Indeed, in a departure from some of his earlier writing, Habermas (1990) acknowledges this, arguing for the need to find 'counter examples' (p. 6), for 'critical testing' (p. 7) and empirical verification (p. 117). He acknowledges that his views have only 'hypothetical status' (p. 32)

that need to be checked against specific cases (p. 9). One could suggest, for instance, that the effectiveness of his critical theory can be examined by charting the extent to which: (a) equality, freedom, democracy, emancipation, empowerment have been realized by his theory; (b) transformative practices have been addressed or occurred as a result of his theory; (c) subscribers to his theory have been able to assert their agency; and (d) his theories have broken down the barriers of instrumental rationality. The operationalization and testing (or empirical investigation) of his theories clearly is a major undertaking. Without this, critical theory, a theory that strives to improve practical living, runs the risk of becoming merely contemplative.

There are several criticisms that have been voiced against critical approaches. Morrison (1995a) suggests that there is an artificial separation between Habermas's three interests – they are drawn far too sharply (Hesse, 1982; Bernstein, 1983, p. 33). For example, one has to bring hermeneutic knowledge to bear on positivist science and vice versa in order to make meaning of each other and in order to judge their own status. Further, the link between ideology critique and emancipation is neither clear nor proven, nor a logical necessity (Morrison, 1995a, p. 67) – whether a person or society can become emancipated simply by the exercise of ideology critique or action research is an empirical rather than a logical matter (Morrison, 1995a; Wardekker and Miedama, 1997). Indeed one can become emancipated by means other than ideology critique; emancipated societies do not necessarily demonstrate or require an awareness of ideology critique. Moreover, it could be argued that the rationalistic appeal of ideology critique actually obstructs action designed to bring about emancipation. Roderick (1986, p. 65), for example, questions whether the espousal of ideology critique is itself as ideological as the approaches that it proscribes. Habermas, in his allegiance to the social construction of knowledge through 'interests', is inviting the charge of relativism.

Whilst the claim to there being three forms of knowledge has the epistemological attraction of simplicity, one has to question this very simplicity (e.g. Keat, 1981, p. 67); there are a multitude of interests and ways of understanding the world and it is simply artificial to reduce these to three. Indeed it is unclear whether Habermas, in his three knowledge-constitutive interests, is dealing with a conceptual model, a political analysis, a set of generalities, a set of transhistorical principles, a set of temporally specific observations, or a set of loosely defined slogans (Morrison, 1995a, p. 71) that survive only by dint of their ambiguity (Kolakowsi, 1978). Lakomski (1999) questions the acceptability of the consensus theory of truth on which Habermas's work is premised (pp. 179–82); she argues that Habermas's work is silent on social change, and is little more than speculation and idealism, a view echoed by Fendler's (1999) criticism of critical theory as inadequately problematizing subjectivity and ahistoricity.

More fundamental to a critique of this approach is the view that critical theory has a deliberate political agenda, and that the task of the researcher is not to be an ideologue or to have an agenda, but to be dispassionate, disinterested and objective (Morrison, 1995a). Of course, critical theorists would argue that the call for researchers to be ideologically neutral is itself ideologically saturated with laissez-faire values which allow the status quo to be reproduced, i.e. that the call for researchers to be neutral and disinterested is just as value-laden as is the call for them to intrude their own perspectives. The rights of the researcher to move beyond disinterestedness are clearly contentious, though the safeguard here is that the researcher's is only one voice in the community of scholars (Kemmis, 1982). Critical theorists as researchers have been hoisted by their own petard, for if they are to become more than merely negative Jeremiahs and sceptics, berating a particular social order that is dominated by scientism and instrumental rationality (Eagleton, 1991; Wardekker and Miedama, 1997), they have to generate a positive agenda, but in so doing they are violating the traditional objectivity of researchers. Because their focus is on an ideological agenda, they themselves cannot avoid acting ideologically (Morrison, 1995a).

Claims have been made for the power of action research to empower participants as researchers (e.g. Carr and Kemmis, 1986; Grundy, 1987). This might be over-optimistic in a world in which power often operates through statute; the reality of political power seldom extends to teachers. That teachers might be able to exercise some power in schools but with little effect on society at large was caught in Bernstein's famous comment (1970) that 'education cannot compensate for society'. Giving action researchers a small degree of power (to research their own situations) has little effect on the *real* locus of power and decision making, which often lies outside the control of action researchers. Is action research genuinely and full-bloodedly empowering and emancipatory? Where is the evidence?

3.3 Participatory research and critical theory

The call to action in research, particularly in terms of participatory action by and with oppressed, disempowered, underprivileged and exploited groups, finds its

research voice in terms of participatory research (PR) (e.g. Freire, 1972; Giroux, 1989). Here the groups (e.g. community groups) themselves establish and implement interventions to bring about change, development and improvement to their lives, acting collectively rather than individually.

PR, an instance of critical theory in research, breaks with conventional ways of construing research, as it concerns doing research *with* people and communities rather than doing research *to* or *for* people and communities. It is premised on the view that research can be conducted by everyday people rather than an elite group of researchers, and that ordinary people are entirely capable of reflective and critical analysis of their situation (Pinto, 2000, p. 7). It is profoundly democratic, with all participants as equals; it strives for a participatory rather than a representative democracy (Giroux, 1983, 1989). PR regards power as shared and equalized, rather than as the property of an elite, and the researcher shares his or her humanity with the participants (Tandon, 2005a, p. 23). In PR, the emphasis is on research for change and development of communities; emphasis is placed on knowledge that is useful in improving lives rather than for the interests of, and under the control of, the academic or the researcher. It is research with a practical intent, for transforming lives and communities; it makes the practical more political and the political more practical (cf. Giroux, 1983). As Tandon (2005a, p. 23) writes: 'the very act of inquiry tends to have some impact on the social system under study'.

Campbell (2002, p. 20) suggests that PR arose as a reaction to those researchers and developers who adopted a 'top-down' approach to working with local communities, neglecting and relegating their local knowledge and neglecting their empowerment and improvement. Rather, PR is emancipatory (p. 20), eclectic and, like mixed methods research, adopts whatever research methodology will deliver the results that enable action and local development to follow. As with mixed methods research and action research, it is pragmatic, and, if necessary, sacrifices 'rigorous control, for the sake of "pragmatic utility" ' (Brown, 2005a, p. 92). PR challenges the conventional distance between researchers and participants; *together* they work for local development. It focuses on micro-development rather than macro-development, using knowledge to pursue well-being (Tandon, 2005b, p. ix; Brown, 2005a, p. 98).

PR respects the indigenous, popular knowledge that resides in communities rather than the relatively antiseptic world and knowledge of the expert researcher. Like Freire's work it is itself educative. Local community knowledge is legitimized in PR (Pinto, 2000, p. 21), and participants are active and powerful in the research rather than passive subjects. Local people can transform their lives through knowledge and their use of that knowledge; knowledge is power, with local community members collectively being active and in control. Researchers are facilitators, catalysts and change agents rather than assuming dominatory or controlling positions (Pinto, 2000, p. 13). The agenda of PR is empowerment of all and liberation from oppression, exploitation and poverty. Research here promotes both understanding and change. As one of its proponents, Lewin (1946, p. 34), wrote: 'if you want truly to understand something, try to change it'. PR blends knowledge and action (Tandon, 2005c, p. 49).

PR recognizes the centrality of power in research and everyday life, and has an explicit agenda of wresting power from those elites who hold it, and returning it to the grass roots, the communities, the mainstream citizenry. As Pinto (2000, p. 13) remarks, a core feature that runs right through all stages of PR is the nagging question of 'who controls?'.

PR has as its object the betterment of communities, societies and groups, often the disempowered, oppressed, impoverished and exploited communities, groups and societies, the poor, the 'have-nots' (Hall, 2005, p. 10; Tandon, 2005c, p. 50). Its principles concern improvement, group decision making, the need for research to have a practical outcome that benefits communities and in which participants are agents of their own decisions (Hall, 2005, p. 10; INCITE, 2010). It starts with problems as experienced in the local communities or workplace, and brings together into an ongoing working relationship both researchers and participants. As Bryeson *et al*. (2005, p. 183) remark, PR is a 'three-pronged activity' in which the investigation has the full and active participation by the community in question, involves action for development and which is an 'educational process of mobilization for development', and in which these three elements are interwoven. These features enter all stages of the research, from identification of problems to the design and implementation of the research, data analysis, reporting and catalysed changes and developments in the community. Empowerment and development are both the medium and the outcome of the research. Tandon (2005c, p. 30) sets out a sequence for PR (Figure 3.1).

Whilst conventional approaches to data collection may have their value (e.g. surveys, interviews), too often these are instruments that regard people solely as sources of information rather than as participants in their own community development (Hall, 2005, p. 13). Indeed Tandon (2005d, p. 106) reports that, in many

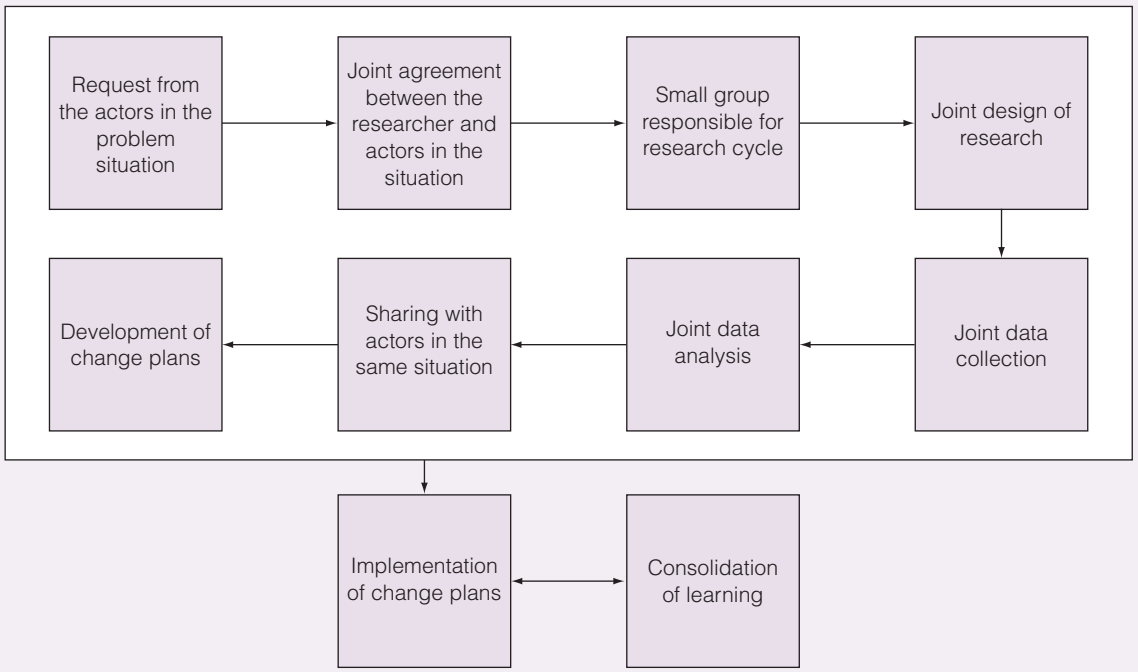

FIGURE 3.1 Steps in an 'ideal' participatory research approach

Source: Tandon (2005c, p. 30), reproduced with permission of Mosaic Books, New Delhi

cases, surveys are entirely irrelevant to the communities involved in the research, and alternative forms of collecting data have to be used, for example, dialogue (Tandon, 2005e), enumeration such as census data (though clearly these are used in conventional research) (Batliwala and Patel, 2005), and popular theatre for consciousness-raising (Khot, 2005). Hall (2005) cites the example of the UNESCO evaluation of the Experimental World Literacy Programme, in which local expertise was neglected, which over-simplified the phenomena under investigation and disempowered the very communities under review. Such research is alienating rather than empowering. Rather, he avers, researchers should respect, and take seriously, resident knowledge (he gives the example of adult learning).

Hall (2005, pp. 17–19) sets out several principles for PR:

1 A research project – both process and results – can be of immediate and direct benefit to a community (as opposed to serving merely as the basis of an academic paper of obscure policy analysis).
2 A research project should involve the community in the entire research project, from the formulation of the problem and the interpretation of the findings to planning corrective action based upon them.
3 The research process should be seen as part of a total educational experience which serves to determine community needs, and to increase awareness of problems and commitment to solutions within the community.
4 Research should be viewed as a dialectic process, a dialogue over time, and not a static picture of reality at one point in time.
5 The object of research, like the object of education, should be the liberation of human creative potential and the mobilization of human resources for the solution of social problems.
6 Research has ideological implications.… First is the re-affirmation of the political nature of all we do.… Research that allows for popular involvement and increased capacities of analysis will also make conflictual action possible, or necessary.

(Hall, 2005, pp. 17–19)

In PR the problem to be investigated originates in, and is defined by, the community or workplace. It members are involved in the research and have control over it,

and the research leads to development and improvement of their lives and communities (Brown and Tandon, 2005, p. 55). Brown and Tandon (p. 60) recognize the challenge (and likely resistance) that these principles might pose for the powerful, specific dominant interest groups, but they argue that this is unavoidable, as the researcher typically mobilizes community groups to action (p. 61). Hence PR has to consider the likely responses of the researchers, the participants and their possible opponents (p. 62); as Giroux avers (1983), knowledge is not only powerful, but dangerous, and participants may run substantial risks (Brown and Tandon, 2005, p. 65) in conducting this type of research, for it upsets existing power structures in society and the workplace.

PR has some affinity to action research (INCITE, 2010), though it is intensely more political than action research. It is not without its critics. For example, Brown (2005b) argues that participatory action research is ambiguous about:

a its research objectives (e.g. social change, raising awareness, development work, challenging conventional research paradigms);
b the relationships between the researcher and participants (e.g. over-emphasizing similarities and neglecting differences between them);
c the methods and technologies that it uses (e.g. being over-critical of conventional approaches which might serve the interests of participatory research, and the lack of a clear method for data collection); and
d the outcomes of participatory research (e.g. what these are, when these are decided, and who decides).

Notwithstanding these, however, PR is a clear instance of the tenets of critical theory, transformative action and empowerment put into practice.

3.4 Feminist research

It is no mere coincidence that feminist research should surface as a serious issue at the same time as ideology-critical paradigms for research; they are closely connected. Usher (1996) sets out several principles of feminist research that resonate with the ideology critique of the Frankfurt School:

- the acknowledgement of the pervasive influence of gender as a category of analysis and organization;
- the deconstruction of traditional commitments to truth, objectivity and neutrality;
- the adoption of an approach to knowledge creation which recognizes that all theories are perspectival;
- the utilization of a multiplicity of research methods;
- the inter-disciplinary nature of feminist research;
- involvement of the researcher and the people being researched;
- the deconstruction of the theory/practice relationship.

Her suggestions build on the recognition of the significance of addressing the 'power issue' in research ('whose research', 'research for whom', 'research in whose interests') and the need to address the emancipatory element of educational research: research should be empowering to all participants. Critical theory questions the putative objective, neutral, value-free, positivist, 'scientific' paradigm for the sundering of theory and practice and for its reproduction of asymmetries of power (reproducing power differentials in the research community and for treating participants/respondents instrumentally, as objects).

Robson (1993, p. 64) suggests seven sources of sexism in research:

- *androcentricity*: seeing the world through male eyes and applying male research paradigms to females;
- *overgeneralization*: when a study generalizes from males to females;
- *gender insensitivity*: ignoring gender as a possible variable;
- *double standards*: using male criteria, measures and standards to judge the behaviour of women and vice versa (e.g. in terms of social status);
- *sex appropriateness*: for example, that child-rearing is women's responsibility;
- *familism*: treating the family, rather than the individual, as the unit of analysis;
- *sexual dichotomism*: treating the sexes as distinct social groups when, in fact, they may share characteristics.

Feminist research challenges the legitimacy of research that does not empower oppressed and otherwise invisible groups – women. Ezzy (2002, p. 20) writes of the need to replace a traditional masculine picture of science with an emancipatory commitment to knowledge that stems from a feminist perspective, since, if researchers analyse women's experiences 'using only theories and observations from the standpoint of men, the resulting theories oppress women' (p. 23). Gender, as Ezzy writes (p. 43), is 'a category of experience'.

Positivist research serves a given set of power relations, typically empowering the white, male-dominated research community at the expense of other groups whose voices are silenced. Feminist research seeks to demolish and replace this with a different substantive

agenda of empowerment, voice, emancipation, equality and representation for oppressed groups. In doing so, it recognizes the necessity for foregrounding issues of power, silencing and voicing, ideology critique and a questioning of the legitimacy of research that does not emancipate hitherto disempowered groups. In feminist research, women's consciousness of oppression, exploitation and disempowerment becomes a focus for research and ideology critique.

Far from treating educational research as objective and value-free, feminists argue that this is merely a smokescreen that serves the existing, disempowering status quo, and that the subject and value-laden nature of research must be surfaced, exposed and engaged (Haig, 1999, p. 223). Supposedly value-free, neutral research perpetuates power differentials. Indeed Jayaratne and Stewart (1991) question the traditional, exploitative nature of much research in which the researchers receive all the rewards whilst the participants remain in their – typically powerless – situation, i.e. in which the status quo of oppression, underprivilege and inequality remain undisturbed. Scott (1985, p. 80) writes that 'we may simply use other women's experiences to further our own aims and careers' and questions how ethical it is for a woman researcher to interview those who are less privileged and more exploited than she herself is. Creswell (1998, p. 83), too, suggests that feminist research strives to establish collaborative and non-exploitative relationships.

Researchers, then, must take seriously issues of reflexivity, the effects of the research on the researched and the researchers, the breakdown of the positivist paradigm, and the raising of consciousness of the purposes and effects of the research. Ezzy (2002, p. 153) notes that an integral element of the research is the personal experience of the researcher himself/herself, reinforcing the point that objectivity is a false claim by researchers.

Denzin (1989), Mies (1993), Haig (1999) and De Laine (2000) argue for several principles in feminist research:

- the asymmetry of gender relations and representation must be studied reflexively as constituting a fundamental aspect of social life (which includes educational research);
- women's issues, their history, biography and biology, feature as a substantive agenda/focus in research – moving beyond mere perspectival/methodological issues to setting a research agenda;
- the raising of consciousness of oppression, exploitation, empowerment, equality, voice and representation is a methodological tool;
- the acceptability and notion of objectivity and objective research must be challenged;
- the substantive, value-laden dimensions and purposes of feminist research must be paramount;
- research must empower women;
- research need not only be undertaken by academic experts;
- collective research is necessary – women need to collectivize their own individual histories if they are to appropriate these histories for emancipation;
- there is a commitment to revealing core processes and recurring features of women's oppression;
- an insistence on the inseparability of theory and practice;
- an insistence on the connections between the private and the public, between the domestic and the political;
- a concern with the construction and reproduction of gender and sexual differences;
- a rejection of narrow disciplinary boundaries;
- a rejection of the artificial subject/researcher dualism;
- a rejection of positivism and objectivity as male mythology;
- the increased use of qualitative, introspective biographical research techniques;
- a recognition of the gendered nature of social research and the development of anti-sexist research strategies;
- a review of the research process as consciousness and awareness raising and as fundamentally participatory;
- the primacy of women's personal subjective experience;
- the rejection of hierarchies in social research;
- the vertical, hierarchical relationships of researchers/research community and research objects, in which the research itself can become an instrument of domination and the reproduction and legitimation of power elites, must be replaced by research that promotes the interests of dominated, oppressed, exploited groups;
- the recognition of equal status and reciprocal relationships between subjects and researchers;
- the need to change the status quo, not merely to understand or interpret it;
- the research must be a process of conscientization, not research solely by experts for experts, but to empower oppressed participants.

Webb *et al*. (2004) set out six principles for a feminist pedagogy in the teaching of research methodology:

1 reformulation of the professor–student relationship (from hierarchy to equality and sharing);

2 empowerment (for a participatory democracy);
3 building community (through collaborative learning);
4 privileging the individual voice (not only the lecturer's);
5 respect for diversity of personal experience (rooted, for example, in gender, race, ethnicity, class, sexual preference);
6 challenging traditional views (e.g. the sociology of knowledge).

Gender shapes research agendas, the choice of topics, foci, data-collection techniques and the relationships between researchers and researched. Several methodological principles flow from a 'rationale' for feminist research (Denzin, 1989; Mies, 1993; Haig, 1997, 1999; De Laine, 2000):

- the replacement of quantitative, positivist, objective research with qualitative, interpretive, ethnographic reflexive research, as objectivity in quantitative research is a smokescreen for masculine interests and agendas;
- collaborative, collectivist research undertaken by collectives – often of women – combining researchers and researched in order to break subject/object and hierarchical, non-reciprocal relationships;
- the appeal to alleged value-free, neutral, indifferent and impartial research has to be replaced by conscious, deliberate partiality – through researchers identifying with participants;
- the use of ideology-critical approaches and paradigms for research;
- the spectator theory or contemplative theory of knowledge in which researchers research from ivory towers must be replaced by a participatory approach – for example, action research – in which all participants (including researchers) engage in the struggle for women's emancipation – a liberatory methodology;
- the need to change the status quo is the starting point for social research;
- the extended use of triangulation, multiple methods (including visual techniques such as video, photography and film), linguistic techniques such as conversational analysis and of textual analysis such as deconstruction of documents and texts about women;
- the use of meta-analysis to synthesize findings from individual studies (see Chapter 21);
- a move away from numerical surveys and a critical evaluation of them, including a critique of question wording.

Edwards and Mauthner (2002, pp. 15, 27) characterize feminist research as that which concerns a critique of dominatory and value-free research, the surfacing and rejection of exploitative power hierarchies between the researcher and the participants, and the espousal of close – even intimate – relationships between the researcher and the researched. Positivist research is rejected as per se oppressive (Gillies and Alldred, 2002, p. 34) and inherently unable to abide by its own principle of objectivity; it is a flawed epistemology. Research and its underpinning epistemologies are rooted in, and inseparable from, interests (Habermas, 1972).

The move is towards 'participatory action research' which promotes empowerment and emancipation and which is an involved, engaged and collaborative process (e.g. De Laine, 2000, pp. 109ff.). Participation recognizes imbalances of power and the imperative to 'engage oppressed people as agents of their own change' (Ezzy, 2002, p. 44), whilst action research recognizes the value of utilizing the findings from research to inform decisions about interventions (p. 44). As De Laine (2000, p. 16) writes, the call is for 'more participation and less observation, of *being with* and *for* the other, not *looking at*', with relations of reciprocity and equality rather than impersonality, exploitation and power/status differentials between researcher and participants.

The relationship between the researcher and participant, De Laine argues, must break a conventional patriarchy. The emphasis is on partnerships between researchers and participants (p. 107), with researchers as participants rather than outsiders and with participants shaping the research process as co-researchers (p. 107), defining the problem, methods, data collection and analysis, interpretation and dissemination. The relationship between researchers and participants is one of equality, and outsider, objective, distant, positivist research relations are off the agenda; researchers are inextricably bound up in the lives of those they research. That this may bring difficulties in participant and researcher reactivity is a matter to be engaged rather than built out of the research.

Thapar-Björkert and Henry (2004) argue that the conventional, one-sided and unidirectional view of the researcher as powerful and the research participants as less powerful, with the researcher exploiting and manipulating the researched, could be a construction by western white researchers. They report research that indicates that power is exercised by the researched as well as the researchers, and is a much more fluid, shifting and negotiated matter than conventionally suggested, being dispersed through both the researcher and

the researched. Indeed they show how the research participants can, and do, exercise considerable power over the researchers, both before, during and after the research process. They provide a fascinating example of interviewing women in their homes in India, where, far from being a location of oppression, the home was a site of their power and control.

With regard to methods of data collection, Oakley (1981) suggests that interviewing women in the standardized, impersonal style which expects a response to a prescribed agenda and set of questions may be a 'contradiction in terms', as it implies an exploitative relationship. Rather, the subject/object relationship should be replaced by a guided dialogue. She criticizes the conventional notion of 'rapport' in conducting interviews (p. 35), arguing that such interviews are instrumental, non-reciprocal and hierarchical, all of which are masculine traits. Rapport in this sense, she argues, is not genuine in that the researcher is using it for scientific rather than human ends (p. 55). Here researchers are 'faking friendship' for their own ends (Duncombe and Jessop, 2002, p. 108), equating 'doing rapport' with trust, and, thereby, operating a very 'detached' form of friendship (p. 110) (see also Thapar-Björkert and Henry, 2004).

Duncombe and Jessop (2002, p. 111) question whether, if interviewees are persuaded to take part in an interview by virtue of the researcher's demonstration of empathy and 'rapport', this is really giving informed consent. They suggest that informed consent, particularly in exploratory interviews, has to be continually renegotiated and care has to be taken by the interviewer not to be too intrusive. Personal testimonies, oral narratives and long interviews also figure highly in feminist approaches (De Laine, 2000, p. 110; Thapar-Björkert and Henry, 2004), not least in those which touch on sensitive issues. These, it is argued (Ezzy, 2002, p. 45), enable women's voices to be heard, to be close to lived experiences, and avoid unwarranted assumptions about people's experiences.

The drive towards collective, egalitarian and emancipatory qualitative research is seen as necessary if women are to avoid colluding in their own oppression by undertaking positivist, uninvolved, dispassionate, objective research. Mies (1993, p. 67) argues that for women to undertake this latter form of research puts them into a schizophrenic position of having to adopt methods which contribute to their own subjugation and repression by ignoring their experience (however vicarious) of oppression and by forcing them to abide by the 'rules of the game' of the competitive, male-dominated academic world. In this view, argue Roman and Apple (1990, p. 59), it is not enough for women simply to embrace ethnographic forms of research, as this does not necessarily challenge the existing and constituting forces of oppression or asymmetries of power. Ethnographic research, they argue, has to be accompanied by ideology critique; indeed they argue that the transformative, empowering, emancipatory potential of research is a critical standard for evaluating the research.

This latter point resonates with the call by Lather (1991) for researchers to be concerned with the political consequences of their research (e.g. consequential validity), not only the conduct of the research and data analysis itself. Research must lead to change and improvement for women (Gillies and Alldred, 2002, p. 32). Research is a political activity with a political agenda (p. 33; see also Lather, 1991). Research and action – praxis – must combine: 'knowledge *for*' as well as 'knowledge *what*' (Ezzy, 2002, p. 47). As Marx reminds us in his *Theses on Feuerbach*: 'the philosophers have only interpreted the world, in various ways; the point, however, is to change it'. Gillies and Alldred (2002, p. 45), however, point out that 'many feminists have agonized over whether politicizing participants is necessarily helpful', as it raises awareness of constraints on their actions without being able to offer solutions or to challenge their structural causes. Research, thus politicized but unable to change conditions, may actually be disempowering and, indeed, patronizing in its simplistic call for enlightenment and emancipation. It could render women more vulnerable than before. Emancipation is a struggle.

Several of these views of feminist research and methodology are contested by other feminist researchers. For example, Jayaratne (1993, p. 109) argues for 'fitness for purpose', suggesting that an exclusive focus on qualitative methodologies might not be appropriate either for the research purposes or, indeed, for advancing the feminist agenda (see also Scott, 1985, pp. 82–3). Jayaratne refutes the argument that quantitative methods are unsuitable for feminists because they neglect the emotions of the people under study. Indeed she argues for beating quantitative research on its own grounds (1993, p. 121), suggesting the need for feminist quantitative data and methodologies in order to counter sexist quantitative data in the social sciences. She suggests that feminist researchers can accomplish this without 'selling out' to the positivist, male-dominated academic research community. Indeed Oakley (1998) suggests that the separation of women from quantitative methodology may have the unintended effect of perpetuating women as the 'other', and, thereby, discriminating against them. Finch (2004) argues that, whilst qualitative research might have

helped to establish the early feminist movement, it is important to recognize the place of both quantitative and qualitative methods as the stuff of feminist research.

De Laine (2000, p. 1132) reports work that suggests that close relationships between researchers and participants may be construed as being as exploitative, if disguised, as conventional researcher roles, and that they may bring considerable problems if data that were revealed in an intimate account between friends (researcher and participant) are then used in public research. The researcher is caught in a dilemma: if she is a true friend then this imposes constraints on the researcher, and yet if she is only pretending to be a friend, or limiting that friendship, then this provokes questions of honesty and personal integrity. Are research friendships real, ephemeral or impression management used to gather data?

De Laine (p. 115) suggests that it may be misguided to privilege qualitative research for its claim to non-exploitative relationships. Whilst she acknowledges that quantitative approaches may perpetuate power differentials and exploitation, there is no guarantee that qualitative research will not do the same, only in a more disguised way. Qualitative approaches too, she suggests, can create and perpetuate unequal relations, not least simply because the researcher is in the field qua researcher rather than a friend; if it were not for the research then the researcher would not be present. Stacey (1988) suggests that the intimacy advocated for feminist ethnography may render exploitative relationships *more* rather than *less* likely. We refer readers to Chapter 13 on sensitive educational research for a further discussion of these issues. Ezzy (2002, p. 44) reports that, just as there is no single feminist methodology, both quantitative and qualitative methods are entirely legitimate. Indeed Kelly (1978) argues that a feminist commitment should enter research at the stages of formulating the research topic and interpreting the results, but it should be left out during the stages of data collection and conduct of the research.

Gillies and Alldred (2002, pp. 43–6) suggest that action research, an area strongly supported by some feminist researchers, is itself problematic. It risks being an intervention in people's lives (i.e. a potential abuse of power), and the researcher typically plays a significant, if not central, role in initiating, facilitating, crystallizing and developing the meanings involved in, or stemming from, the research, i.e. the researcher is the one exercising power and influence.

Thapar-Björkert and Henry (2004) indicate that the researcher being an outsider might bring more advantages than if she were an insider. For example, being a white female researching non-white females may not be a handicap, as many non-white women might disclose information to white women that they would not disclose to a non-white person. Similarly, having interviewers and interviewees of the same racial and ethnic background does not mean that non-hierarchical relationships will not still be present. They also report that the categories of 'insider' and 'outsider' are much more fuzzy than exclusive. Researchers are both 'subject' and 'object', and those being researched are both 'observed' and 'observers'.

De Laine (2000, p. 110) suggests that there is a division among feminists between those who advocate closeness in relationships between researchers and subjects – a human researching fellow humans – and those who advocate 'respectful distance' between researchers and those being studied. Duncombe and Jessop (2002, p. 111) comment that close relationships may turn into quasi-therapeutic situations rather than research, yet it may be important to establish closeness in reaching deeper issues, and they question how far close relationships lead to reciprocal and mutual disclosure (p. 120). The debate is open: should the researcher share, be close and be prepared for more intimate social relations – a 'feminist ethic of care' (p. 111) – or keep those cool, outsider relations which might objectify those being researched? It is a moral as well as a methodological matter.

The issue runs deep: the suggestion is that emotions and feelings are integral to the research, rather than to be built out of the research in the interests of objectivity (Edwards and Mauthner, 2002, p. 19). Emotions should not be seen as disruptive of research or as irrelevant (De Laine, 2000, pp. 151–2), but central to it, just as they are central to human life; indeed emotional responses are essential in establishing the veracity of inquiries and data, and the 'feminist communitarian model' which De Laine outlines (pp. 212–13) values connectedness at several levels: emotions, emotionality and personal expressiveness, empathy. The egalitarian feminism that De Laine (2000) and others advocate suggests a community of insiders in the same culture, in which empathy, reciprocity and egalitarianism are hallmarks (p. 108).

Swantz (1996, p. 134) argues that there may be some self-deception by the researcher in adopting a dual role as a researcher and one who shares the situation and interests of the participants. She questions the extent to which the researcher may be able to be genuinely involved with the participants in other than a peripheral way and whether, simply because the researcher may have 'superior knowledge', a covert power differential may exist. De Laine (2000, p. 114)

suggests that such superior knowledge may stem from the researcher's own background in anthropology or ethnography, or simply more education. The primary purpose of the researcher is research, and that is different from the primary purpose of the participants.

The researcher's desire for identification and solidarity with her research subjects may be pious but unrealistic optimism, not least because she may not share the same race, ethnicity, background, life chances, experiences or colour as those being researched. Indeed Gillies and Alldred (2002, pp. 39–40) raise the question of how far researchers can, or should, try to represent groups to which they themselves do not belong, including those groups without power or voice, as this itself is a form of colonization and oppression. Affinity, they argue (p. 40), is no authoritative basis for representative research. Even the notion of affinity becomes suspect when it overlooks or underplays the significance of difference, thereby homogenizing groups and their particular experiences. In response to this, some feminist researchers (p. 40) suggest that researchers only have the warrant to confine themselves to their own immediate communities, though this is a contentious issue. There is value in speaking for others, not least for those who are silenced and marginalized, and in not speaking for others for fear of oppression and colonization. They also question the acceptability and appropriateness of, and fidelity to, the feminist ethic, if one represents and uses others' stories (p. 41).

3.5 A note on post-colonial theory and queer theory

Under the umbrella of critical theory also fall post-colonial theory, queer theory and critical race theory. Whilst this chapter does not unpack these, it notes them as avenues for educational researchers to explore. For example, post-colonial theory, as its name suggests, with an affinity to postmodernism, addresses the experiences (often through film, literature, cultural studies, political and social sciences) of post-colonial societies and the cultural legacies of colonialism. It examines the after-effects, or continuation, of ideologies and discourses of imperialism, domination and repression, value systems (e.g. the domination of western values and the delegitimization of non-western values), their effects on the daily lived experiences of participants, i.e. their materiality, and the regard in which peoples in post-colonial societies are held (e.g. Said's (1978) work on orientalism and the casting down of non-western groups as the 'other'). It also discusses the valorization of multiple voices and heterogeneity in post-colonial societies, the resistance to marginalization of groups within them (Bhabha, 1994, p. 113) and the construction of identities in a post-colonial world.

Queer theory builds on, but moves beyond, feminist theory and gay/lesbian/LGBTI studies to explore the social construction and privileging or denial of identities, sexual behaviour, deviant behaviour and the categorizations and ideologies involved in such constructions. It deconstructs 'social categories and binary identities' (Marshall and Rossman, 2016, p. 26) in striving to demonstrate that such categories are, in reality, more fluid and transparent than is often assumed or bounded. Identity, for queer theorists, is not singular, fixed and firm, but multiple, unstable and fluid, and that when applied to commonly held categories such as heterosexuality, it reveals such fluidity.

Halperin (1997) writes that queer theory focuses on whatever is 'at odds with the normal, the legitimate, the dominant' (p. 62). Its task is to explore, problematize and interrogate gender, sexual orientation and also their mediation by, and intersection with, other characteristics or forms of oppression, for example, social class, ethnicity, colour, disability, nationality, age, able-ness (Marshall and Rossman, 2016, p. 27). However, it does not confine itself to matters of sexuality but makes 'queer' a range of commonly held categories. It rejects simplistic categorizations of individuals, and argues for the respect of their individuality and uniqueness. Queer theory does not adhere to a single research method but advocates multiple methods which promote collaborative understandings and reflexivity on the part of research participants and researchers.

3.6 Value-neutrality in educational research

Lather (1986a) argues that, as neither education nor research is neutral, researchers do not need to apologize for undertaking clearly ideological research and its intention to change the status quo of inequality (p. 67). However, the case is made that research should be disinterested and objective, that value-neutrality is an ideal and that research should concern itself only with the pursuit and production of facts and knowledge and not play politics, but that this does not preclude value-relevant research, i.e. topics that may be of concern to certain parties. Politics and research are not the same and it is illegitimate for the researcher to let a political agenda enter into – to bias – the conduct of, and conclusions from, research.

However, it is argued that developments in the philosophy of science indicate that researchers make all kinds of assumptions about the world, both factual and

evaluative, and that these shape the research (Hammersley, 2000, p. 3), i.e. that there is no such thing as objective knowledge but only knowledge that is socio-culturally situated. This is the argument brought forward by post-positivism, postmodernism and post-structuralism, though Hammersley notes that, whilst values might, indeed maybe should, determine what is considered to be value-relevant research (i.e. what topics to focus on), and that this is completely within the scope of factual research, nevertheless 'research must necessarily be committed to value neutrality simply because it cannot validate value conclusions' (p. 32).

Should researchers be objective, value-neutral, non-partisan, unbiased and strictly disinterested, simply providing a service in bringing forward factual evidence, data and explanations on such-and-such a matter, or is it acceptable for them to declare their values, biases and interests and then proceed from there, acting on those commitments? Should researchers have a political or social agenda that colours their research? Should they be 'committed' or should they be disinterested? Hammersley's (2000) comments on 'standpoint epistemology' feature here (pp. 6–7), where he notes that, in Marxism, the working class is in a privileged position in understanding capitalist society and how it should be and can be transformed. Similarly he gives the example of women as oppressed or marginalized groups in patriarchal societies and he questions whether this might give them a position on and understanding of oppression and power that is simply not available to men (Hammersley, 2011, pp. 97–9).

Do we only ask white males about the experience of being a non-white woman, or do we only ask non-white women about their experiences, or do we ask both groups, since their perspectives and knowledge might differ? Is there any guarantee that any of these groups will see 'reality' clearly (cf. Hammersley, 2011, p. 99)? What warrant can be brought forward to justify the privileging of one group's views over those of another?

If a researcher happens to believe in democracy, social justice and equality, or free-market neo-liberalism, or communism, or is African-American or a white working-class female, should that affect how he or she conducts research and the conclusions and prescriptions that he or she draws from it? Should researchers push their own or others' political or social agendas?

Hammersley (2000) unpicked dangers of partisanship, 'committed' positions and 'privileged' discourse on the part of researchers as this can 'encourage the idea that research can, by itself, tell us what is desirable and undesirable, and what should be done; thereby obscuring the value judgements involved in policy and practice' (Hammersley, 2011 p. 87). He focuses on critical social science, particularly critical realism, noting that whilst value argument is important, indeed is essential to politics, social scientists 'have no distinctive authority to determine what is good or bad about the situations they seek to describe and explain; or what, if anything, should be done about them' (2014, p. 94). He argues (p. 94) that they, among other parties, have the authority of expertise concerning matters of fact but not to matters of value.

This echoes Weber's (1949) comment that an empirical science should not be committed to providing 'binding norms and ideals from which directives for immediate practical activity can be derived' (p. 52). Researchers may have their own political agendas or interests and these might determine their choice of areas of research, but that is an entirely different matter from saying that they will or should push their own views and personal political agendas, making prescriptions that emanate from their research for their own partisan agendas (cf. Pawson's (2013, pp. 61ff.) critique of critical realism for its disguised normative premises).

Phillips and Burbules (2000) note that whilst extra-scientific values might determine the focus of the research, this does not mean that those values should influence the conduct of the research (p. 53). Risjord (2014, p. 18) argues for 'epistemic values' (objective scientific reasoning) to be the hallmarks of research, and that these should not be confused with 'non-epistemic values' (moral and political values). Similarly Hammersley (2000, pp. 17–18) suggests that arguing against value-neutrality in research confuses the conduct of research (concerning itself with factual content) with its consequences and implications, and that, save for ethical limits, researchers do not have responsibility for what happens with regard to the consequences of their research. In other words, researchers remain disinterested and neutral, provide evidence, explanations and facts, even recommendations, but leave politics alone. Fact and value differ.

On the other hand, the question is raised that, by not addressing consequences and implications, researchers enable the status quo of inequality, social injustice and oppression to be perpetuated and that it is incumbent on researchers not to hide behind putative value-neutrality, because, in effect, such research is not value-neutral but reinforces the dominant ideology and the interests of the powerful (Hammersley, 2000, p. 136). One cannot pretend that oppression does not exist, and, therefore, to argue for value-neutrality demonstrates a political or moral commitment (Risjord, 2014, p. 28).

In response to this, however, the argument is brought forward that the nature of society is much more contested, complex, dissonant and unclear than critical theorists would argue, and, indeed, that their view of society is more an article of faith, an assumption or presupposition, a value or, indeed, a dogma or ideology that closes itself up to critical enquiry and sound knowledge, or that it harks back to the foundationalism so roundly criticized by post-positivists and post-structuralists. Social reality is not necessarily the taken-for-granted world as that seen through the eyes of critical theorists. In other words, critical theory may be as biased as those views of society it seeks to criticize, and to see society in such dichotomous, either/or terms – equal or unequal, socially just or socially unjust, democratic or undemocratic, free or unfree – or to see it as more complex but still characterized as being marked by oppression, ideology and injustice, is naive, not least as the same circumstances that gave rise to what critical theorists would call inequality also gave rise to greater equality. Just as there is no single, one-dimensional view of society and social reality, so there is no single view of how it must be viewed or researched. In this case, the researcher must regard the claims of critical theorists as hypotheses to be tested rather than as cases that are already proven.

Further, the terminology used by critical theorists is problematic (Hammersley, 2000, p. 139); terms such as 'equality', 'discrimination', 'inequality' are open to differences of interpretation, and, indeed, to differences in value. The same term has different meanings, interpretations and values; indeed, to derive values from facts is to conflate an 'is' with an 'ought', and this is not the stuff of research (see Hammersley's (2014) criticism of critical realism on these grounds).

Is the job of researchers only to provide evidence and explanation, or does it extend into promoting political agendas? Should researchers be partisan or non-partisan, 'committed' or 'disinterested'? Should their own political values or views of what society should be like enter into their research? Whilst objectivity and value-neutrality have been called into question by the post-positivists, indeed by many researchers, what is the limit of this? Here we have two distinct, perhaps irreconcilable views of the tasks and roles of the researcher and research: to provide information – to be a 'methodological purist' (Hammersley, 2000), or to be a political activist. Of course, serving political goals does not preclude the possibility that: (a) knowledge will be produced or facilitated by taking a political stance; (b) those who do not subscribe to the values or views of critical theorists are not simply 'ideological dopes of stunning mediocrity' (Giddens, 1979, p. 52); (c) those who are committed to value-neutrality are not free from the chance of making errors; (d) power differentials do exist in society regardless of which lens one uses to view it. Is there common ground between the analytical, value-neutral researcher and the partisan researcher, whether the latter espouses critical theory or some value system? Is it the case, as Hammersley (2000) so trenchantly puts it, that 'the critical approach disqualifies itself as a form of academic research: it turns sociology into a political morality play' (p. 150)?

3.7 A summary of three major paradigms

The three chapters so far have discussed very different approaches to educational research, which rest on quantitative, qualitative and critical theoretical foundations, or a combination of these.

Table 3.2 summarizes some of the broad differences between the approaches that we have made so far. We present the paradigms and their affiliates in Figure 3.2.

The companion website to the book provides PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: www.routledge.com/cw/cohen.

TABLE 3.2 DIFFERING APPROACHES TO THE STUDY OF BEHAVIOUR

Normative	*Interpretive*	*Complexity theoretical*	*Critical*
Society and the social system	The individual	Wholes, groups, systems and the individuals within them	Societies, groups and individuals
Medium/large-scale research	Small-scale research	Micro- and macro-scale research	Small-scale research
Impersonal, anonymous forces regulating behaviour	Human actions continuously recreating social life	Individuals and their environments constantly and dynamically interact to produce new, emergent systems and behaviours through self-organization, connectedness and feedback	Political, ideological factors, power and interests shaping behaviour
Model of natural sciences	Non-statistical	Action research, case study and narrative research	Ideology critique, action research and critical ethnography
Quantitative, objective	Qualitative, subjective	Quantitative, qualitative, objective and subjective, algorithmic	Ideology critique, participatory, objective and subjective
Positivist and scientific	Hermeneutic and interpretive	Systems-driven, social network driven	Ideology critical
Linear causality	Multiple directions of causality	Multiple directions of causality	Main trends of causality
Reductionist and atomistic	Phenomenologists, symbolic interactionists, ethnomethodologists	Holistic understanding of emergent conditions and systems	Change and emancipation
Research conducted 'from the outside'	Insider and outsider research	Non-reductionist	Interpretive, macro- and micro-concepts: political and ideological interests, operations of power
Outsider research	Personal involvement of the researcher	Objective analysis of systems	Critical theorists, action researchers, practitioner researchers
Generalizing from the specific	Interpreting the specific	Understanding wholes	Collectivity
Explaining behaviour/seeking causes	Understanding actions/meanings rather than causes	Understanding causal interactions	Participant researchers, researchers and facilitators
Assuming the taken-for-granted	Investigating the taken-for-granted	Investigating emergent systems	Critiquing the specific
Macro-concepts: society, institutions, norms, positions, roles, expectations	Micro-concepts: individual perspective, personal constructs, negotiated meanings, definitions of situations	Micro- and macro-level analysis informing each other	Understanding, interrogating, critiquing, transforming actions and interests
Structuralists	Hermeneutic	Explaining and observing, iterative	Interrogating, critiquing and changing the taken-for-granted
Prediction and control	Understanding and explanation	Understanding emergence of complex adaptive systems	Transformation and praxis
Technical interest	Practical interest	Technical and practical interest	Emancipatory interest

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Theory in educational research

CHAPTER 4

Educational researchers are frequently exhorted to root their research in a theoretical framework. This short chapter explores what this means and addresses the following issues:

- What does 'theory' mean and how does it relate to research?
- Where does 'theory' come from, and how is it used? What is it for?
- Do we really need theory in conducting research?
- What kinds of theory are there?

4.1 What is theory?

Theory is a slippery term. It sometimes connotes binary oppositions (theory versus practice, abstract versus concrete, possible but unlikely ('in theory') versus actual or empirical ('in practice'), general versus specific, theoretical versus useful) (cf. Biesta *et al*., 2011; Hammersley, 2012). 'Theory' can mean an opinion or belief ('I have a theory that secondary school males deliberately underperform'), or a tentative explanation ('secondary school males underperform at school in order to look cool in front of their peers'). It can mean a bundle of concepts, for example, a theory of effective schools which includes leadership, achievement orientation, resources, curricular matters, pedagogy and assessment, student motivation, parental support and so on. Such concepts may be related and internally coherent, for example, a theory of 'merit' in a meritocracy which is premised on the combination of IQ and effort. It can mean an explanatory framework, a way of looking at a situation. It can mean law-like statements, for example, 'large organizations have a proclivity to bureaucratization' (though whether there are 'laws' of social behaviour is questionable). It can comprise advocacy or normative principles, for example, 'I have a theory that all children should go to school for a minimum of fifteen years'. It is easy for the educational researcher facing these many interpretations to be lost in a sea of different, indeed contradictory meanings. How, then, can we define 'theory'? In the bullet points that follow, we crystallize several characteristics of 'theory'.

Bacharach (1989) defines theory as 'a statement of relations among concepts within a boundary set of assumptions and constraints' (p. 496), and which approximate to the empirical world (p. 498):

- A theory is a statement, suggestion or proposition that brings together concepts and constructs into a coherent whole, framework or system which has clearly set limits and assumptions.

Huff (2009) notes that theories are explanations of a generalized nature which enable the researcher to compare and analyse empirical data (p. 44). Leong *et al*. (2012) echo this in their comment that theory is 'the story behind the variables … the explanation as to why the variables are related' (p. 122). Hammersley (2012) sets out several meanings of a theory:

> *Theory in relation to practice*. Ideas about how an activity of a particular type *ought to be* carried out, why, what its value is, and so on. On this interpretation, theory is normative in character …
>
> *Theory versus fact*. Sometimes it is said that a particular statement is 'only a theory', implying that it is not well-established knowledge but hypothetical interpretations. Here, theories are factual rather than normative but at the same time speculative in character: their validity is uncertain, or they may even be viewed as idealizations …
>
> *Theory as abstraction as against concrete particulars*.… [T]he distinctive feature of theory here is that it operates at a level of abstraction that is higher than immediate experience or commonsense knowledge …
>
> *Theory as concerned with the macro, as against accounts of the local*. … [T]he term 'theory' being restricted to accounts that have a broad rather than a local focus …
>
> *Theory by contrast with description*. Theories tell us 'what causes what' …

> *Theory as an explanatory language.* Wider than a single explanatory principle … any true theory must be a *set* of principles that tell us about the *whole range of behaviour* of some type of social phenomenon … basic principles of causal systems, these being hidden from ordinary forms of perception and cognition.
>
> *Theory as an approach or 'paradigm'.…* [I]nvolving whole philosophies, in the sense of distinctive sets of ontological, epistemological, and perhaps also praxiological, assumptions.
>
> (Hammersley, 2012, pp. 393–9)

Echoing Bacharach (1989), Alvesson and Sandberg (2013) note that a theory is not 'free-floating' (p. 51) but 'based on and bounded by researchers' assumptions about the subject matter in question' (p. 51). Bacharach argues that theories serve to eliminate or simplify the 'complexity of the real world' (1989, p. 497) but they are not, themselves, data or their categorization, typologies or metaphors. Theories move beyond the 'what' to the 'why', 'how' and 'when' questions (p. 497), i.e. they explain.

Theory is defined by its purposes. How we define theory is made clear by what we want theory to do, the uses to which it is put, for example, to describe, clarify, understand (and more broadly and deeply), make sense of, make intelligible, conceptualize, interpret, explain, predict, generalize, provide answers, empower and emancipate. Definitions of theory are differentiated by its purposes. Biesta *et al*. (2011) remark that we need theory in any sort of educational research, as the essence of research is unavoidably interpretative (p. 230). They give the example of research into 'learning' (p. 233): unless we have a clear concept of what we mean by 'learning' then we cannot usefully research it, and different views of 'learning', for example, as changing behaviour, as processing information, as acquiring knowledge (p. 233), have different areas of focus, methodologies and definitions of what counts as relevant data.

Biesta *et al*. (2011) suggest that one important and enduring quality of theory is to make visible and intelligible those things which might not be so or which might not be immediately able to be observed (p. 227). In an empirical world we need theory to infer causality and causal processes or mechanisms (p. 228), to generate explanations, to give 'plausibility' to explanations (p. 229). As they remark, one task of theory is to enable questions to be answered concerning why people say what they do, do what they do and act as they act (p. 230). Without theory we can only observe correlations, and we need theory to infer or make sense of putative causality. In a hermeneutic world we need theory to understand and interpret experiences, social behaviour, societies, texts and discourses. In the world of critical theory we need theory to interrogate unequal power relations that disfigure lives, to critique inequalities, to emancipate and to transform participants and societies. In other words, theories not only differ by their purposes but by their consequences.

'Theory' has been defined by Kerlinger (1970) as 'a set of interrelated constructs (concepts), definitions, and propositions that presents a systematic view of phenomena by specifying relations among variables, with the purpose of explaining and predicting the phenomena' (p. 9), i.e.:

- A theory specifies the relationship between its elements or component parts, concepts and constructs;
- A theory describes;
- A theory explains;
- A theory predicts.

Theory gathers together all the isolated pieces of empirical data into a coherent conceptual framework of wider applicability. For Bacharach (1989), a theory can be regarded as 'a system of constructs and variables in which the constructs are related to each other by propositions and the variables are related to each other by hypotheses' (p. 498). More than this, however, theory is itself a potential source of further information and discoveries, a source of new hypotheses and hitherto unasked questions; it identifies critical areas for further investigation; it discloses gaps in our knowledge; and it enables a researcher to postulate the existence of previously unknown phenomena.

Theoretical frameworks differ from conceptual frameworks. Conceptual frameworks specify the key concepts being employed in a particular study, how they are used to explore the phenomenon in question, the sequence in which the concepts figure in the research and the direction of relationships of the variables and concepts in the framework. A conceptual framework indicates the relationships of concepts which are concrete and specific to the piece of research in question. By contrast, theoretical frameworks seek to explain and predict, and are at a higher level of abstraction and generality than conceptual frameworks; indeed they appeal to generalizability, which is not the stuff of conceptual frameworks. They are based on the accumulated wisdom of multiple tests and research; they are the general ideas which underpin the conceptual relationships, and are not specific to the study in question. The theory might explain why relationships between

concepts exist, what connects them. Theory is abstract, a generalization that explains relationships between concepts and phenomena.

For example, a researcher looking at learning may have a conceptual framework which suggests the variables involved in understanding how a particular pedagogic strategy improves student's academic achievement. The theoretical framework underpinning this might be, for example, stimulus-response theory, or motivational theory, or self-efficacy theory, or constructivist theory.

A further characteristic of a theory concerns its scope. Whereas an *explanation* might hold for a specific event, situation or issue:

- A theory is a generalized and generalizable statement, i.e. it holds true across contexts beyond those that gave rise to the theory and beyond the specific case in question.

A theory and an explanation are different. Explanations tend to be more specific than theories, or, put another way, theories are more general than explanations, specifying *principles*. Whereas an explanation may focus on a specific case, a theory focuses on *types* of cases or phenomena (Hammersley, 2014, p. 34), drawing on principles; it is independent of the specific case or phenomenon under consideration. Theories hold true beyond the case, population or phenomenon in question (p. 35), and appeal to more general principles and/or causal statements or claims.

A theory lies behind a proposition or hypothesis which is tested, which is falsifiable; it informs, generates, gives rise to a proposition, hypothesis or research question:

- A theory is a general set of principles that are independent of the specific case, situation, phenomenon or observation to be explained.

For example, a theory of effective learning may hold that students learn effectively when non-cognitive factors are included in learning, and this theory may give rise to a hypothesis: 'Students whose intrinsic motivation and self-esteem are high score higher in mathematics than students whose intrinsic motivation and self-esteem are low.' Behind the hypothesis is a framework of coherent, related elements, for example, effective learning is influenced by interrelated non-cognitive elements of personality such as motivation, self-esteem, self-image, disposition and attitudes to learning, interests, sense of responsibility and so on, some of which are included in the hypothesis here.

A theory, standing behind a particular case or phenomenon under investigation, comprises its own set of interrelated constructs or concepts, like Kuhn's (1962) view of a paradigm:

- A theory is a way of looking at and seeing things, conducting research (methodologies, methods and truth tests) and setting research agendas: what has to be researched and how.

For example, I can view the world of schooling through the lens of the hidden curriculum of crowds, praise, power and denial (Jackson, 1968), or I can look at the drive for qualifications through the lens of the credentialist spiral (Oxenham, 1984). These drive what we see, underlining the view that observations are not theory-free (Popper, 1968, 1980). Indeed, observations are inescapably theory-laden in terms of what to look at or for, what not to look at or for, how to look and how to interpret what we see. The theory determines the observation. An artist looking at a rocky mountainous landscape will focus on certain features and see it differently from, say, a mountaineer, a farmer or a geologist. For example, I may investigate the increasingly tight relationship between education and occupational status, to determine whether it is a result of:

- meritocracy and the move away from ascription and towards achievement;
- increased credentialism (qualifications becoming the first filter in job appointments);
- lean-and-mean employment practices (reduced numbers of workers in a company/organization combined with greater demand on those who are employed);
- increased skill-level requirements;
- increased competition for jobs;
- limited employment and career prospects (the supply side);
- increasing demands (the demand side);
- a range of diverse individual motives that are not caught in simple, generalized independent variables.

What I look for, how I look, what evidence I gather and how I interpret the data are determined by the theoretical lenses through which I am looking at the situation.

Theories must be put to the test of rigorous evidence, and we filter out, or do not even consider, what we think are irrelevant factors or data. This is not to say that we cannot proceed in research unless we have deliberately articulated and made explicit our theory; indeed we can conduct educational research without having such articulation. A case can be made for

conducting research without any explicit appeal to a specific theory (e.g. Carr, 2006). As Gorard (2013, p. 31) remarks, 'theory is very much the junior partner in the research process', not least since any case, situation or phenomenon can be explained by any number of theories (Ary *et al.*, 2006). Indeed theories may be unnecessarily and undesirably restricting if we only operate with the delimited boundaries of specific theories when investigating complex, multi-dimensional, multi-perspectival matters.

Hitchcock and Hughes (1995) draw together several strands of the previous discussion in describing a theory thus:

> Theory is seen as being concerned with the development of systematic construction of knowledge of the social world. In doing this theory employs the use of concepts, systems, models, structures, beliefs and ideas, hypotheses (theories) in order to make statements about particular types of actions, events or activities, so as to make analyses of their causes, consequences and process. That is, to explain events in ways which are consistent with a particular philosophical rationale or, for example, a particular sociological or psychological perspective. Theories therefore aim to both propose and analyze sets of relations existing between a number of variables when certain regularities and continuities can be demonstrated via empirical enquiry.
>
> (Hitchcock and Hughes, 1995, pp. 20–1)

Do we need theory in order to conduct educational research? The answer depends on what we mean by 'theory', what kinds of theory we are addressing, what role a theory plays (what we want it to do). The bullet points we have identified so far set out some characteristics of 'theory'.

4.2 Why have theory?

A theory helps us to select, classify and organize ideas, processes and concepts. It helps us to explain, clarify and articulate the heart of the issue. Theory helps us to formulate and find causal relationships; it helps us to understand what, how and why observed phenomena and regularities occur. Theory helps us to predict, for example, outcomes, relationships, and to answer the question 'what will happen if…?' It guides the direction of the research, identifying key fields, methods of working, key concepts; in other words, it serves as a basis for action.

Having a firm theoretical base strengthens research, as it identifies assumptions and enables the researcher to evaluate and critique them. Theory and theoretical frameworks connect the researcher to existing knowledge in the field, are a frame of reference, identify new issues and areas in that field and provide a basis for hypothesis formulation and testing. Theoretical frameworks identify key variables operating in a phenomenon, key concepts and the conceptual basis and framework of the research; they identify and articulate research problems/questions and how to research them. Having a theoretical framework to the research clarifies which facts and evidence will and will not be relevant and important in the research and what are the important research questions that need to be posed to understand and explain an issue. Theory enables the researcher to move to generalization and to identify some of the limits of a generalization.

4.3 What makes a theory interesting?

Educational researchers seeking to ensure that their research is influential, with high impact, should work with 'interesting' theories, i.e. those theories which break new ground or cause us to look at phenomena differently, or discover new features of a phenomenon. Echoing Davis (1971), Alvesson and Sandberg (2013) argue that 'interesting theories' are those that challenge our 'taken-for-granted assumptions in some significant way' (p. 4), that problematize them. In this respect they have higher impact than 'incremental' and 'gap spotting' theories (pp. 4–5), as these latter two tend to work within given agendas rather than to challenge them. Indeed Davis's seminal article indicates twelve ways in which theory can be interesting by challenging the 'taken-for-granted world of their audience' (Davis, 1971, p. 311) (see Morrison and van der Werf (2015) for examples of how Davis's work is illustrated in educational research):

1. *Organization*: What appears to be an unstructured mass of disorganized matter or phenomena is actually the opposite, and vice versa (p. 311).
2. *Composition*: What appear to be assorted matters or phenomena are actually a single matter or phenomenon, and vice versa (p. 315).
3. *Abstraction*: What appears to be an individual matter or phenomenon is actually a holistic matter or phenomenon, and vice versa (p. 316).
4. *Generalization*: What appears to be a local matter or phenomenon is actually a general matter or phenomenon, and vice versa (p. 317).
5. *Stabilization*: What appears to be a stable and immutable matter or phenomenon is actually the opposite, and vice versa (p. 318).

6 *Function*: What appears to be something that works poorly in achieving an aim is actually the opposite, and vice versa (pp. 319–20).
7 *Evaluation*: What appears to be a bad matter or phenomenon is actually the opposite, and vice versa (p. 321).
8 *Co-relation*: What appear to be unrelated items or phenomena are actually the opposite, i.e. are interdependent, and vice versa (p. 322).
9 *Coexistence*: What appear to be matters or phenomena that can coexist actually cannot, and vice versa (pp. 23–4).
10 *Co-variation*: What appear to be positive co-variations between matters or phenomena actually are negative co-variations, and vice versa (p. 324).
11 *Opposition*: What appear to be identical or very similar matters or phenomena are actually the opposite, and vice versa (p. 325).
12 *Causation*: What appears to be an independent causal variable is actually a dependent variable, and vice versa (p. 326).

Alvesson's and Sandberg's (2013) methodology for generating 'interesting' research requires researchers to expose and evaluate assumptions (e.g. in the literature, in 'theories'), and, from there, to develop and evaluate an alternative ground of assumptions (p. 56). Some 'interesting' theories act as a bridge between two or more different theories (Bacharach, 1989, p. 511) or identify redundant or incorrect earlier theories, i.e. help us to re-evaluate existing theories. As Kaplan (1964) remarks: a 'new theory requires its own terms and generates its own laws: the concepts are not merely reorganized, but reconstituted, the old laws are not just connected but given a new meaning' (p. 297).

How we conduct research is informed by the *types* of theory in which we are working or which underpin the research, and these are introduced below.

4.4 Types of theory

There are several different types of theory, and each type of theory defines its own kinds of 'proof': for example, *empirical theory*, '*grand*' *theory*, *normative theory* and *grounded theory* (discussed below), and '*critical*' *theory* (introduced below as an instance of normative theory and which has the entire Chapter 3 devoted to it). The status of theory varies quite considerably according to the discipline or area of knowledge in question. Some theories, as in the natural sciences, are characterized by a high degree of elegance and sophistication; others, perhaps like educational theory, are only at the early stages of formulation and are thus characterized by unevenness.

Empirical theories

Many definitions of 'theory', which add to the features of 'theory' set out in the bullet points earlier, include a requirement that locates it in an empirical context, relating to observational evidence (widely defined), of which scientific theories are prime examples:

- A theory is based on, and guides, empirical research, typically in hypothesis testing or testing by making systematic, objective predictions and observations;
- A theory is testable and, therefore, falsifiable and provisional, such as a scientific theory;
- A theory is conjectural, suggesting relations (e.g. correlational or causal) between two or more items (however defined, for example, variables, factors, observations).

Kettley (2012) suggests that an empirical theory is a 'coherent description and explanation of observed phenomena which provides a testable, verifiable or falsifiable, representation of social relationships' which 'enables the researcher to speculate about future social activity and, perhaps, to predict behaviour drawing on the inferences of the explanation' (p. 9). Gorard (2013), too, suggests that a theory 'is a tentative explanation' (p. 31). He holds that a reasonable theory is one that offers a reasonable explanation based on the research evidence, that this is surpassed by a theory which not only explains the observations but holds true when tested further, and, in turn, this is surpassed by a theory which not only explains and survives further testing, but which has predictive value for something which is completely unexpected (p. 31).

Here a theory has a tentative, impermanent and conjectural quality; it can be tested, upheld, disproved or modified, and its strength resides in its surviving such 'severe tests', i.e. those tests which are deliberately designed to try to falsify the theory (Popper, 1968, 1980). Popper's (1968) view of a scientific theory takes the form of a universal law applying to a particular type of phenomenon. Such a law should demonstrate precision and universality, 'it should set the criteria for its own falsification' (p. 92) and possess explanatory and predictive power. Indeed Popper (1968) comments that the 'best theory' is that which is testable, survives being tested, has greater explanatory power than competing theories and has the greatest content and simplicity (p. 419).

Popper (1968), Lakatos (1970), Mouly (1978), Laudan (1990) and Rasmussen (1990) identify the following

characteristics of a sound empirical theory (cf. Morrison, 1995a). It should:

- be operationalizable precisely;
- be testable, and against evidence which is different from that which gave rise to the theory, i.e. moving beyond simply corroboration and induction and towards 'testing', identifying the type of evidence which is required to confirm or refute the theory;
- permit deductions to be made;
- have explanatory and causal power;
- be compatible with both observation and previously validated theories. It must be grounded in empirical data that have been verified and must rest on sound postulates and hypotheses. The better the theory, the more adequately it can explain the phenomena under consideration, and the more facts it can incorporate into a meaningful structure of ever-greater generalizability. There should be internal consistency between these facts;
- clarify the precise terms in which it seeks to explain, predict and generalize about empirical phenomena;
- be tentative, conjectural, provisional and falsifiable, stating the grounds, criteria and circumstances for its own empirical verification, proof, falsification or rejection;
- demonstrate precision and universality, identifying the nature and operation of a 'severe test' (Popper, 1968), permit deductions that can be tested empirically, i.e. it must provide the means for its confirmation or rejection. One can test the validity of a theory through the validity of the propositions (hypotheses) that can be derived from it. If repeated attempts to disconfirm its various hypotheses fail, then greater confidence can be placed in its validity. This can go on indefinitely;
- clarify its methodologies (e.g. hypothetico-deductive, inductive);
- be faithful to the subject matter and evidence/data from which it has been derived;
- be useful: describe and explain all the relevant data and observations;
- be clear: clarify the conceptual framework and the paradigm in which it works;
- demonstrate internal coherence of its component elements, consistency and internal logic;
- have great explanatory, predictive, retrodictive and generalizable potential;
- be replicable;
- have logical and empirical adequacy and internal coherence;
- be able to respond to observed anomalies;
- be parsimonious, excluding any unnecessary ideas and explanations and stated in simple terms; that theory is best which explains the most in the simplest way. A theory must explain the data adequately and yet must not be so comprehensive as to be unwieldy. On the other hand, it must not overlook variables simply because they are difficult to explain;
- be corrigible in light of further evidence;
- be a spur to empirical research, spawning research and new ideas (fertility);
- lead to new ideas that would otherwise not have emerged.

Empirical theories, by their very nature, are provisional. A theory can never be complete in the sense that it encompasses all that can be known or understood or certain about the given phenomenon. As Mouly (1978) argues, one (scientific) theory is replaced by a superior, more sophisticated theory, as new knowledge is acquired (echoing Kuhn's (1962) discussion of paradigms and paradigm shifts). An empirical theory gathers together all the isolated bits of empirical data into a coherent conceptual framework of wider applicability. More than this, however, empirical theory is itself a potential source of further information and discoveries. In this way it is a source of new hypotheses and hitherto unasked questions; it identifies critical areas for further investigation; it discloses gaps in our knowledge; and enables a researcher to postulate the existence of previously unknown phenomena.

Grand theory

Not all theories are testable. Some theories are artefacts comprising abstract concepts, for example, theories of modernism and postmodernism, Freudian theory, Talcott Parsons's theory of social formations and systems, Habermas's theory of communicative action, Bourdieu's theory of *habitus*. Such theories are very different from testable theories or hypotheses, and often include large-scale conceptual frameworks which are used to comment on or understand phenomena or explain them in broad terms ('grand theory'), and are not bounded by space and time (Bacharach, 1989, p. 500).

Such 'grand theory' (from Mills's *The Sociological Imagination*, 1959) is typically abstract and removed from a specific situation, standing back to set out a view of the world through a conceptual framework. It can be formal, conceptual, speculative, overarching and non-empirical, and it defines areas of study, clarifies and refines their conceptual frameworks and enlarges the way we consider the social and educational world. Grand theory sets out some fundamental ontological and epistemological frameworks and concepts which

define an area of study or domain of enquiry (cf. Layder, 1994, pp. 28–30). Grand theory is untestable and unable to be 'proved' or 'disproved', being a way of considering the world, and, in that respect, is more like an orientation, a rationalization, a belief or an article of faith (cf. Gorard, 2013, p. 32) than a testable, scientific theory. It is a discourse.

Grand theory is a metanarrative, defining an area of study, being speculative, clarifying conceptual structures and frameworks and enlarging the way we consider phenomena (Layder, 1994). It defines a field of enquiry (Hughes, 1976) and uses empirical material by way of illustration rather than 'proof' (p. 44). This is the stuff of some sociological theories, for example Marxism, rational choice theory, structuralism and functionalism.

Whilst sociologists may be excited by the totalizing and all-encompassing nature of such grand theories, they have been subject to considerable critique. For example, Merton (1957), Coser and Rosenberg (1969), Doll (1993) and Layder (1994) contend that whilst they might possess the attraction of large philosophical systems of considerable – Byzantine – architectonic splendour and logical consistency, nevertheless they are scientifically sterile, irrelevant and out of touch with a world that is characterized by openness, fluidity, change, heterogeneity and fragmentation.

However, Murphy (2013) makes a strong case for the applicability of such social theories to everyday practices and lives, as they can explain: social change and development; how and why people behave as they do; the operations of power, culture and social structures; issues of gender, race, class, ability and identity; modernity and postmodernity; institutions and their operations, and so on. He argues powerfully for the role of social theory in educational research, indeed his website for Social Theory Applied (http://socialtheoryapplied.com) provides many links between theory, practice and research. For example, in the field of education he argues that social theory can inform topics such as inequality and inclusion, educational selves and subjectivities, curricular and pedagogic practice, and governance and management (pp. 8–9), and he draws on the social theories of Habermas, Foucault, Bourdieu and Derrida.

Grand theories have been criticized for their aridity and inability to stand empirical scrutiny or testing (Merton, 1957; Mills, 1959; Layder, 1994). This charge, however, might appear unfair, attempting to judge a theory by criteria which it does not strive to meet. There remains the problem that too easily grand theory can become empty rationalization; for example, Hughes (1976) comments that 'this form of theorizing is just so much over-elaboration of concepts almost to the wilful exclusion of any empirical import' (p. 45) and that it involves elaborating distinctions arbitrarily which do little or nothing to increase understanding or make greater sense of experience (Mills, 1959, p. 33). This echoes Merton's (1957) view that, though they may have the architectonic splendour of 'large philosophical systems', they are also marked by 'scientific sterility' (p. 10) and, whilst being admirable for their logical consistency, are largely of no relevance to the everyday world (Coser and Rosenberg, 1969, p. 14). To add to this is the familiar critique of grand theory as being totalizing metanarratives in a world in which no single metanarrative is operable.

For the educational researcher, grand theories can inform an understanding of the world and articulate a way of looking at phenomena or explain the context of a study, and, in this respect, might prompt the development of research questions (cf. White, 2009, p. 26). Whereas empirical theory looks to 'proof' as a criterion of its validity, grand theory looks to logical coherence, explanatory potential and articulation of key concepts in understanding a phenomenon.

Middle-range theory

Between 'grand' theory and small-scale theories or minor working hypotheses lie what Merton (1967) termed 'middle-range theories': subsets of overarching theories which focus on specific topics and seek to explain them. These typify much educational research. Middle-range theory focuses on a particular phenomenon or case in context, and seeks to explain it in terms of underlying mechanisms, factors or principles that give rise to the phenomenon or case in point. It uses a limited set of assumptions to derive hypotheses/questions logically which can be tested empirically (Merton, 1957). It starts with a specific empirical phenomenon (in contrast to a broad abstract area such as 'capitalism' or 'social structure', which is the stuff of 'grand theory') and abstracts and creates from the phenomenon general statements which can be verified by data.

Merton (1967), in defining middle-range theories, notes that this intermediate position uses abstractions and concepts 'close enough to observed data to be incorporated in propositions that permit empirical testing' (p. 39) in studying delimited aspects of social life. Here 'theory' comprises propositions which are logically interconnected and from which 'empirical uniformities' can be derived to explain all the observed uniformities of social behaviour, social organization and social change (p. 39). He is against theories that are so abstract that they cannot be tested, but he also argues

for middle-range theories which can apply abstract concepts to different spheres of social structure and social behaviour, i.e. which bridge micro- and macro-social problems, looking at here-and-now matters.

Pawson (2008) provides an example of middle-range theory in education. In improving higher education, recourse may be made to a variant of 'naming and shaming', based on the theory that publishing comparative data on higher education institutions (e.g. rankings) will stimulate competition between them, and thereby drive up standards (p. 18).

Middle-range theory draws on empirical evidence, and embraces, but does not confine itself to, hypothesis testing, prediction, isolation and control of variables. It can be explanatory and interpretive, seeking to understand a situation in its context, a hermeneutic, practical exercise, following the *verstehen* approaches of Weber, looking at meaning in social contexts. Much educational research appeals to middle-range theory, focusing on a specific case or phenomenon and seeking to explain it using concepts and hypotheses which, whilst being somewhat abstracted from the specific case in question, are not part of the parlance of grand, totalizing theoretical edifices.

Normative theory

Normative theories explain how people, groups, institutions etc. *ought* to operate within a specific system of social values (norms). They are prescriptive, for example: 'all students should be taught ideology critique'; 'schools should promote democracy'.

A clear example of a normative theory is critical theory, which is such a large field that we devote an entire chapter to it (Chapter 3). Critical theory seeks to uncover the interests at work in particular situations, to interrogate the legitimacy of those interests and to identify the extent to which they are legitimate in serving equality and democracy. It has a deliberate intention of being *transformative* and *emancipatory*, promoting democracy and individual freedoms. It is practical and political, to bring about a more just, egalitarian society in which individual and collective freedoms operate, and it seeks to eradicate the exercise and effects of illegitimate power.

Critical theory, operating through ideology critique, identifies unequal power relations in society, interrogates their legitimacy, identifies what has brought an individual or social group to relative powerlessness or, indeed, to power, and questions the legitimacy of repression, voice, ideology, power, participation, representation, inclusion and interests. It argues that much behaviour (including research behaviour) is the outcome of particular illegitimate, dominatory and repressive factors, illegitimate in the sense that they do not operate in the general interest – one person's or group's freedom and power is bought at the price of another's freedom and power.

For the educational researcher, a normative theory, of which critical theory is an example, should be clear in its methodology, set criteria for its validation (both empirical and non-empirical) and denote the type(s) of evidence that could substantiate the theory. As with other views of 'theory', normative theory must have substantive concepts which are internally coherent and logically tenable. It might be a middle-range theory, 'grand theory' or empirical theory. It should demonstrate appropriate precision and universality, possess explanatory power and predictive validity, and, as for other theories, have greater validity claims and warrants than rival theories. Criteria for judging its worth include its ability to achieve the norms and values explicit in the theory, for example, for critical theory this means its potential for, and achievement of, practical empowerment, freedom, equality, social justice, democracy and emancipation.

A contentious issue raised by normative theory is whether it is the task of educational research to have an explicit political or ideological agenda, to engage in political activism and/or policy making, or whether educational research should simply stick to providing factual knowledge that is used by others for political, normative agendas and policy making (Hammersley, 2014). Should educational researchers be concerned only with the neutral, disinterested pursuit and provision of knowledge (recognizing that this is itself a value position) or seek to press home a particular ideology or set of values? Should educational researchers directly answer questions of values, of desirability, of right and wrong, or should they just stick to facts, not values? We discuss this in Chapter 3.

Grounded theory

Grounded theory (addressed fully in Chapter 37) is not predetermined, but, rather, emerges from, and is consequent to, data (Glaser and Strauss, 1967), i.e. it is grounded in data and rises up from the ground of data: a 'bottom-up' process. It seeks to *generate* rather than simply to test an existing theory. Grounded theory commences with data on a topic or phenomenon of concern, and then, using tools such as theoretical sampling, coding, constant comparison, identification of the core variable, and saturation, the theory – the explanation and explanatory framework – emerges from the analysis and study of, and reflection on, the phenomena and data under scrutiny (cf. Strauss and Corbin, 1990, p. 23). Grounded theory identifies key features and

relationships emerging from data and categories and then proposes a plausible explanation of the phenomenon under study by drawing on the data generated, ensuring that the theory explains all the data without exception.

A concern of researchers working with grounded theory is how far one can generalize from it: is the grounded theory limited to the specific study; can it be applied to other similar situations; does it have wider generalizability like a 'grand' theory? We explore this in Chapter 37, noting that grounded theory researchers often refer to 'transferability' of the findings from one situation to another, which is based on the judgement of the researcher or reader, and that it is problematic to rely too heavily on reader judgement in determining the status of the grounded theory. Grounded theory has some affinity to 'middle-range' theories.

Empirical, grand, middle-range, normative and grounded theories have practical value. They underpin research design, data analysis and, indeed, the generation of new theories. For example, they suggest the relationships between variables and concepts; they can be used to set up the research, what it seeks to do and what key concepts are included in the research; they can predict and explain findings, suggesting at a high level of abstraction *why* such and such occurs.

Social theories and psychological theories can be usefully brought into educational research. We give a fully worked example in Chapter 6, and we refer readers to this. By way of summary of that example here, Goldthorpe (2007) plans, conducts and reports research which explains the causes of 'persistent differentials in educational attainment' despite increased educational expansion, provision and uptake across the class structure (p. 21). In his research, theory plays a part at each of seven stages:

Stage 1: Establish exactly what has to be explained, examining regularities and patterns of relevant phenomena.
Stage 2: Set out possible theoretical foundations for the investigation, which utilize high-level sociological and economic theory (Marxist theory, liberal theory, cultural theory and rational choice theory).
Stage 3: Examine, evaluate and eliminate rival theoretical foundations, selecting the most fitting and justifying the selection (in his research it is rational choice theory).
Stage 4: Hypothesize a causal explanation on the basis of the best theoretical foundation. This operates at a sophisticated theoretical level, arguing that different classes view the costs, risks and benefits differently (p. 34).
Stage 5: Set out the assumptions underlying the causal explanation (which concerns income differentials, class differentials, risk aversion, anticipated costs and benefits).
Stage 6: Test the causal hypotheses empirically, in which data are collected on differences in aspirations and decisions by social class which are caused by: (a) perceptions of costs; (b) relative risk aversion; and (c) perceptions of relative benefit.
Stage 7: Draw conclusions based on the test. Here, there are class differences in terms of relative ambition, risk aversion, perceived costs and benefits, amounts of effort required, assurances of success (and the significance of this), fear of downward social mobility, income, occupational choices, and the need for qualifications. These, in turn, based on empirical data, support his explanation of the factors of relative risk aversion and fear of downward social mobility exerting causal power on educational decision making which, in turn, lead to class differentials in educational attainment being maintained (p. 99).

In this example, grand theory (sociological theory of rational choice), empirical theory (e.g. hypothesis generation and testing) and middle-range theory (the explanation of a particular phenomenon) all have their place at different stages of the research. We advise readers to look at the example in Chapter 6 for a fuller account of this.

4.5 Where does theory come from?

Where does a theory come from? How does one establish a theory? Clearly there are many starting points. One starting point may be through observation and analysis, for example, of observed regularities or relationships, of an association of events, of data; another is through reflection and creativity. Another may be through asking a 'what if' question, for example, 'if assessment were to become more authentic, would it increase student motivation?', or 'does repeating a year at school improve student performance?' Another starting point might be less concerned with regularities than a single instance: 'why did such-and-such happen?' or 'why is such-and-such happening?' Another starting point may be from literature which gives rise to a theory, or previous research.

Echoing C. Wright Mills's (1959) view of *The Sociological Imagination*, theory generation is a human act. It is the creative imagination in the minds of humans which links concepts and sets the grounds for logical coherence and theory validation. As Bacharach (1989) argues, theories derive from people's 'creative imagination and

ideological orientation or life experience' (p. 498). Theory comes from humans creating and connecting ideas and concepts into an explanatory framework within articulated boundaries, and testing them.

Similarly, it is humans who decide whether a theory holds water; who proffer explanations, predictions and generalizations; who select what is relevant to include in a theory; and who determine how to test, validate and falsify the theory. Whilst observations and data may provide the fuel for theory generation and testing, they are not the theory itself.

Theory typically precedes research questions; research does not start with research questions. We assemble observations, ideas, concepts, reflections, consider what they mean, and then formulate our theories, our frameworks of related concepts and propositions. Then we construct our tests of the theories, which may utilise a hypothetico-deductive empirical method (e.g. correlational, causal analysis, difference testing, regressions, or other kinds of analysis and intervention), a hermeneutic method, an emancipatory, transformative method through ideology critique, a grounded theory approach, or others.

Depending on the type of research and research question, we often commence with a theory and then test it, moving from theory to hypothesis generation to hypothesis testing and observation to prediction to conclusion to generalization. Alternatively, as in a grounded theory approach, we may conduct post hoc theory generation, i.e. starting with data and, through the tools of grounded theory, end up with an emergent theory which subsequently we may wish to test in other contexts and conditions.

4.6 Questions about theory for researchers

In considering the role of theory in educational research, researchers can address the following questions:

- What definition of theory are you using?
- What is your theory (state it clearly)? Is it a hypothesis, a set of related concepts, a value system, a political/ideological agenda, an explanatory framework, a possible explanation, an opinion, an approach etc.?
- What is the theory/theoretical framework in which you are working? What are its key components, constructs, concepts and elements, and how do they relate to each other logically and coherently?
- What is your theory seeking to describe ('what'), explain ('how', 'why', 'when'), predict ('what if'), generalize, i.e. what is it a theory of, and why is this relevant for your research?
- What makes your theory interesting?
- How important is theory in your research? (Why) do you need to make it explicit?
- What theories are you using, and why these: how relevant are they to your study?
- What is the purpose of your research with regard to theory, for example, to test, apply, explain, understand, generate, critique, validate, extend, refine, refute a theory?
- What is the relationship between your theory, your research and your research question(s)?
- What type of theory are you using (e.g. empirical, grand, normative, middle-range, critical, grounded)?
- What methodologies are you using to work with your theory (e.g. empirical testing, hermeneutic interpretation and explanation, ideology critique)?
- What criteria are you using to validate your theory (e.g. compatibility with empirical data, logical coherence and adequacy, explanatory potential, achievement of transformative and emancipatory potential etc.)? How will you validate your theory?
- How does your theory give rise to testable propositions/hypotheses, or inform a hermeneutic exercise, or bring about its espoused values or normative intentions?
- What are the boundaries of, and assumptions in, your theory?

4.7 Conclusion

Researchers frequently pose the question 'do we need theory?' This is an inappropriate question, for, one the one hand, like it or not, we cannot escape theory: it is there, it underpins what we do, whether or not we are conscious of it. One of the contributions of the post-positivists is in drawing attention to the point that no observation is theory-free. A more useful question is what we need theory for, as, by itself, it may underdetermine or unnecessarily constrict the full gamut of the research enterprise.

Theories help us to think. They articulate and organize ways of approaching a problem or phenomenon. They assemble and clarify key concepts and their relationships, principles and abstractions, explanations and propositions. They can stimulate research questions and hypotheses. Theories connect concepts into a logical and coherent whole or framework.

Theories help us to learn: they can render ideas testable, define ways of working, tell us which ideas, statements, conclusions, lines of reasoning stand fast when tested rigorously and which appear to be valid, reliable,

credible, legitimate, sound, reasonable and useful. Some theories (e.g. descriptive, analytical, explanatory) help us to understand a phenomenon; others define an approach, conceptual frame and reference system (e.g. grand theory); yet others (e.g. normative, critical) seek to change the world or to promote an agenda. Theories are tools for thinking, describing, understanding, predicting, explaining, proving, organizing, connecting ideas and concepts, generalizing, generating research enterprises and suggesting research questions and answers. It is for each researcher to decide which meaning(s) of 'theory' is/are being used in a specific research project.

Like it or not, use them or not, one or more theories lie behind an educational research study. Whether these drive the research, are incidental or unimportant to it are matters for each researcher. Perhaps middle-range theory is both a useful compromise and, more positively, a useful way forward.

Evaluation and research

CHAPTER 5

This brief chapter indicates some key similarities and differences between research and evaluation. The chapter sets out:

- similarities between research and evaluation
- differences between research and evaluation
- connections between evaluation, research, politics and policy making

5.1 Similarities and differences between research and evaluation

There are many similarities between research and evaluation. Both share commonalities in terms of methodologies, ethical issues, sampling, reliability and validity, instrumentation and data analysis, i.e. their operational practices (Arthur and Cox, 2014, p. 139; Garcia *et al*., 2014). However, there are also differences; the problem of trying to identify differences between evaluation and research is compounded because not only do they share several of the same methodological characteristics, but one branch of research is called *evaluative research* or *applied research*. This is often kept separate from 'blue-skies' research in that the latter is open-ended, exploratory, contributes something original to the substantive field and extends the frontiers of knowledge and theory, whereas in the former the theory is *given* rather than *interrogated* or *tested*. Plewis and Mason (2005, p. 192) suggest that evaluation research is, at heart, applied research that uses the tools of research in the social sciences to provide answers to the effectiveness and effects of programmes. One can detect many similarities between the two in that they both use methodologies and methods of social science research generally (Norris, 1990), covering, for example:

- the need to clarify the purposes of the investigation;
- the need to operationalize purposes and areas of investigation;
- the need to address principles of research design that include:
  - **a** formulating *operational questions*,
  - **b** deciding appropriate *methodologies*,
  - **c** deciding which *instruments* to use for data collection,
  - **d** deciding on the *sample* for the investigation,
  - **e** addressing *reliability* and *validity* in the investigation and instrumentation,
  - **f** addressing *ethical* issues in conducting the investigation,
  - **g** deciding on *data-analysis* techniques,
  - **h** deciding on *reporting* and *interpreting* results.

The features outlined above embrace many elements of the scientific method (see Chapter 1).

Researchers and evaluators pose questions and hypotheses, select samples, manipulate and measure variables, compute statistics and data, and state conclusions (cf. Garcia *et al*., 2014). Nevertheless there are important differences between evaluation and research that are not always obvious simply by looking at publications. Publications do not always make clear the background events that gave rise to the investigation, nor do they always make clear the uses of the material that they report, nor do they always make clear what the dissemination rights are (Sanday, 1993) and who holds them. Several commentators set out some of the differences between evaluation and research. For example, Smith and Glass (1987) offer eight main differences:

1. *The intents and purposes of the investigation*: the researcher wants to advance the frontiers of knowledge of phenomena, to contribute to theory and to be able to make generalizations; the evaluator is less interested in contributing to theory or the general body of knowledge. Evaluation is more parochial than universal (pp. 33–4).
2. *The scope of the investigation*: evaluation studies tend to be more comprehensive than research in the number and variety of aspects of a programme that are being studied (p. 34).
3. *Values in the investigation*: much research aspires to value-neutrality. Evaluations must represent multiple sets of values and include data on these values.

4 *The origins of the study*: research has its origins and motivation in the researcher's curiosity and desire to know (p. 34). The researcher is autonomous and answerable to colleagues and scientists (i.e. the research community), whereas the evaluator is answerable to clients and stakeholders. The researcher is motivated by a search for knowledge; the evaluator is motivated by the need to solve problems, allocate resources and make decisions. Research studies are public; evaluations are for a restricted audience.
5 *The uses of the study*: the research is used to further knowledge; evaluations are used to inform decisions.
6 *The timeliness of the study*: evaluations must be timely; research need not be. Evaluators' timescales are given; researchers' timescales need not be given.
7 *Criteria for judging the study*: evaluations are judged by the criteria of utility and credibility; research is judged methodologically and by the contribution that it makes to the field (i.e. internal and external validity).
8 *The agendas of the study*: an evaluator's agenda is given; a researcher's agenda is her own.

Norris (1990) reports work by Glass and Worthen in which they identified eleven main differences between evaluation and research:

1 *The motivation of the enquirer*: Research is pursued largely to satisfy curiosity; evaluation is undertaken to contribute to the solution of a problem.
2 *The objectives of the search*: Research and evaluation seek different ends. Research seeks conclusions; evaluation leads to decisions.
3 *Laws versus description*: Research is the quest for laws (nomothetic); evaluation merely seeks to describe a particular thing (idiographic).
4 *The role of explanation*: Proper and useful evaluation can be conducted without producing an explanation of why the product or project is good or bad or of how it operates to produce its effects.
5 *The autonomy of the enquiry*: Evaluation is undertaken at the behest of a client; researchers set their own problems.
6 *Properties of the phenomena that are assessed*: Evaluation seeks to assess social utility directly; research may yield evidence of social utility but often only indirectly.
7 *Universality of the phenomena studied*: Researchers work with constructs having a currency and scope of application that make the objects of evaluation seem parochial by comparison.
8 *Salience of the value question*: In evaluation, value questions are central and usually determine what information is sought.
9 *Investigative techniques*: While there may be legitimate differences between research and evaluation methods, there are far more similarities than differences with regard to techniques and procedures for judging validity.
10 *Criteria for assessing the activity*: The two most important criteria for judging the adequacy of research are internal and external validity; for evaluation they are utility and credibility.
11 *Disciplinary base*: The researcher can afford to pursue inquiry within one discipline; the evaluator cannot.

However, we include below a more comprehensive set of distinguishing features, but it must be emphasized that they are not at all as rigidly separate as the bullet points below might suggest:

- *Origins*: Research questions originate from scholars working in a field; evaluation questions issue from stakeholders.
- *Audiences*: Evaluations are often commissioned and they become the property of the sponsors and are not for the public domain; research is disseminated widely and publicly.
- *Purposes*: Research contributes to knowledge in the field, regardless of its practical application, and provides empirical information, i.e. 'what is'; evaluation is designed to use that information and those facts to judge the worth, merit, value, efficacy, impact and effectiveness of something (Scriven, 2004; Arthur and Cox, 2014), i.e. 'what is valuable' (Mathison, 2007, p. 189). Research is conducted to gain, expand and extend knowledge; evaluation is conducted to assess performance and to provide feedback (Levin-Rozalis, 2003). Research is to generate theory; evaluation is to inform policy making (Patton, 2002). Research is to discover; evaluation is to uncover (Arthur and Cox, 2014). Research seeks to predict what will happen; evaluation concerns what has happened or what is happening (ibid.).
- *Stance*: The evaluator is reactive (e.g. to a programme); the researcher is active and proactive (Levin-Rozalis, 2003, p. 15).
- *Status*: Evaluation is a means to an end; research is an end in itself (Levin-Rozalis, 2003).
- *Focus*: Evaluation is concerned with how well something works; research is concerned with how something works (Mathison, 2007).

- *Outcome focus*: Evaluation is concerned with the achievement of intended outcomes; research may not prescribe or know its intended outcomes in advance (science concerns the unknown).
- *Participants*: Evaluation focuses almost exclusively on stakeholders; research has no such focus (Mathison, 2007).
- *Scope*: Evaluations are concerned with the particular, for example, a focus only on specific programmes. They seek to ensure internal validity and often have a more limited scope than research. Research often seeks to generalize (external validity) and, indeed, may not include evaluation (Priest, 2001).
- *Setting of the agenda*: The evaluator works within a given brief; the researcher has greater control over what will be researched (though often constrained by funding providers). Evaluators work within a set of 'givens', for example, programme, field, participants, terms of reference and agenda, variables; researchers create and construct the field.
- *Relevance*: Relevance to the programme or what is being evaluated is a prime feature of evaluations; relevance for researchers has wider boundaries (e.g. in order to generalize to a wider community). Research may be prompted by interest rather than relevance. For the evaluator, relevance has to take account of timeliness and particularity (Levin-Rozalis, 2003, pp. 20–1).
- *Time frames*: Evaluation begins at the start of the project and finishes at its end; research is ongoing and less time-bound (Levin-Rozalis, 2003) (though this may not be the case with funded research).
- *Uses of results*: Evaluation is designed to improve; research is designed to demonstrate or prove (Stufflebeam, 2001). Evaluation 'provides the basis for decision making; research provides the basis for drawing conclusions' (Mathison, 2007, p. 189). Evaluations might be used to increase or withhold resources or to change practice; research provides information on which others might or might not act, i.e. it does not prescribe.
- *Decision making*: Evaluation is used for micro decision making; research is used for macro decision making (Mathison, 2007, p. 191).
- *Data sources and types*: Evaluation has a wide field of coverage (e.g. costs, benefits, feasibility, justifiability, needs, value for money), so evaluators employ a wider and more eclectic range of evidence from an array of disciplines and sources than researchers.
- *Ownership of data*: The evaluator often cedes ownership to the sponsor, upon completion; the researcher holds onto the intellectual property.
- *Politics of the situation*: The evaluator may be unable to stand outside the politics of the purposes and uses of, or participants in, an evaluation; the researcher provides information for others to use.
- *Use of theory*: Researchers base their studies in social science theory; this is not a necessary component of evaluation (Scriven, 1991). Research is theory-dependent; evaluation is 'field-dependent', i.e. not theory-driven but derived from the participants, the project and stakeholders. Researchers create the research findings; evaluators may (or may not) use research findings (Levin-Rozalis, 2003, pp. 10–11).
- *Reporting*: Evaluators report to stakeholders/commissioners of research; researchers may include these and may also report more widely, for example, in publications (Beney, 2011).
- *Standards for judging quality*: Judgements of research quality are made by peers; judgements of evaluation are made by stakeholders (Patton, 2014). For researchers, standards for judging quality include validity, reliability, accuracy, causality, generalizability, rigour; for evaluators, to these are added utility, feasibility, involvement of stakeholders, side effects, efficacy, fitness for purpose (though, increasingly, utility value and impact are seen as elements for judging research) (Patton, 1998).

Mathison (2007) comments that the two major dimensions for distinguishing between research and evaluation are on the particularization/generalization continuum and the decision-oriented/conclusion-oriented continuum.

The statements above are set out in an either/or manner for conceptual clarity. However, the reality of the situation is nowhere near as clear as this; research and evaluation are not mutually exclusive binary oppositions, nor, in reality, are there differences between them. Their boundaries are permeable, similarities are often greater than differences and there is often overlap; indeed, evaluative research and applied research often bring the two together (Levin-Rozalis, 2003, p. 3); indeed Arthur and Cox (2014) note how easily the two have elided in research and assessment exercises. For each of the above there are many exceptions. For example, both evaluation and research might be concerned with generalization, or, indeed with the particular; evaluation may not be for decision making whereas research may be precisely for this purpose (Mathison, 2007). Both research and evaluation are concerned to produce information and to promote explanation and understanding, both of which can contribute to decision making and policy formation, i.e. both are intimately concerned with politics and both involve political processes, with differences between them being more

matters of degree, and both can operate at different levels: individual, local and institutional to national and international (Arthur and Cox, 2014). Elliott (1991) notes that evaluation is an essential ingredient of action research. Patton (1998) argues that differences between research and evaluation are often arbitrary, and cases can be made for saying that they are the same or, indeed, are different.

Mathison (2007) reports that some people put research as a subset of evaluation whilst others put evaluation as a subset of research (p. 189). MacDonald (1987) argues that '[t]he danger therefore of conceptualizing evaluation as a branch of research is that evaluators become trapped in the restrictive tentacles of research respectability.… How much more productive it would be to define research as a branch of evaluation' (p. 43).

A clue to some of the differences between evaluation and research can be seen in the definition of evaluation. Most definitions of evaluation include reference to several key features: (1) answering specific, given questions; (2) gathering information; (3) making judgements; (4) taking decisions; (5) addressing the politics of a situation (Morrison, 1993, p. 2). Morrison provides one definition of evaluation as: 'the provision of information about specified issues upon which judgements are based and from which decisions for action are taken' (p. 2).

5.2 Evaluation research and policy making

In an era in which educational innovations come thick and fast, often on the crest of one wave after another of government policies and interventions, evaluation has to take to task any notion that quick fixes from interventions 'work' straightforwardly, or at all. This runs counter to claims that slogans of evidence-based practice and 'what works' are unproblematic. Rather, identifying 'what works' contains myriad complexities and challenges. Understanding 'what works' in education recognizes that an intervention often unfolds in unexpected ways because of the complex interplay of participants and contingencies. Often as not, this may frustrate the clean, antiseptic world of policy makers. Innovations rarely 'work' entirely in the ways in which they are intended. A range of factors operate on the situation, and impact, effectiveness and efficacy are viewed differently by different participants. Hence key questions for evaluation concern, for example, which part(s) of an intervention or programme are working well/less well, why, for whom, under what contingencies and conditions, in what circumstances and over what time period (cf. Pawson, 2013, p. 167).

Take, for example, the 'healthy attachments' programme in a range of UK schools, which Pawson (2013) reports. This project was designed to improve students' 'well-being, sense of security and positive regard' (p. 73), which, in turn, sought to reduce risks to health associated with tobacco, alcohol and illegal drugs (p. 73). Pawson, carefully dissecting out the claims made for the intervention, shows that it is typical of 'black-box analysis' (p. 74) and that, actually, the positive results overlooked important elements and were far less clear than the claims made for the project's success. Why? Because a range of events and factors occurred, and people's perspectives and situations were neglected in the evaluation which, if taken more seriously, would have led to much more cautious claims. As he says, in response to the question 'is this the correct interpretation?' an accurate answer should be '[p]ossibly. Possibly not' (p. 75). Pawson demonstrates clearly the dangers of making unequivocal claims on the basis of under-researched, over-interpreted, neglectful data and narrow enquiry, and he counsels caution in making simplistic claims. As he says, there are reasons why we may not believe the claims made (p. 16), and evaluators worth their salt would do well to keep this to the fore in understanding how educational interventions unfold. This may come as unwelcome news to policy makers who seek unequivocal results.

Pawson notes that the search for 'what it is about an intervention that works for whom, in what circumstances, in what respects, over which duration' (2013, p. 167), i.e. to focus on the contexts, mechanism and outcomes of the intervention, is a complex, pragmatic and ongoing endeavour. In this he notes for evaluators the significance of context (pp. 36–8) and of attention to the personal and interpersonal dimensions of interventions (pp. 127–31, 139–46). Epistemological and substantive support for his approach finds voice in: (a) Popperian doubt, with its emphasis on conjectures, refutations and the tentative, conditional, falsifiable nature of scientific 'truths' (p. 99); and (b) Rossi's disconcerting 'iron law' (p. 12) which states that the value of any assessment of impact of a large-scale programme is typically zero (p. 12). This may be uncomfortable for both policy makers and evaluators, but that is the reality of many interventions.

In putting forward his case for a realist approach to evaluation, Pawson uses acronyms to identify key elements and foci of evaluation:

- CMOs: Contexts, Mechanisms and Outcomes (pp. 21–6) (redolent of Stufflebeam's (1967) Context, Input, Process and Product model of educational evaluation);

- VICTORE: Volitions, Implementation, Contexts, Time, Outcomes, Rivalry and Emergence (pp. 33–46);
- TARMATO: Theory, Abstraction, Reusable Conceptual Platforms, Model Building, Adjudication, Trust and Organized Scepticism (pp. 85–111).

Even though it may not be good news for policy makers, Pawson notes that many interventions typically work and then don't work. This, he avers, is due in part to context, situations, perspectives, participants, circumstances and affinity to decision makers' agendas. He notes that an evaluation is prone to distortion and misrepresentation of the multiple factors in, and interpretations of, an intervention phenomenon if: (a) it neglects understanding how the perceptions, actions, agency and circumstances of humans unfold in, and affect, an intervention; and (b) it is selective on whose interpretation of a project is adopted. This is salutatory advice for both evaluators and policy makers.

The effectiveness of interventions vary from school to school and from individual to individual (see also Cartwright and Hardie, 2012). Policy makers are attracted by 'what works'. However, Pawson (2013) shows that what works for some is unlikely to work for all, that it is massive over-determination rather than the intervention itself which frequently contributes to policy uptake, regardless of impact, and that, even though some policies are doomed to be implemented, to expect them to provide only gains rather than losses is simply naive. In other words, 'what works' is problematic. This being the case, evaluation seeks to identify the contingencies and conditions surrounding a decision or intervention, for example, if we want to do such-and-such then it would be better to adopt approach A and B, targeted at M and N, and to be aware of dangers of X and Y (cf. Pawson, 2013, p. 190).

5.3 Research, evaluation, politics and policy making

Evaluation and research are beset with issues of politics; they take place within a political environment, which might be a micro-environment (e.g. a single school) or a larger environment (e.g. a funding body, a research institute). MacDonald (1987) comments that the evaluator:

> is faced with competing interest groups, with divergent definitions of the situation and conflicting informational needs.… He has to decide which decision-makers he will serve, what information will be of most use, when it is needed and how it can be obtained.… The resolution of these issues commits the evaluator to a political stance, an attitude to the government of education. No such commitment is required of the researcher. He stands outside the political process, and values his detachment from it. For him the production of new knowledge and its social use are separated. The evaluator is embroiled in the action, built into a political process which concerns the distribution of power, i.e. the allocation of resources and the determination of goals, roles and tasks.… When evaluation data influences power relationships the evaluator is compelled to weight carefully the consequences of his task specification. … The researcher is free to select his questions, and to seek answers to them. The evaluator, on the other hand, must never fall into the error of answering questions which no one but he is asking.
>
> (MacDonald, 1987, p. 42)

Whether that holds as true at the present moment as when it was written is a moot point, as funded research often has a strong political motive, and institutional politics (e.g. internal funding decisions) may have a bearing on research. MacDonald argues that evaluation is an inherently political enterprise. His much-used threefold typology of evaluations as autocratic, bureaucratic and democratic is premised on a political reading of evaluation (see also Chelinsky and Mulhauser (1993), who refer to 'the inescapability of politics' (p. 54) in the world of evaluation).

The reality of politics often blurs distinctions between research and evaluation. Two principal causes of this blurring lie in the *funding* and the *politics* of both evaluation and research. For example, the view of research as uncontaminated by everyday life is naive and simplistic; Norris (1990, p. 99) argues that such an antiseptic view of research ignores the social context of educational research, some of which is located in the hierarchies of universities and research communities and the funding support provided for some but not all research projects by governments. His point has a pedigree that reaches back to Kuhn (1962), and is a comment on the politics of research funding and research utilization. For decades one can detect a huge rise in 'categorical' funding of projects, i.e. defined, *given* projects (often by government or research sponsors) for which bids have to be placed. This may seem unsurprising if one is discussing research grants from government bodies, which are typically deliberately policy-oriented, though one can also detect in projects which have been granted by non-governmental organizations a move towards sponsoring policy-oriented projects rather than the 'blue-skies' research mentioned

earlier, and the rise of the evidence-based movement in research and policy making draws this link ever tighter. Indeed Burgess (1993b) argues that 'researchers are little more than contract workers.… [R]esearch in education must become policy relevant.… [R]esearch must come closer to the requirement of practitioners' (p. 1), echoing Stenhouse's (1975) advocacy of the teacher-as-researcher and more recently in Pring's (2015) comments on the centrality of practitioner research in educational research. Burgess's view also points to the constraints under which research is undertaken; if it is not concerned with policy issues then research may not be funded, and research must have some impact on policy making.

The view of the tension between research, evaluation and politics is reinforced by several articles in the collection edited by Anderson and Biddle (1991) which show that research and politics go together uncomfortably because researchers have different agendas and longer timescales than politicians and try to address the complexity of situations, whereas politicians, anxious for short-term survival, want telescoped timescales, simple remedies and research that will be consonant with their political agendas. As James (1993) notes:

> the power of research-based evaluation to provide evidence on which rational decisions can be expected to be made is quite limited. Policy-makers will always find reasons to ignore, or be highly selective of, evaluation findings if the information does not support the particular political agenda operating at the time when decisions have to be made.
>
> (James, 1993, p. 135)

Her comments demonstrate a remarkable prescience as, if anything, the situation has become even more acute than when it was written.

Not only is *research* a political issue, but this extends to the use being made of *evaluation* studies. Whilst evaluations can provide useful data to inform decision making, as evaluation has become more politicized so its uses (or non-uses) have become more politicized. Indeed Norris (1990) provides examples of how politics frequently overrides evaluation or research evidence, and, despite the evidence-based movement, it is common to read how politicians introduce interventions in education on the basis of poor, scant or, indeed, no evidence of their efficacy. Gorard (2005, 2014), for example, demonstrates that 'academies' in the UK were doomed to succeed as there was no evidence to suggest that they were any better than the school which they replaced. This echoes James's earlier comment (1993) where she writes:

> The classic definition of the role of evaluation as providing information for decision makers … is a fiction if this is taken to mean that policy-makers who commission evaluations are expected to make rational decisions based on the best (valid and reliable) information available to them.
>
> (James, 1993, p. 119)

Where evaluations are commissioned and have heavily political implications, Stronach and Morris (1994) argue that the response to this is that evaluations become more 'conformative', possessing several characteristics:

1. short-term, taking project goals as given and supporting their realization;
2. ignoring the evaluation of longer-term learning outcomes, or anticipated economic/social consequences of the programme;
3. giving undue weight to the perceptions of programme participants who are responsible for the successful development and implementation of the programme; as a result, tending to 'over-report' change;
4. neglecting and 'under-reporting' the views of classroom practitioners and programme critics;
5. adopting an atheoretical approach, and generally regarding the aggregation of opinion as the determination of overall significance;
6. involving a tight contractual relationship with the programme sponsors that either disbars public reporting, or encourages self-censorship in order to protect future funding prospects;
7. undertaking various forms of implicit advocacy for the programme in its reporting style;
8. creating and reinforcing a professional schizophrenia in the research and evaluation community, whereby individuals come to hold divergent public and private opinions, or offer criticisms in general rather than in particular, or quietly develop 'academic' critiques which are at variance with their contractual evaluation activities, alternating between 'critical' and 'conformative' selves.

The points raised so far can apply to large-scale and small-scale projects. Hoyle (1986), for example, notes that evaluation data are used to bring resources into, or take resources out of, a department or faculty. In this respect the evaluator may have to choose carefully his or her affinities and allegiances (Barton, 2002), as the outcomes and consequences of the evaluation may call these into question. Barton writes that, although the evaluator may wish to remain passive and apolitical, in

reality this view is not shared by those who commission the evaluation or the reality of the situation, not least when the evaluation data are used in ways that distort the data or use them selectively to justify different options (p. 377).

The issue relates to both evaluations and research, as school-based research is often concerned more with finding out the most successful ways of organization, planning, teaching and assessment of a *given agenda* rather than *setting agendas* and following one's own research agendas. This is *problem solving* rather than *problem setting*. That evaluation and research are being drawn together by politics at both a macro- and micro-level is evidence of a continuing interventionism by politics into education, reinforcing the hegemony of the government in power.

Several points have been made so far:

- There is considerable overlap between evaluation and research;
- There are some conceptual differences between evaluation and research, though, in practice, there is considerable blurring of the edges of the differences between the two;
- The funding and control of research and research agendas often reflect the persuasions of political decision makers;
- Evaluative research has increased in response to categorical funding of research projects;
- The attention being given to, and utilization of, evaluation varies according to the consonance between the findings and their political attractiveness to political decision makers.

There is very considerable blurring of the edges between evaluation and research because of the political intrusion into, and use of, these two types of study. One response to this can be seen in Burgess's (1993a) view that a researcher needs to be able to meet the sponsor's requirements for evaluation whilst also generating research data (engaging the issues of the need to negotiate ownership of the data and intellectual property rights); for an example of this, see Garcia *et al*. (2014).

Research and politics are inextricably bound together. Researchers in education are advised to give serious consideration to the politics of their research enterprise and the ways in which politics can steer research (Hammersley, 2014). For example, one can detect a trend in educational research towards more evaluative research, where, for example, a researcher's task is to evaluate the effectiveness (often of the implementation) of given policies and projects. This is particularly true in the case of 'categorically funded' and commissioned research – research which is funded by policy makers (e.g. governments, fund-awarding bodies) under any number of different headings that those policy makers devise. On the one hand this is laudable, for it targets research directly towards policy (e.g. the 'what works' initiatives); on the other hand it is dangerous in that it enables others to set the research agenda. Research ceases to become open-ended, pure research and, instead, becomes the evaluation of *given* initiatives.

Evaluators may have the power to control the operation of the evaluation project and may influence the brief given, whilst the sponsor can only support but not control the independence of the evaluator. The issue of sponsoring research reaches beyond simply commissioning research towards the dissemination (or not) of research: who will receive or have access to the findings and how the findings will be used and reported. This, in turn, raises the fundamental issue of who owns and controls data, and who controls the release of research findings. Unfavourable reports might be withheld for a time, suppressed or selectively released. In other words, research can be brought into the service of wider educational purposes, for example, the politics of a local education authority, or indeed the politics of government agencies.

Though research and politics intertwine, the relationships between educational research, politics and policy making are complex because research designs strive to address a complex social reality (Anderson and Biddle, 1991). A piece of research does not feed simplistically or directly into a specific piece of policy making. Rather, research generates a range of different types of knowledge: concepts, propositions, explanations, theories, strategies, evidence and methodologies. These feed subtly and often indirectly into the decision-making process, providing, for example, direct inputs, general guidance, a scientific gloss, orienting perspectives, generalizations and new insights.

The degree of influence exerted by research depends on careful dissemination; too little and its message is ignored, too much and data overload confounds decision makers and makes them cynical – the syndrome of the boy who cried wolf (Knott and Wildavsky, 1991). Hence researchers must give care to utilization by policy makers (Weiss, 1991a), reduce jargon, provide summaries and improve links between the two cultures of researchers and policy makers (Cook, 1991) and, further, to the educational community. Researchers must cultivate ways of influencing policy, particularly when policy makers can simply ignore research findings, commission their own research (Cohen and Garet,

1991) or underfund research into social problems (Coleman, 1991; Thomas, 1991). Researchers must recognize their links with the power groups who decide policy. Research utilization takes many forms depending on its location in the process of policy making, for example, in research and development, problem solving, interactive and tactical models (Weiss, 1991b).

The impact of research on policy making depends on its degree of consonance with the political agendas of governments (Thomas, 1991) and policy makers anxious for their own political survival (Cook, 1991) and the promotion of their social programmes. Research is used if it is politically acceptable. That the impact of research on policy is intensely and inescapably political is a truism. Research too easily becomes simply an 'affirmatory text' which 'exonerates the system' (Wineburg, 1991) and is used by those who seek to hear in it only echoes of their own voices and wishes (Kogan and Atkin, 1991).

There is a significant tension between researchers and policy makers. The two parties have different, and often conflicting, interests, agendas, audiences, timescales, terminology and concern for topicality (Levin, 1991). These have huge implications for research styles. Policy makers anxious for the quick fix of superficial facts seek unequivocal data, short-term solutions and simple, clear remedies for complex and generalized social problems (Cartwright, 1991; Cook, 1991; Radford, 2008, p. 506; Cartwright and Hardie, 2012): the Simple Impact model (Biddle and Anderson, 1991; Weiss, 1991a, 1991b). Moreover, policy makers often find much research too uncertain in its effects (Kerlinger, 1991; Cohen and Garet, 1991), too unspecific and too complex in its designs, and of limited applicability (Finn, 1991). This, reply the researchers, misrepresents the nature of their work (Shavelson and Berliner, 1991) and belies the complex reality which they are trying to investigate (Blalock, 1991). Capturing social complexity and serving political utility can run counter to each other. As Radford (2008, p. 506) remarks, the work of researchers is often driven by objectivity and independence from, or disinterestedness in, ideology, whereas policy makers are driven by interests, ideologies and values.

The issue of the connection between research and politics – power and decision making – is complex. On another dimension, the notion that research is inherently a political act because it is part of the political processes of society has not been lost on researchers (cf. Hammersley, 2011, 2014), and this harks back to Chapter 3 in its discussion of value-neutrality and partisan research. Researchers cannot be blind to politics, just as politicians and decision makers should not be blind to research evidence and evaluation. As evaluation and research draw ever closer together it is prudent for researchers to reflect on Becker's (1967) rallying call for researchers to consider carefully 'whose side are we on'.

The search for causation

CHAPTER 6

This chapter introduces key issues in understanding causation in educational research. These include:

- causes and conditions
- causal inference and probabilistic causation
- causation, explanation, prediction and correlation
- causal over-determination
- the timing and scope of the cause and the effect
- causal direction, directness and indirectness
- establishing causation
- the role of action narratives in causation
- researching causes and effects
- researching the effects of causes
- researching the causes of effects

6.1 Introduction

Our brains seemed to be hard-wired to think causally, but, for educational researchers, tracing and using causality is challenging. Working with cause and effect, researchers must address the importance of being able to use educational research findings in the 'real world', that is, the world in which we have not isolated and controlled out a swathe of pertinent factors, or made so many assumptions and *ceteris paribus* get-out clauses (Kincaid, 2009) as to render the research of little or no value, or found effects which are wonderful in the sanitized, artificial world of the laboratory but useless in the 'real world' outside it (e.g. Cartwright and Hardie, 2012).

There is a wide vocabulary of causality in research, with many relevant words and phrases: for example, 'are caused by', 'influence' (verb and noun), 'attributed to', 'depend on', 'impact' (verb and noun), 'effect' (verb and noun), 'direction of the relationship', 'positive influence', 'positive impact', 'result' (verb and noun), 'mediation effect', 'effect of', 'due to', 'condition' (verb), 'leading to', 'consequences of', 'because of', 'affect', 'reason for', 'to force', 'driven', 'lead to' etc. Though the vocabulary is varied, the issue of demonstrating causality remains a challenge to researchers.

Educationists and social scientists are concerned not only for 'what works' but 'why', 'how', 'for whom' and 'under what conditions and circumstances'. They want to predict what will happen if such-and-such an intervention is introduced, and how and why it will produce a particular effect. This points us to an important feature of educational research, which is to look for causation: what are the effects of causes and what are the causes of effects? This is not a straightforward enterprise, not least because causation is often not observable but can only be inferred, and it is highly unlikely that indisputable causality is ever completely discoverable in the social sciences. At best probabilistic causation offers a more fitting characterization of causation in educational research. Causation is often considered to be the 'holy grail' of educational research, and this chapter introduces some key considerations in investigating causation.

6.2 Causes and conditions

Novice researchers are faced with many questions concerning causation in their research, for example:

- whether the research is seeking to establish causation, and if so, why;
- deciding when causation is demonstrated, recognizing that causation is never 100 per cent certain;
- deciding what constitutes a cause and what constitutes an effect;
- deciding what constitutes evidence of the cause and evidence of the effect;
- deciding the kind of research and the methodology of research needed if causation is to be investigated;
- deciding whether the research is investigating the cause of an effect, the effect of a cause, or both.

To infer simple, deterministic or regular causation may be to misread many situations, excepting, perhaps, those where massive single causation is clear. It may be more useful for the researcher to consider causal processes rather than single events (Salmon, 1998), not least because there is often more than a single cause at work in any effect and there may be more than one effect from a single cause. Indeed, the researcher has to

distinguish between causes, reasons, motives, determination and entailment, and whilst these might all exert causal force in some circumstances or enable us to make causal explanations or predictions, in other circumstances they do not.

What, then, makes a cause a cause, and an effect an effect? How do we know? Though we can say that causation takes places in a temporal sequence – the cause precedes the effect, and with temporal succession (Hume's criterion of 'priority'; Hume, 1955; Norton and Norton, 2000), this does not help the researcher very much.

One distinguishing indication that causation is taking place or has taken place is the presence of counterfactuals (Mackie, 1993), i.e. the determination that the absence of X (the supposed cause) would have led to the absence of Y (the effect); 'if X had not happened then Y would not have happened'. If we are seeking to establish that such-and-such is a contributing cause (X) of an effect (Y) we ask ourselves whether, if that supposed cause had not been present, then would the effect have occurred or been what it actually was; if the answer is 'no' then we can suppose that X is a true cause. For example, if there had been no ice on a path then I would not have fallen over and broken my arm. So the presence of ice must have been a contributing cause of the effect, one of many causes (e.g. my poor sense of balance, my poor eyesight in not seeing the ice, the ambient darkness, wearing slippery-soled shoes, brittle bones because of age etc.).

The counterfactual argument is persuasive, but problematical: how do we know, for example, what the outcome would have been if there had been no patch of ice on the path where I was walking? Can we predict with sufficient certainty to attribute counterfactual causality here? How can we prove that the effect would *not* have happened if a particular cause had not been present? How do we know that I would or would not have slipped and fallen if the ice had not been present? In true experiments this is addressed by having a control group: the control group is supposed to indicate what would have happened if the intervention had not occurred. The problem is that much research is not experimental.

If it were only the presence of ice that caused me to fall and break my arm, then this would be a very simple indication of causality; the problem is that the presence of ice in this instance is perhaps not a sufficient cause – had my balance been good, my eyesight good, the ambient light good, and if my shoes had had good grips on their soles and my bones were less brittle, then I would not have fallen and broken my arm.

The difficulty here also is to establish the role (if any) and relative strength of the causes in a multi-causal situation, i.e. the several conditions that, themselves, contribute to the accident. The presence of those causes that are included affects their relative strengths in a specific context, and the absence of some of these causes in the same context may raise or lower the relative strengths of others.

The example of falling on the ice also indicates an important feature of causation: causes cannot be taken in isolation, they may need to be taken together (compound causes, i.e. they only exert causative force when acting in concert), and there may be interaction effects between them. On its own, the patch of ice might not have caused my fall and broken arm; it was perhaps neither sufficient nor necessary, as I could have fallen and broken my arm anyway because of my slippery shoes and poor balance. On its own, my poor balance did not cause me to fall and break my arm. On its own, the darkness did not cause me to fall and break my arm. On their own, my slippery soles did not cause me to fall and break my arm. On their own, my brittle bones did not cause me to fall and break my arm. But put all these together and we have sufficient conditions to cause the accident. For the researcher, looking for individual causes in a contextualized situation may be futile.

In understanding the causes of effects, one has to understand the circumstances and conditions in which the two independent factors – the cause and the effect – are located and linked (the link is contingent rather than analytic). Discovering the circumstances – conditions – in which one variable causes an effect on another is vital in understanding causation, for it is the specific combination of necessary and/or sufficient conditions that may produce an effect. Causes of effects work in specific circumstances and situations, and account has to be taken of these circumstances and conditions.

For the researcher, the difficulty in unravelling the effects of causes and the causes of effects is heightened by the fact that causes may be indirect rather than direct (cause A causes effect B, and effect B causes effect C) or that they may only become a cause in the presence of other factors (I may fall over on ice and not break my arm if I am young and land well, but, as an older person with more brittle bones, I may land awkwardly and break my arm – the fall is not a sufficient condition or cause of my broken arm).

6.3 Causal inference and probabilistic causation

Identifying and understanding causation may be problematic for researchers, as effects may not be direct linear functions of causes, and because there may be few, many, increasing, reducing, unpredictable, i.e.

non-linear effects of causes (see Chapter 1 on complexity theory). A small cause can bring about a large or irregular effect (or, indeed, no effect, in the presence of other factors); a large cause may bring about a small or irregular effect (or, again, no effect, in the presence of other factors). Causation is often an inductive and empirical matter rather than a logical, deductive matter, and, indeed, it is often unclear what constitutes a cause and what constitutes an effect as these are often umbrella terms, under which are sub-causes and sub-effects, causal processes, causal chains, causal webs and causal links bringing several factors together both at a particular point in time (the moment of falling, in the example above) and in a temporal sequence.

Further, there is an asymmetry at work in causation effect – a cause can produce an effect but not vice versa: being young, good-looking and female may help me to pass my driving test if I am in the presence of a leering male examiner, but passing my driving test does not cause me to be young, good-looking and female.

It is often dangerous to say that such-and-such is *definitely* the cause of something, or that such-and-such is *definitely* the effect of something. Causation in the human sciences is much more tentative, and may be probabilistic rather than deterministic. Hume's (2000) own rules for causation are:

- contiguity (of space and time) (the cause is contiguous with the effect);
- priority/succession (the cause precedes the effect);
- constant conjunction (the coupling of one event and its successor are found to recur repeatedly);
- necessary connection (which is learned from experience, habit and custom rather than from deductive, logical, necessary proof).

One can detect correlation in Hume's ideas rather than actual causation. He argues that causation is inferred, inductively, by humans rather than being an objective matter. To try to gain some purchase on causality, Mill (2006) sets out five main approaches to establishing causality, and these are outlined below.

Mill's method of *agreement*: Let us say that in different regions of a country there are several combined educational reforms taking place, designed to increase student mobility (Table 6.1): (a) increased educational financing; (b) curriculum reforms; (c) providing more places in vocational training; and (d) introducing National Qualifications Frameworks (NQFs). We wish to see which of these factors is causing increased student mobility.

Mill's method of agreement here states that in all the cases where the effect occurs ('increased student mobility'), if there is only one factor common to all the cases then that factor is the cause. Here only one column ('Introducing the NQF') has all four factors present. Is it safe to conclude that, *ceteris paribus*, the NQF is the cause of the increased student mobility? Perhaps. If these were the only relevant factors in the situation then the conclusion might be safe, but, of course, it is not; the real situation includes far more factors. Mill's method is an over-simplification in the empirical world.

Mill's method of *difference*: Let us say that different regions of a country have several reforms taking place, designed to increase student mobility (Table 6.2). One region did not have an NQF, and this is the only factor where there is no increased student mobility. Is it safe to conclude that the NQF is the cause of the increased student mobility? Perhaps. As before, if these were the only relevant factors in the situation then the conclusion might be safe, but in the 'real' world of multiple factors, it is not.

Mill's method of *agreement and difference*: This applies both the preceding methods (Table 6.3) together. Here the method suggests that the NQF may be the cause of increased student mobility:

1 It could not be 'increased educational financing', as it is present where there is no 'increased student mobility' in region 1.

TABLE 6.1 MILL'S METHOD OF AGREEMENT

Region	*Increased educational financing*	*Curriculum reforms*	*More places for vocational training*	*Introducing the NQF*	*Increased student mobility*
Region 1	✓	✓	✓	✓	✓
Region 2	No	✓	No	✓	✓
Region 3	✓	No	No	✓	✓
Region 4	No	No	✓	✓	✓

TABLE 6.2 MILL'S METHOD OF DIFFERENCE

Region	*Increased educational financing*	*Curriculum reforms*	*More places for vocational training*	*Introducing the NQF*	*Increased student mobility*
Region 1	✓	✓	✓	No	No
Region 2	✓	✓	✓	✓	✓
Region 3	✓	✓	✓	✓	✓
Region 4	✓	✓	✓	✓	✓

TABLE 6.3 MILL'S METHOD OF AGREEMENT AND DIFFERENCE

Region	*Increased educational financing*	*Curriculum reforms*	*More places for vocational training*	*Introducing the NQF*	*Increased student mobility*
Region 1	✓	No	✓	No	No
Region 2	✓	✓	No	✓	✓
Region 3	✓	No	✓	✓	✓
Region 4	✓	✓	✓	✓	✓

2 It could not be 'curriculum reforms', as it is absent where there is 'increased student mobility'.
3 It could not be 'more places for vocational training', as it is absent where there is 'increased student mobility'.
4 This leaves NQF, which is the only item which is remaining when (1) to (3) above are taken into account.

As with the two previous cases, is it safe to conclude that the NQF is the cause of the increased student mobility? Perhaps. Again, if these were the only relevant factors in the situation then the conclusion might be safe, but in the 'real' world, it is not.

Mill's method of *concomitant variation*: If, across several factors, one finds that the property (e.g. the amount) of variation in Factor (A) is similar to, or the same as, the amount of variation in the effect (Factor (B)), whilst such common variation is not demonstrated in other independent variables, then it may be reasonable to infer that Factor (A) is the cause of Factor (B) (Table 6.4, matching the row entry for each cause with the effects on the same row). Table 6.4 indicates that the only concomitant variation between the independent and dependent variable ('increased student mobility') is for the variable 'introducing the NQF', suggesting that it is the NQF which might be causing the effect. Is it safe to conclude that the NQF is the cause of the increased student mobility? Perhaps. Again, if these were the only relevant factors in the situation then the conclusion might be safe, but in the 'real' world, it is not.

Mill's method of *residues*: If one is able to remove (e.g. control out) all the factors but one that may be causing all the effects but one, then the remaining factor is the cause of the remaining effect (Table 6.5).

Here, we have a range of possible causes and effects; we see that all the factors except 'introducing the NQF' are causing all the effects (those in the top row of Table 6.5) except one ('increased student mobility'). Hence we hold that it is 'introducing the NQF' which is the cause of 'increased student mobility'. Is it safe to conclude that the NQF is the cause of the increased student mobility? Perhaps. As with all the previous four methods from Mill, if these were the only relevant factors in the situation then the conclusion might be safe, but in the 'real' world, it is not.

Mill's methods are only as powerful as the factors included, and, in their search for the single cause, may overlook the interplay of myriad causes in producing the effect and, indeed, assume a deterministic rather than probabilistic view of causation (Kincaid, 2009). Further, Mill's approach to establishing causality in this instance operates at a single country level. Imagine,

TABLE 6.4 MILL'S METHOD OF CONCOMITANT VARIATION

Causes			*Effect*

Introducing the NQF	✓	✓	✓	✓

then, the additional complexity where his approach is applied to more than one country at a time; the problem expands exponentially in trying to detect the causal links between one factor and its putative effects. Nevertheless Mill's view has substantially informed more recent enterprises in working with causation, for example in the work of Ragin (1987, 2008).

Whilst statistical modellers may argue that it is possible to operate controls and to utilize structural equation modelling, these necessarily simplify the complex, dynamic, changing scenario of the relationship between the NQF, its instigator, its context and the multiple outcomes operating in a situation. It is impossible to isolate and control variables in a situation (cf. Cartwright

and Hardie, 2012); indeed the situation may rely on the dynamic interplay of these variables. This frustrates any easy attempts to utilize Mill's (2006) five main approaches to establishing causality.

Methods for establishing whether an effect is truly the result of a cause are beset with problems. Even if we observe outcomes, we cannot conclude with any certainty that these are unequivocally caused by the NQF in the example here. Even though probabilistic causality may replace deterministic causality, this does not attenuate the problem of deciding what is legitimate and illegitimate inference.

The inferential, conjectural and probabilistic nature of much causation in educational research (rather than being absolute, deductive and deterministic), coupled with the fact that causation is frequently unobservable, renders the study of causation challenging for educational researchers. Indeed there is a danger in isolating and focusing on singular causes separately from other contributing causes, contexts and conditions, and it is perhaps more fitting to regard causes as processes over time rather than single events. Further, in an interconnected world of multiple causes and causal nets, conditions and interactions may provide better accounts of causation than linear determinism (Morrison, 2012).

In unravelling causes and effects, the researcher is faced with the task of identifying what actually constitutes a cause and what constitutes an effect. The contexts and conditions of an event are as important as the trigger of an effect, and may be contributing causes. In the example earlier, my falling and breaking my arm was precipitated – triggered – by the ice on the path, but, without the presence of other contributing factors I might not have fallen and I might not have broken my arm. The trigger of the effect may not be its sole cause but only the last cause in a causal chain, sequence of events, series or network of conditions before the effect occurs, even though causes often raise the likelihood of their effects rather than guaranteeing them (Mellor, 1995, pp. 69–70). Indeed, whilst probability often concerns identifying *likelihood*, the strongest probability is not always the same as the strongest causation. I might think that putting pressure on a child to succeed has the strongest possibility of causing her success, but the actual cause might lie elsewhere, for example, the teacher might be very effective, the students might be highly motivated or the examination might be very easy.

6.4 Causation, explanation, prediction and correlation

The demonstration of causation is difficult. Causation is not the same as explanation (Clogg and Haritou, 1997, p. 106; Salmon, 1998, pp. 5–8) (e.g. an explanation may be wrong, or it may be giving the meaning of something, or it may be indicating how to do something). Nor is causation the same as giving a reason. For example, I might take a day off from work, giving the reason that I am sick, but the real reason may be simply that I am lazy or want to go shopping.

Nor is causation the same as prediction. Just because I observe something happening once does not mean I can predict that it will happen again (the problem of induction, see Chapter 1), as the conditions could be different, or, indeed, even if the conditions were very similar (as chaos theory tells us). I might be able to predict something even though my prediction is based on the wrong identification of causes, for example, I can predict that there will be a storm because I have observed the barometric reading falling, but the fall in the barometric reading does not cause the storm. Formally put, the two variables – the barometric reading and the storm – are 'screened off', separated and kept apart from each other (Reichenbach, 1956; Salmon, 1998). They have correlational but no causal relationships to each other, and are both caused by a third factor – the drop in air pressure (see Figure 6.1).

I might predict that a person's hands might be large if she has large feet, but having large hands does not cause her to have large feet – the cause might lie in a genetic predisposition to both. It is one thing to say that a change in one variable (A) is associated with a change in another variable (B); it is an entirely different thing to say that a change in one variable (A) *brings about* a change in another variable (B); and it is an entirely different thing again to say that a change in one variable (B) is brought about by a change in another variable (A), i.e. that it *is caused* by that change in variable A.

In attributing genuine causation, it is useful to 'screen off' unrelated dependent variables from the variables that are directly relevant to the situation being researched, i.e. to ensure that the effect of one variable is removed from the equation, to discount that variable or to control for the effects of other variables, for

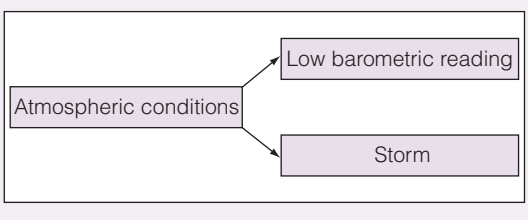

FIGURE 6.1 Two unrelated factors caused by a third factor

example, the presence of a third variable or several variables, by partial correlations. It is also important in screening off to ensure that one variable is not deemed to have an influence on another when, in fact, this is not the case. This presumes that it is actually possible to identify which factors to screen off from which. Pearl (2009, pp. 423–7) indicates how this can be approached; in the case of multiple causality (or in the cases of over-determination, discussed below), this may not be possible.

Screening off requires the ability to separate out causes, and this may be difficult to the point of impossibility. However, in seeking to establish genuine causation, the researcher must consider controlling for the effects of additional variables, be they prior/exogenous variables or intervening/endogenous variables, as these might exert a non-causal influence on the dependent variables.

In conducting research that seeks to attribute causation, it is important to control for the effects of variables, i.e. to hold them constant so that fair attribution of causality and the weight of causal variables can be assessed (though relative weights of causes are, strictly speaking, superfluous in discussing causation; they are questionable indicators of causation). Further, identifying the relative strengths of causes depends on the presence or absence of other causes. For example, in looking at examination success (the effect), if my research confines itself to looking at the relative strength of causes A (hours of study), B (IQ) and C (motivation) in producing the effect, I might find that C (motivation) is the strongest of the three causes. However, if I were to add a new variable (D) (an outstanding teacher helping the student), then it may be that D is the overriding cause and that A, B and C are of equally low strength, or that A becomes the second strongest factor.

Statistical tools such as crosstabulations, correlation and partial correlation, regression and multiple regression, and structural equation models (see Chapters 40–43) can be used to assist here in the analysis of causation, though it is often difficult to control direct, indirect, antecedent, intervening and combined influences of variables on outcomes (though statistical tools and graphical methods can assist here; Pearl, 2009, pp. 423–7).

In considering the control of variables, let us examine, for example, the subject choices of secondary school male and female students (Table 6.6).

Here we can see overwhelmingly that males choose physics far more than females, and females choose biology far more than males. The researcher wishes to know if the allocation of certain teachers to teach the secondary school science subjects affects the students' choice (i.e. whether it is the subject or the teacher, or some combination of these, that is causing the students to choose the subjects that they choose). The researcher introduces the third variable of the 'teacher' as a control variable, with two values: Teacher A and Teacher B, and then partitions the data for males and females according to either Teacher A or Teacher B (see Table 6.7).

TABLE 6.6 SCIENCE CHOICES OF SECONDARY SCHOOL MALES AND FEMALES

	Male	*Female*	*Total*
Preference for physics	175 (55.1%)	87 (27.9%)	262 (41.6% of total)
Preference for biology	143 (44.9%)	225 (72.1%)	368 (58.4% of total)
Column total	318 (100%)	312 (100%)	630
Percentage of total	50.5%	49.5%	100%

TABLE 6.7 SCIENCE CHOICES OF MALE AND FEMALE SECONDARY STUDENTS WITH TEACHER A OR B

	Males with Teacher A	*Females with Teacher A*	*Males with Teacher B*	*Females with Teacher B*	*Total*
Preference for physics	86 (55.8%)	44 (28.4%)	89 (54.3%)	43 (27.4%)	262 (62.5% of total)
Preference for biology	68 (44.2%)	111 (71.6%)	75 (45.7%)	114 (72.6%)	368 (37.5% of total)
Column total	154 (100%)	155 (100%)	164 (100%)	157 (100%)	630
Percentage of total	24.4%	24.6%	26.1%	24.9%	100%

When the data are partitioned by teacher (Teacher A and Teacher B) the researcher notes that the percentages in each of the partial tables (one part of the table for Teacher A and the other part of the table for Teacher B) in Table 6.7 are very similar to the original percentages of the root table (Table 6.6). She concludes that whether Teacher A or Teacher B is teaching the class makes no appreciable difference to the choices made by the students. The percentages in the new table (Table 6.7) replicate very closely those in the original (Table 6.6). The researcher concludes that the teacher involved is exerting no causal influence on the choice of subjects by the secondary school males and females.

However, let us imagine that the partial tables had yielded different data (Table 6.8). This time the results of the choices made by males and females who are with Teacher A and Teacher B are very different. The percentages in the new table (Table 6.8) are very different from those in the original (Table 6.6). This suggests to the researcher that, in this instance, the teacher of the class in question is making a causal difference to the choices of science subject made by the students.

However, this only tells us the 'what' of causation, or, to be more precise, it only gives us an indication of association and possible causation: it appears that the teacher makes no difference in Table 6.7 but *does* make a difference in Table 6.8. How this becomes a *causal* matter is another question altogether: how does the teacher *actually* affect the males' or females' choices of which science subject to follow. For example is it that: (a) Teacher A is male and Teacher B is female, and students tend to prefer to be with teachers of their own gender; (b) Teacher A has a better reputation than Teacher B for helping students to pass public examinations with high grades, and students are anxious to do well; (c) Teacher A is more sympathetic than Teacher B, so that students can relate more easily to Teacher A, and so they choose Teacher A; (d) Teacher A has a better sense of humour than Teacher B, and students prefer a good-humoured teacher; (e) Teacher A explains matters more clearly than Teacher B, and students prefer clear explanations, and so on. The point here is that, though one can deduce certain points from contingency tables and partial tables, they may not actually indicate causality. The same principle for holding variables constant, this time in correlational research, is discussed in Chapter 40.

In establishing causation, it is important to separate covariance and correlation between two unrelated and non-interacting dependent variables due to a common cause from the interaction of dependent variables due to the presence of a common cause (the examples of the barometer and the storm earlier).

6.5 Causal over-determination

It is rare to find a single cause of a single effect. It more often the case that there are several causes at work in a single situation and that these produce a multiplicity of effects (see the discussion of evaluation in Chapter 5, and the work of Pawson (2013) in that chapter). For example, why are so many young children well-behaved at school, when nobody has explicitly taught them the hidden curriculum (Jackson, 1968) of rules, regulations, taking turns, sharing, being quiet, knowing that the teacher is in charge and has all the power, putting up with delay, denial and only being one out of many children who has to gain the teacher's attention? One answer is over-determination: many events, both separately and in combination, lead to the same outcome – the young child must do as she is told, and having a nice time at school depends on how effectively she learns these rules and abides by them. Many causes; same effect: good behaviour.

Causal over-determination is 'where a particular effect is the outcome of more than one cause, each of which, in itself, would have been sufficient to have produced the effect' (Morrison, 2009, p. 51). A familiar example is the issue of which bullet can be said to have killed a man, which causes his death (Horwich, 1993),

TABLE 6.8 FURTHER SCIENCE CHOICES OF MALE AND FEMALE SECONDARY STUDENTS WITH TEACHER A OR B

	Boys with Teacher A	*Girls with Teacher A*	*Boys with Teacher B*	*Girls with Teacher B*	*Total*
Preference for physics	133 (56.8%)	55 (23.5%)	39 (46.4%)	35 (44.8%)	262 (62.5% of total)
Preference for biology	101 (43.2%)	179 (76.5%)	45 (53.6%)	43 (55.1%)	368 (37.5% of total)
Column total	234 (100%)	234 (100%)	84 (100%)	78 (100%)	630
Percentage of total	37.1%	37.1%	13.3%	12.5%	100%

if two bullets simultaneously strike a man's head. Either one bullet *or* the other caused the death (cf. Mellor, 1995, p. 102). Let us say that, in a study of homework and its effect on mathematics performance, a rise in homework might produce a rise in students' mathematics performance. However, this is not all: there may have been tremendous parental pressure on the child to do well in mathematics, or the student might have been promised a vast sum of money if her mathematics performance increased, or the school might have exerted huge pressure on the student to succeed, or the offer of a university place was contingent on a high mathematics score. The rise in mathematics performance may not have required all of the factors to have been present in order to bring about the effect; any one of them could have produced the effect. The effect is 'over-determined'. One effect may have one or several causes. Whilst this is commonplace, it is important to note this in order to refute claims frequently made by protagonists of such-and-such an intervention in education that it alone improves performance; if only it were that simple!

6.6 The timing and scope of the cause and the effect

Turn back to the earlier example of my falling on the ice and breaking my arm. Maybe I had a weakness in my arm from an injury many years before, and maybe when I injured my arm years before I could not have predicted that, many years later, I would have fallen on ice and broken my arm. The issue is not idle for researchers, for it requires them to consider, in terms of temporality, what are relevant causes and what to include and exclude from studies of causation, how far back in time to go in establishing causes and how far forward in time to go in establishing effects.

Just as the timing of causes may be unclear, so the timing of the effects of a cause may be unclear. Effects may be short-term only, delayed, instantaneous, immediate, cumulative and long-term; indeed the full effects of a cause may not be revealed in a single instance, as an effect may be a covering term for many effects that emerge over time (e.g. the onset and presenting of cancer has several stages; cancer is not a single event at one point in time). Temporality and causation are intimately connected but separate.

The examples above also indicate that terms such as 'cause' and 'effect' are, in many cases, shorthand for many sub-causes, sub-processes and sub-effects. Further, causes and effects may only reveal themselves over time, and, indeed, it may be difficult to indicate when a cause begins (which cigarette brought about the onset of cancer, or when did smoking first bring about the onset of cancer) or ends, and when an effect begins (e.g. I may continue smoking even after the early onset of lung cancer). I might hate studying mathematics at school but find it very attractive twenty years later; had my interest in mathematics been post-tested immediately I left school, the result would have been lower than if I had been tested twenty years later.

Where a cause begins and ends, where an effect begins and ends, when and how causes and effects should be measured, evaluated, ascertained and assessed, are often open questions, requiring educational researchers to clarify and justify their decisions on timings in isolating and investigating causes and effects. Quantitative data may be useful for identifying the 'what' of causation – what causes an effect – but qualitative data are pre-eminently useful for identifying the 'how' of causation – how causation actually works, the causal processes at work.

Consider, too, the reason for the ice patch being present on the path in the earlier example, and my being on the ice on the day in question. Maybe the local government services had not properly cleared the path of ice on that day, or maybe, as an ailing pensioner, I would normally be accompanied by a carer or an assistant whenever I went out, but on that day the person failed to turn up, so I was forced to go out on my own. Again, the issue is not idle for researchers, for it requires them to consider how widely or narrowly to cast their net in terms of looking for causes (how far out and how far in). In determining what are relevant causes, the researcher has to decide what to include and exclude from studies of causation, for example, from the psychological to the social, from the micro to the macro, and to decide the direction and combination of such causes.

The determination of a cause involves decisions on how far back to go in a temporal causal chain or network of events, and how wide or narrow to go in the causal space (how many conditions and circumstances contribute to the causation at work in a given situation). It may be difficult, if not impossible, to identify and include all the causal antecedents in a piece of research. Here the concepts of *necessary* and *sufficient* conditions are raised, as is the importance of identifying the causal trigger in a situation (the last cause in a causal chain or a linkage of several conditions). The striking of a match might cause it to flare, but that is not the only factor to be taken into account. Whether it flares depends on the abrasiveness of the striking surface, the materials used in the match, the dryness of the materials, the strength of the strike, the duration of the strike, the presence of sufficient oxygen in the atmosphere, and so on.

There may be an infinite number of causes and effects, depending on how far back one goes in time and how wide one goes in terms of contexts. This presents a problem of where to establish the 'cut-off' point in identifying causes of an effect. Whilst this may be addressed through the identification of necessary and sufficient conditions (Mackie, 1993) or the screening off of some 'ancestors' (antecedents) (Pearl, 2009), in fact this does little to attenuate the problem in social sciences, as not only is it problematic to identify what qualify as necessary or sufficient conditions, but these will vary from context to context, and even though there may be regularities of cause and effect from context to context, there are also differences from context to context.

The issue to be faced by researchers here is one of 'boundary conditions' and 'circumscription' (Pearl, 2009, p. 420): which factors we include or exclude can affect our judgements of causality. If, in a study of student performance, I only look at teacher behaviour and its influence on student performance then I might be led to believe that teacher behaviour is the cause of student performance, whereas if I only look at student motivation and its influence on student performance then I might be led to believe that student motivation is the cause of student performance. Researchers rarely, if ever, include the universe of conditions, but rather only a selection from that universe, and this might distort the judgements made about causation or where to look for causation. Whilst it may not be possible to identify the universe of conditions, the researcher has to be aware of the dangers of circularity, i.e. I am only interested in effect Y, so I only look at possible cause X, and then I find, unsurprisingly, that X is the cause of Y, simply because I have not considered alternatives. It is important to identify and justify the inclusion and exclusion of variables in researching causation, to select the field of focus sufficiently widely and to consider possible alternative explanations of cause and effect.

6.7 Causal direction, directness and indirectness

The problem of identifying causes and effects is further compounded by consideration of direct and indirect causes and effects and causal directions. Many models of causality often make too great a claim for unidirectionality rather than, for example, multi-directionality and mutual-directionality, or overlook clusters of causes that act together in multiple directions (Morrison, 2012).

Whilst the research may wish to identify the cause A that brings about the effect B, in practice this is seldom the case, as between A and B might be a huge number of intervening, prior or additional variables and processes operating, both exogenous and endogenous.

An exogenous variable is one whose values are determined outside the model (e.g. a structural equation model or a causal model) in which that variable is being used, or which is considered not to be caused by another variable in the model, or which is extraneous to the model.

An endogenous variable is one whose values or variations are explained by other variables within the model, or which is caused by one or more variables within the model. It is important to identify which causes mediate, and are mediated by, other causes. One also has to consider the role of moderators and mediator variables (the former influences the strength of a relationship between two variables, and the latter explains the relationship between two variables). How the researcher does this takes many forms, from theoretical modelling and testing of the model with data, to eliciting from participants what are the causes.

Whilst causation is not straightforward to demonstrate, this is not to suggest that establishing causation should not be attempted. There are regularities, likelihoods (probabilities) based on experience and previous research, and similarities between situations and people. Indeed the similarities may be stronger than the differences. This suggests that establishing probabilistic causation or inferring causation, whilst complex and daunting, may be possible for the researcher.

The problem for the researcher is to decide which variables to include, as the identification and inclusion/exclusion of relevant variables in determining causation is a major difficulty in research. Causes, like effects, might often be better regarded in conjunction with other causes, circumstances and conditions rather than in isolation (Morrison, 2009, 2012). Contextuality – the conditions in which the cause and effect take place – and the careful identification and inclusion of all relevant causes, are key factors in identifying causation.

6.8 Establishing causation

It is not easy to establish causation. For example, causation may be present but unobserved and indeed unobservable, particularly in the presence of stronger causes or impeding factors. I might take medication for a headache but the headache becomes worse; this is not to say that the medication has not worked, as the headache might have become even stronger without the medication. The effects of some causes may be masked by the presence or strength of others, but nonetheless causation may be occurring.

Morrison (2009, p. 45) gives an example where, in the case of the causal relationship between smoking (A), heart disease (B) and exercise (C), smoking (A) is highly correlated with exercise (C): smokers exercise much more than non-smokers. Though smoking causes heart disease, exercise actually is an even stronger preventative measure that one can take against heart disease. The corollary of this is that smoking prevents heart disease (cf. Hitchcock, 2002, p. 9).

The way in which the cause operates may also be unclear. There are many examples one can give here. Morrison (2009, p. 45), for instance, gives the example of small class teaching. In one class operating with small class teaching, the teacher in that class uses highly didactic, formal teaching with marked social distance between the teacher and the student (Factor A), and this is deemed to be an inhibitor of the beneficial effects of small class teaching on students' attainment in mathematics: didactic teaching reduces mathematics performance. However, the same highly didactic, formal class teaching (Factor A) significantly raises the amount of pressure placed on the students to achieve highly (Factor B), and this (Factor B) is known to be the *overriding* cause of any rise in students' performance in mathematics, for example, in small classes the teacher can monitor very closely the work of each child: high pressure raises mathematics performance. Now, it could be argued that Factor A – an ostensibly *inhibiting* factor for the benefits of small class teaching – actually causes *improvements* in mathematics performance in the small class teaching situation.

Another example is where greater examination pressure (A) on students increases their lack of self-confidence (C), but it also increases the student's hard work (B), and hard work reduces the student's lack of self-confidence (C). In other words, the likelihood of the effect of A on C may be lower than the effect of B on C, given A. Let us say that A increases the likelihood of C by 20 per cent, and A increases the likelihood of B by 35 per cent, whilst B reduces the likelihood of C by 75 per cent. In this instance increasing examination pressure increases the student's self-confidence rather than reduces it (see Figure 6.2).

The point here is that a cause might raise the likelihood of an effect, but it may also lower that likelihood, and the presence of other conditions or causes affects the likelihood of an effect of a cause. A diagrammatic representation of these examples is in Figure 6.2 (note that the length of the lines indicates the relative strength of the influence). A cause might lower the likelihood of an effect rather than increase it.

Many cause-and-effect models are premised on linear relationships between cause and effect (i.e. a regular relationship, e.g. a small cause has a regular small effect and a large cause has a regular large effect, or a small cause has a regular large effect and a large cause has a regular small effect). However, seeking linear relations between cause and effect might be misguided, as the effects of causes might be non-linear (e.g. a small or large cause may produce a large, small, irregular or no effect), and it might be to deal with singular or a few causes and singular or a few effects, overlooking the interrelatedness and interactions of multiple causes with each other, with multiple effects and indeed with the multiple interactions of multiple effects. Relationships and their analysis may be probabilistic, conditional and subjunctive rather than linear. Indeed nets and conditions of causation might be more fitting descriptions of causation than causal lines or chains of events or factors (Morrison, 2012).

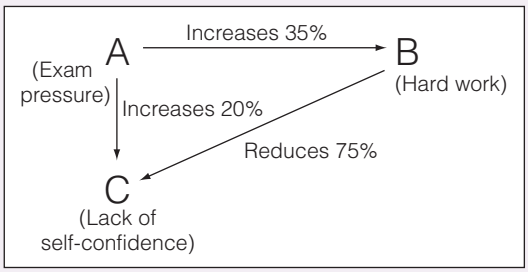

FIGURE 6.2 Positive and negative causes on an effect (1)

One way of focusing on a causal explanation is to examine regularities and then to consider rival explanations of causes and rival hypotheses of these regularities. The observation of regularities, however, is not essential to an understanding of causation, as all cases may be different but no less causative. Further, the best causal explanation is that which is founded on, and draws from, the most comprehensive theory (e.g. that theory which embraces intentionality, agency, interaction as well as structure, i.e. micro- and macro-factors), that explains all the elements of the phenomenon, that fits the *explanandum* (that which is to be explained) and data more fully than rival theories, and which is tested in contexts and with data other than those that have given rise to the theory and causal explanation.

Given the complexity of probabilistic causation, it would be invidious to suppose that a particular intervention will necessarily bring about the intended effect. Any cause or intervention is embedded in a web of other causes, contexts, conditions, circumstances and effects, and these can exert a mediating and altering influence between the cause and its effect.

6.9 The role of action narratives in causation

Statistics, both inferential and descriptive, can indicate powerful relationships. However, these do not necessarily establish unequivocal, direct causation; they may establish the 'what' of causation but not the 'how'. I might assume that A and B cause C, and that C causes D; it is a causal model, and I might measure the effects of A and B on C and the effect of C on D. However, causation here lies in the assumptions behind the model rather than in the statistical tests of the model, and the causal assumptions that lie behind the model derive from theory rather than the model itself (see Chapter 4). Statistics alone do not prove causation. Rather, causation is embodied in the theoretical underpinnings and assumptions that support the model, and the role of statistics is to confirm, challenge, extend and refine these underpinnings and assumptions. Behind statistics that may illuminate causation lie theories and models, and it is in the construct validity of these that causation lies. It is the *mechanisms* of causation – the how and why – that might concern researchers rather than solely numbers and statistical explanations – the what.

Many statistics rely on correlational analysis or on assumptions that pre-exist the statistics, i.e. the statistics might only reinforce existing assumptions and models rather than identify actual causation. Even sophisticated statistics such as structural equation modelling, multiple regression and multivariate analysis succumb to the charge of being no more powerful than the assumptions of causation underpinning them, and, indeed, they often grossly simplify the number or range of causes in a situation, in the pursuit of a simple, clear and easily identifiable model.

How is it that X causes Y; what is happening in X to cause Y? In short, what are the processes of causation? In order to understand this involves regarding causation as dynamic rather than static, as a process rather than a single event, and as involving motives, volitions, reasons, understandings, perceptions, individuality, conditions and context, and the dynamic and emerging interplay of factors, more often than not over time. It is here that qualitative data come into their own, for they 'get inside the head' of the actors in a situation.

A neat example of this is what has come to be known as 'the Rashomon effect' in social sciences (e.g. Roth and Mehta, 2002). It is over sixty-five years since Kurosawa's film *Rashomon* stunned audiences at the Venice Film Festival. It provides four discrepant witness accounts of the same event – an encounter between a samurai, his wife and a bandit, that led to the effect of the samurai's death – in which the causes could have been murder or suicide, consensual sex or rape, fidelity or infidelity. The causal accounts are given by a woodcutter, the bandit, the wife and the spirit of the dead samurai speaking through a medium. Each self-serving account protects the honour of the teller and tries to exonerate each. At the end, there is no clear statement of whose version is correct; truth flounders in the quagmire of epistemology, perception and motives.

Anthropologists, lawyers and social scientists (Roth and Mehta, 2002) seized on the film as an example of the multilayered, contested truth of any situation or its interpretation, coining the term 'the Rashomon effect' to describe an event or truth which is reported or explained in contradictory terms, that gives differing and incompatible causal accounts of an effect: a death. There is more than one causal explanation at work in a situation, and it is the task of the researcher to uncover these, and to examine the causation through the eyes of those imputing the causation.

Action narratives and agency are important in accounting for causation and effects, and, because there is a multiplicity of action narratives and individual motivations in a situation, there are multiple pathways of causation rather than simple input–output models. In understanding the processes of causation, the power of qualitative data is immense, and, indeed, mixed methods may be useful in establishing causation.

Causal explanations that dwell at the level of aggregate variables are incomplete, as behind them, and feeding into them, lie individuals' motives, values, goals and circumstances, and it is these that could be exerting the causal influence; hence a theory of individual motives may be required in understanding and explaining causation.

For example, it is commonplace for a survey to ask respondents to indicate their sex, but it is an entirely different matter – even if different responses are given by males and females to rating scales in a survey – to say that sex *causes* the differences in response. How, actually, is sex a causal factor? Similarly, does social class actually *cause* an effect? It is only a constructed aggregate, a sum of individual characteristics (cf. Kincaid, 2009).

Further, between aggregate independent and dependent variables of cause and effect respectively lie a whole range of causal processes, and these could be influencing the effect and, therefore, have to be taken into account in any causal explanation. How macro-structural features from society actually enter into individuals' actions and interactions, and how individuals' actions and interactions determine social structures – the causal processes involved – need cautious elucidation,

their current status often being opaque processes in a black-box, input–output model of causation.

6.10 Researching causes and effects

The researcher investigating the effects of a cause or the causes of an effect has many questions to answer, for example:

- What is the causal connection between the cause and the effect (how does the cause bring about the effect and how has the effect been brought about by the cause)?
- What are the causal processes at work in the situation being investigated?
- What constitutes the evidence of the causal connection?
- On what basis will the inference of causality be made?
- What constitutes the evidence that a cause is a cause and that an effect is an effect?
- What constitutes the evidence that a cause is the cause (and that there is not another cause) and that an effect is the effect (and that there is not another effect)?
- Is the research investigating the effects of a cause (an interventionist strategy) or the cause of an effect (a post hoc investigation)?
- How will the research separate out a range of possible causes and effects, and how will decisions be made to include and/or exclude possible causes and effects?
- What methodology will be chosen to examine the effects of causes?
- What methodology will be chosen to examine the causes of effects?
- What kind of data will establish probabilistic causation?
- When will the data be collected from which causation will be inferred?

As mentioned earlier, the timing of data collection is a critical feature in establishing causation and the effects of causes. Here the greater the need to establish causal processes, the closer and more frequent should be the data-collection points. Moreover, qualitative data could hold pre-eminence over quantitative methods in establishing causation and causal processes. Further, longitudinal studies might yield accounts of causation that are more robust than cross-sectional studies in which the necessary temporality of causation is built out in favour of the single instance of the data-collection point.

It is not enough to say *that* such-and-such a cause brings about such-and-such an effect, for, whilst it might establish the likelihood *that* the cause brings about an effect or that an effect has been brought about by a cause, this does not tell the researcher *how* the cause brings about the effect or how the effect has been brought about by the cause, i.e. what are the causal processes at work in connecting the cause with the effect and vice versa. If the research really wishes to investigate the processes of causation then this requires detailed, in-depth analysis of the connections between causes and effects.

For example, it is not enough to say that smoking can cause cancer; what is required is to know *how* smoking can cause cancer – what happens between the inhalation of smoke and the presentation of cancer cells. I might say that turning on a light switch causes the light bulb to shine, but this is inaccurate, as turning on the switch completes a circuit of electricity and the electricity causes a filament to heat up such that, when white hot, it emits light.

In education, it is not enough to say that increasing the time spent on reading causes students' reading to improve; that is naive. What might be required is to know how and why the increase in time devoted to reading improves reading. This opens up many possible causes: motivation; concentration levels and spans; interest level of the materials; empathy between the reader and the material; level of difficulty of the text; purposes of the reading (e.g. for pleasure, for information, for learning, for a test); reading abilities and skills in the reader; subject matter of the text; ambient noise; where, when and for how long the reading is done; prior discussion of, and preparation for, the reading material; follow-up to the reading; choice of reading materials; whether the reading is done individually or in groups; teacher help and support in the reading time; relatedness of the reading to other activities; the nature, contents and timing of the pre-test and post-test; the evidence of improvement (and improvement in which aspects of reading); and so on.

It can be seen in this example of reading that the simple input variable – increasing time for reading – may bring about an improvement in reading, but that may only be one of several causes of the improvement, or an umbrella term, or may liberate a range of other causes to come into play, both direct and indirect causes. Identifying the true cause(s) of an effect is extremely difficult to pin down.

Take, for example, the introduction of total quality management into schools. Here several interventions are introduced into a school for school improvement, and, at the next school inspection, the school is found

to have improved. The problem is trying to decide which intervention(s) has/have brought about the improvement, or which combinations of interventions have worked, or which interventions were counter-productive, and so on. It is akin to one going to the doctor about a digestion problem; the doctor prescribes six medicines and the digestion problem goes. Which medicine(s) was/were responsible for the cure, and in what combinations, or is it really the medicines that have brought about the cure; were there other factors that brought about the cure; would the digestion problem have cured itself naturally over time?

The researcher has to identify which cause (A) or combination of causes have brought about which effect (B), both intended and unintended, or whether the supposed cause (A) brought about another effect (C) which, in turn, became the cause of the effect (B) in question, and whether the effect (B) is really the consequence of the supposed cause(s) (A), and not the consequence of something else. What looks like being a simple cause-and-effect actually explodes into a multiplicity of causes and effects (Figure 6.3) (cf. Morrison, 2009, p. 124).

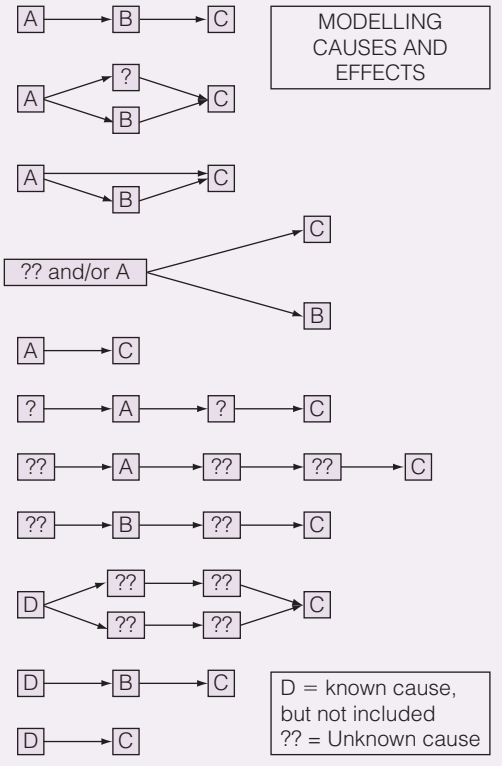

FIGURE 6.3 Positive and negative causes on an effect (2)

How, then, can the researcher proceed in trying to uncover causes and effects? A main principle underpinning how some researchers operate here is through *control*, isolating and controlling all the variables deemed to be at work in the situation. By such isolation and control, one can then manipulate one or more variables and see the difference that they make to the effect. If all the variables in a situation are controlled, and one of these is manipulated, and that changes the effect, then the researcher concludes that the effect is caused by the variable that has been manipulated. Moreover, if the research (e.g. an experiment) can be repeated, or if further data (e.g. survey data) are added, and the same findings are discovered, then this might give added weight to the inferred cause-and-effect connection (though regularity – Hume's (2000) 'constant conjunction' – is no requirement for causation to be demonstrated). This assumes that one has identified, isolated and controlled all the relevant variables, but, as the earlier part of this chapter has suggested, this may be impossible.

One way in which the problem of isolation and control of variables is addressed is through randomization – a key feature of the 'true' experiment (see Chapter 20). For example, random allocation of individuals to a control group or an experimental group is a widely used means of allowing for the many uncontrolled variables that are part of the make-up of the groups in question (Schneider *et al*., 2007). It adopts the *ceteris paribus* condition (all other things being equal) that assumes that these many other variables are evenly distributed across the groups, such that there is no need to control for them. This is a bold and perhaps dangerous assumption to make, not least as chaos and complexity theory tell us that small changes and differences can bring about major differences in outcome.

Whilst control is one prime means of trying to establish causation, it does raise several problems of the possibility, acceptability or manageability of isolating and controlling variables, of disturbing and distorting the real work of the participants, and of operating an undesirable – even unethical – control and manipulation of people. This is the world in which the researcher is king or queen and the participants are subjects – subjected to control and manipulation. On the one hand the claim is made that the research is 'objective', 'clean' (i.e. not affected by the particular factors within each participant), laboratory-based and not prone to bias; on the other hand it is a manipulative and perhaps unrealistic attempt to control a world that cannot in truth be controlled. Are there alternatives?

A major alternative is one that keeps the 'real' world of participants as undisturbed as possible, avoids the

researcher controlling the situation, and uses qualitative data to investigate causation. Here observational, interview and ethnographic methods come to the fore, and these are very powerful in addressing the *processes* of causation and in establishing the causes of an effect as recounted by the participants or the observers themselves. These methods deliberately 'get inside the heads' of individuals and groups, as well as including the researcher's own views, identifying and reporting causation in their terms. They provide considerable authenticity to the causal accounts given or compile a sufficiently detailed account of a situation for the researcher to make informed comments on the workings of causation in the situation under investigation. Further, it is often the participants themselves who identify what are the causes of effects in the situations being investigated (though the researcher would need to be assured that these are genuine, as participants may have reasons for not disclosing the real causes or motives in a situation or, indeed, may be mistaken).

These two approaches are not mutually exclusive in a piece of research, and, as Chapter 2 has indicated, there is an advantage in adopting a mixed methods approach, or, indeed, in a mixed methodology approach, in which positivist and experimental approaches might yield accounts of the 'what' of causation – which variables are operating to produce an effect – whilst an interpretive approach might be used to yield data on the 'how' and 'why' of causation – how the causal processes are actually working.

Researchers examining causes and effects have to decide whether they are researching the effects of causes (e.g. in which they introduce an intervention and see what happens as a consequence) or the causes of effects (e.g. backtracking from an observed situation to try to discover its causes). These are discussed below.

6.11 Researching the effects of causes

In trying to investigate the effects of one or more causes, the researcher can commence with a theory of causality operating in a situation (e.g. bringing pressure to bear on students causes them to work harder, or dropping out of school reduces income at age 50 by a factor of five, or improving self-esteem improves creativity), operationalize it, and then test it, eliminate rival theories and explanations using data other than those which gave rise to the explanation, and then proceed to the drawing and delimiting of conclusions. The use of continuous rather than categorical variables might be more effective in establishing the nature and extent of causation as they indicate the magnitude of causes and effects.

On the other hand, the researcher can proceed along an entirely different track, using qualitative research to really understand the causal processes at work in a situation and in the minds of the participants in that situation – the 'how' and 'why' of causation.

Determining the effects of causes is often undertaken using an interventionist strategy in educational research, installing an intervention either to test a hypothesized causal influence or a causal model, or because it is already known that it may exert a causal influence on effects, i.e. manipulating variables in order to produce effects. (Of course, a non-intervention may also be a cause, for example, I may cause a plant to die by not watering it, i.e. by doing nothing.)

Manipulation takes many forms, including:

- action research (discussed in Chapter 22), but this may raise questions of rigour brought about by a lack of controls and a lack of external checks such that the attribution of causation may be misplaced;
- a range of experimental approaches (discussed in Chapter 20), which assume, perhaps correctly or incorrectly, acceptably or unacceptably, that variables and people can be isolated, controlled and manipulated; and
- participant observation in qualitative research.

In addressing these approaches, however, serious attention has to be paid to a range of issues:

- the context of the intervention and the power of the situation could affect the outcomes and behaviours of participants (the Hawthorne effect or the Lucifer effect (Zimbardo, 2007a));
- the same causes do not always produce the same effects, even with the same people;
- inappropriate timing of the pre-test and post-test measurements of effects could undermine the reliability of the statement of the effects of the cause;
- there are problems of accuracy and reliability, as groups and individuals cannot both be in a group that is and is not receiving an intervention (Holland's (1986, p. 947) 'fundamental problem of causal inference', which may not be sufficiently attenuated by randomization) (see Chapter 20);
- process variables and factors, and not only input variables, as these feature in understanding causation;
- the characteristics, personae and specific individual features of participants and their agency, as these influence interventions and their effects.

Experimental techniques, particularly randomized controlled trials (RCT), have some potency in establishing

causation, and it is here that the identification, isolation and control of independent variables is undertaken, manipulating one independent variable to see if it makes a difference to the outcome. The other variables are held constant and, if a change of outcome is found by manipulating the one independent variable, then the change can be attributed to that independent variable (it becomes the cause), as the other variables have been held constant, i.e. their influence has been ruled out.

In experimental approaches, randomization is an important element in determining causation in order to overcome the myriad range of variables present in, and operating in, participants (the *ceteris paribus* condition discussed earlier), to overcome within-group and between-group differences (cf. Fisher's *The Design of Experiments* (1966)). RCTs and experiments (see Chapter 20) are an example of interventionist approaches that seek to establish the effects of causes by introducing one or more interventions into a situation and observing the outcomes of these under controlled conditions.

However, RCTs are often not possible in education and, indeed, are not immune to criticism. For example, the assumptions on which they are founded may be suspect (e.g. over-simplifying the variables at work in a situation, and overriding the influence of mediating or process variables). They may have limited generalizability (Cartwright and Hardie, 2012) and the measures used in RCTs focus on average results rather than outliers or important sub-sample differences. They frequently do not establish the causal processes or causal chains that obtain in the situation. They neglect participants' motives and motivations. They neglect the context in which the action is located, and they might neglect the moral agency of participants and the ethics of researchers. Indeed context can exert a more powerful causal force than the initial causal intervention, as evidenced in the examples of the Stanford Prison Experiment and the Milgram experiments on obedience (see Chapters 7 and 30).

Caution must be exercised in supposing that RCTs, for some people the epitome of causal manipulation in the determination of the effects of causes, will yield sufficient evidence of causation, as these overlook the significance of context and conditions, of processes, of human intentionality, motives and agency, over-determination etc., in short, of the contiguous causal connections between the intervention and its putative effects. Indeed even the issue of when and whether an effect has an effect (short-term to long-term, immediate or delayed) is problematic, and attention had to be given to effects that have been caused by the intervention other than those in which the researcher might be initially interested. For example, a researcher might find that pressuring students to learn improves their mathematics scores but leads to an enduring dislike of mathematics.

In the context of moves towards judging 'what works', deciding 'what works' is as much a matter of values and judgement as it is of empirical outcomes of causation. Success is a value judgement, not simply a measure or a matter of performance. Judging 'what works' in terms of cause and effect is an incomplete analysis of the situation under investigation. A more fitting question should be 'what works for whom, under what conditions, according to what criteria, with what ethical justifiability, and with what consequences for participants?'

A range of issues in judging the reliability and validity of experimental approaches in establishing causation includes the acceptability of laboratory experiments that are divorced from the 'real world' of multiple human behaviours and actions. Here field experiments and natural experiments (see Chapter 20) may attenuate the difficulties posed by laboratory experiments, though these, too, may also create their own problems of reliability and validity.

As an alternative to action research and experimental methods in determining effects from causes, observational approaches can be used, employing both participant and non-participant approaches (see Chapter 26). Whilst these can catch human intentionality, agency and perceptions of causality and events more fully than experimental methods, nevertheless they encounter the same difficulty as action research and experiments, as they, too, have to provide accounts of causal processes and causal chains. Further, in addressing intentionality and agency in causal processes and chains, it is also possible that, whilst perceptions might be correct, they might also be fallacious, partial, incomplete, selective, blind and misinformed. I might think that there is a mouse in the room (a cause), and act on the basis of this (an effect), but, in fact, there may be no mouse at all in the room.

Interventionist approaches, and the determination of the effects of causes, risk mixing perception with fact, and, regardless of evidence, human inclinations may be to judge data and situations on the basis of personal perceptions and opinions that, indeed, may fly in the face of evidence (the 'base rate fallacy'; Morrison, 2009, pp. 170–1; see also Kahneman, 2012). This is only one source of unreliability, and it is important to consider carefully what actually are the effects of causes rather than jumping to statements of causation based on premature evidence of connections.

6.12 Researching the causes of effects

Determining the causes of effects is even more provisional, tentative and inferential than determining the effects of causes, as data are incomplete and backtracking along causal chains and/or searching within causal nets is difficult, as it requires a search for clues and testing rival hypotheses about causation. It is possible to generate a huge number of potential causes of observed effects, and the problem is in deciding which one(s) is/are correct. Morrison (2009) suggests that one approach which can be adopted in tracing causes from effects is *ex post facto* research (see Chapter 20), but it poses challenges in the sometime inability to control and manipulate independent variables or to establish randomization in the sample. Another approach is to adopt a seven-stage process of tracing causes from effect, thus:

Stage 1: Establish exactly what has to be explained.
Stage 2: Set out possible theoretical foundations for the investigation.
Stage 3: Examine, evaluate and eliminate rival theoretical foundations, selecting the most fitting.
Stage 4: Hypothesize a causal explanation on the basis of the best theoretical foundation.
Stage 5: Set out the assumptions underlying the causal explanation.
Stage 6: Test the causal hypotheses empirically.
Stage 7: Draw conclusions based on the test.

A worked example is provided here, from Goldthorpe (2007). Goldthorpe seeks to explain the causes of 'persistent differentials in educational attainment' despite increased educational expansion, provision and uptake across the class structure (p. 21), i.e. in the context of increased educational opportunity and its putative weakening influence on class-based determination of life chances. He proceeds in the seven stages indicated above. Only after that test does he provide a causal explanation for his observed effects.

Stage 1: Establish what it is that has to be explained

First, Goldthorpe observes some 'regularities' (effects) (2007, p. 45):

a In all economically advanced societies there has been an expansion over time of education provision and in the numbers of students staying on in full-time education beyond the minimum schooling age (e.g. going into higher education).

b At the same time, class differentials in educational attainment have remained stubbornly stable and resistant to change, i.e. though students from all classes have participated in expanded education, class origins and their relationship to the likelihood of them staying on in education or entering higher education has only reduced slightly, if at all, and this applies to most societies.

He is establishing social regularities that any causal and theoretical account should seek to explain: the creation, persistence and continued existence of class stratification in modern societies, and the continuing class-relatedness of educational inequality and life chances (p. 24).

Stage 2: Set out possible theoretical foundations for the investigation

Goldthorpe's work is premised on the view that theories are necessary to provide explanatory foundations for how established regularities come to be as they are (2007, p. 21). He initially suggests four theoretical foundations: Marxist theory, liberal theory, cultural theory and rational choice theory.

Stage 3: Examine, evaluate and eliminate rival theoretical foundations

For several reasons which he gives (2007, pp. 22–34), Goldthorpe rejects the first three of these and argues that rational choice theory provides a fitting theoretical foundation for his investigation of the causes of the effects observed (pp. 34–41). True to rational action theory, Goldthorpe places emphasis on aspirations, in particular noting their relative rather than their absolute status, that is to say, aspirations are relative to class position, as working-class aspirations may not be the same as those of other classes (p. 31). Different social classes have different levels and kinds of aspiration, influenced – as rational action theory suggests – by the constraints under which they operate, and the perceived costs and benefits that obtain when making decisions (p. 32). Taking *relative* rather than absolute views of aspiration enables accounts to be given that include the fact of increased provision of, and participation in, education by students from all social classes, i.e. class differentials have not widened as education provision and participation have widened.

Goldthorpe (2007, p. 32) suggests that cultural theory may account for what Boudon (1973) terms 'primary effects', i.e. initial levels of achievement and ability in the early stages of schooling. However, he is more concerned with Boudon's 'secondary effects',

i.e. those effects which come into play when children reach 'branching points' (transition points, e.g. from primary to secondary schooling, from secondary education to university) (p. 32) and which have increasingly powerful effects as one progresses through schooling. 'Secondary effects' take account of the aspirations and values that children and their parents hold for education, success and life options, i.e. the intentionality and agency of rational action theory in a way that 'primary effects' do not. Goldthorpe notes that, at each successive 'branching point' (p. 32), children from more advantaged backgrounds remain in the educational system and those from less advantaged backgrounds either leave school or choose courses that lead to lower qualifications (hence reducing their opportunities for yet further education).

Goldthorpe (2007, p. 33) argues that more ambitious options may be regarded less favourably by those from less advantaged class backgrounds as they involve: (a) greater risk of failure; (b) greater cost; and (c) relatively less benefit. In other words, the level of aspiration may vary according to class and the associated levels of assessed cost and risk by members of different classes, and children from less advantaged backgrounds have to be more ambitious than those from more advantaged backgrounds if they are to meet the aspirations and success levels of those from more advantaged backgrounds. Class origins influence risk assessment, cost assessment and benefit assessment – all aspects that are embraced in rational action theory. These determine the choices made by children and their parents.

Stage 4: Hypothesize a causal explanation on the basis of the best theoretical foundation

Goldthorpe (2007, p. 34) argues that class differentials in educational attainment have persisted because, even though there has been expansion and reform of education, and even though the overall costs and benefits that are associated with having more ambitious options have encouraged their take-up, in practice there has been little concurrent change in the 'relativities between *class-specific* balances': different classes view the costs, risks and benefits differently (p. 34). This is his working hypothesis in trying to establish cause from effect.

Stage 5: Set out the assumptions underlying the causal explanation

Goldthorpe tests his theory by drawing initial attention to the ongoing income differentials between classes; indeed he argues that they have widened (2007, p. 35), with manual labourers more prone to unemployment than professional or managerial workers, i.e. the costs of education are still a factor for less advantaged families, particularly at the end of the period of compulsory schooling. At the time when their children come to the end of compulsory schooling, the income of manual workers will already have peaked (e.g. when they are in their forties), whereas for professional and managerial workers it will still be rising, i.e. costs are more of a problem for manual workers than for professional and managerial workers, i.e. the costs of higher education relative to income, and the consequent effects on family lifestyle if families are having to finance higher education, are much higher for manual workers. This increased proportion of family income to be spent on education for less advantaged families is coupled with the fact that, if children from these families are to succeed, then they need even more ambition than their professional and managerial class counterparts, i.e. they are at a potential double disadvantage, i.e. relative advantage and disadvantage are not disturbed, a feature on which liberal theory is silent (p. 36).

Goldthorpe makes the point that class position conditions educational decisions made by members of different classes. These different class positions influence different evaluations of the costs and benefits of education, and these are socially reproductive, i.e. the social class position is undisturbed.

Another element of his argument concerns risk aversion. His view is that a major concern of members of different classes is to minimize their risk of downward class mobility, and to maximize their chances for upward class mobility or, at least, to maintain their existing class location (p. 37). This exerts greater pressure on the already-advantaged classes (e.g. the salariat) to have their children complete higher education (in order to preserve intergenerational class stability) than it does on the children from less advantaged classes (e.g. the waged). It costs more for the children of the advantaged classes to preserve their class position than it does for children of the less advantaged classes to preserve theirs.

With regard to families in the less advantaged classes, Goldthorpe (p. 38) suggests that they regard higher education much more guardedly. Not only does it cost less for them to maintain their class position, but it costs relatively more to achieve upward class mobility; their best options might be for vocational education, as it is cheaper and gives a strong guarantee of *not* moving downwards in class situation (e.g. to be unemployed or unskilled).

Further, for children in this class, the costs (and likelihood) of failure in higher education could be

proportionately greater than those for children from more advantaged families. For example, in terms of: the relative costs of the higher education; lost earning time; lost opportunity to follow a vocational route in which they have greater likelihood of being successful (p. 38); loss of social solidarity if working-class children pursue higher education, the consequences of which may be to remove them from their class origin and community (pp. 38–9). These factors combine to suggest that children and families from less advantaged backgrounds will require a greater assurance, or expectation, of success in higher education before committing themselves to it than is the case for children and families from more advantaged backgrounds (p. 68).

Goldthorpe then offers his causal explanation of the effects observed: the persistence of class differentials in educational attainment despite expansion of educational provision and participation (p. 39):

1. Class differentials in the uptake of more ambitious educational options remain because the conditions also remain in which the perceived costs and benefits of these options operate, and these lead to children from less advantaged families generally requiring a greater assurance of success than children from more advantaged families before they (the former) pursue more ambitious educational options;
2. There is a rational explanation for the persistence of these different considerations of ambitious options by class over time, which is rooted in class-based conditions.

These are the two main hypotheses that he seeks to test.

Stage 6: Test the hypotheses empirically

Goldthorpe (2007) then proceeds to test his two hypotheses (pp. 39–44, 53–6, and his chapters 3 and 4), adducing evidence concerning several factors, for example:

- the greater sensitivity of working-class families to the chances of success and failure in comparison to middle-class families (p. 40);
- different levels of ambition in working-class and middle-class families (p. 40);
- relative (class-based) risk aversion in decision making: for example, the risk of failure and/or of closing options (pp. 55–6);
- the loss of forgone earnings (pp. 53–5);
- expectations of success (pp. 55–6);
- evaluation of the potential benefits, value and utility of higher education (pp. 38–9);
- influences on choices and decision making in different classes (his chapter 3);
- actual choices made by members of different classes;
- fear of downward social mobility (pp. 53–4);
- the need to preserve, or improve on, intergenerational mobility (pp. 53–4);
- financial costs (p. 56).

He indicates that students from lower socio-economic groups either cannot afford, or cannot afford to take risks in, higher education, and he identifies three clusters of possible explanations of persistence of class differentials in educational attainment, including (but not limited to):

Cluster 1: Differences in aspirations and decisions are caused by perceptions of costs: (a) loss of earnings during study time (a bigger drawback for families and students from low-income households than for those from privileged backgrounds); (b) students from low-income households have to work harder than privileged students in order to compete with them; (c) students from low-income households must have greater ambition than privileged students in order to be successful in a higher social class; (d) the financial costs of higher education, proportional to income, are higher for less advantaged students than for more advantaged students and families.

Cluster 2: Differences in aspiration and decisions are caused by relative risk aversion: (a) the risk of failure in higher education is greater for students from disadvantaged classes; (b) the risk of loss of further educational opportunities if failure ensues or incorrect options are followed is greater for students from disadvantaged classes than for students from more privileged classes; (c) the risk of loss of social solidarity is greater for students from working-class groups than for students from more privileged classes; (d) less advantaged students must have greater ambition than privileged students in order to be successful in higher social classes.

Cluster 3: Differences in aspiration and decisions are caused by perceptions of relative benefit: (a) the opportunity for upward social mobility through higher education is an attraction for students from lower-class backgrounds; (b) higher education is differentially necessary for preferred or likely employment for those from privileged and less privileged groups.

Stage 7: Draw conclusions based on the test

Goldthorpe (2007) indicates that class differentials have continued to affect the take-up of educational options. He finds that class differentials in terms of the take-up of more ambitious educational options have

been maintained because so too have the conditions in which the perceived costs and benefits of these options lead to children from less advantaged families requiring, on average, a greater assurance of success than their more advantaged counterparts before they decide to pursue such options. There are class differences in terms of relative ambition, risk aversion, perceived costs and benefits, amounts of effort required, assurances of success (and the significance of this), fear of downward social mobility, income, occupational choices and the need for qualifications.

He concludes that the results of empirical tests support his explanation of the factors of relative risk aversion and fear of downward social mobility exerting causal power on educational decision making which, in turn, lead to class differentials in educational attainment being maintained (p. 99).

Goldthorpe argues that this hypothesis is better supported than alternative hypotheses (e.g. educational choices being predetermined by culture, class identity and the class structure).

This lengthy example here offers a robust account of how to track backwards from an effect to a cause and how to evaluate the likelihood that the putative cause of the effect actually is the cause of that effect. In summary, for researchers seeking to establish the causes of effects, the task has several aspects:

- Indicate what needs to be done to test the theory and to falsify it.
- Identify the kinds of data required for the theory to be tested.
- Identify the actual data required to test the theory.
- Identify the test conditions and criteria.
- Construct the empirical test.
- Consider the use of primary and secondary data.
- Consider using existing published evidence as part of the empirical test.
- Ensure that action narratives and intentionality are included in causal accounts.

The fundamental problem in determining causes from effects is the uncertainty that surrounds the status of the putative cause; it can only ever be the best to date, and the researcher does not know if it is the best in absolute terms. One effect stems from many causes, and to try to unravel and support hypotheses about these may present immense difficulties for the researcher. Morrison (2009, p. 204) suggests that there are several ways in which causes may be inferred from effects:

- recognizing that a high level of detail may be required in order to establish causation: high granularity;
- identifying several causal chains, mechanisms and processes in a situation;
- combining micro- and macro-levels of analysis;
- addressing both agency and structure;
- underpinning the data analysis and causal explanation with theory;
- using different kinds of ex post facto analysis;
- using correlational and causal-comparative, criterion group analysis;
- ensuring matching of groups in samples and that similar causes apply to both groups;
- adopting the seven-stage process set out above, of generation, testing and elimination of hypotheses and rival hypotheses;
- ensuring clarity on the direction of causation;
- using empirical data to test the causal explanation;
- identifying which is cause and which is effect, and/or which effect then, subsequently, becomes a cause;
- avoiding the problem of over-selective data;
- ensuring that the data fairly represent the phenomenon under investigation;
- recognizing that cause and effect may be blurred;
- accepting that effects may become causes in a cyclical sequence of causation;
- seeking out and recognizing over-determination at work in causal accounts;
- keeping separate the explanans (the explanation) from the explanandum (that which is to be explained);
- ensuring that alternative theories and causal explanations are explored and tested;
- drawing conclusions based on the evidence, and the evidence alone.

In seeking to establish the causes of effects, there is a need to review and test rival causal theories and to retain those with the greatest explanatory potential and which fit the evidence most comprehensively and securely. Testing rival hypotheses must be done with data that are different from those that gave rise to the hypotheses, in order to avoid circularity.

The determination of causes from effects does not have the luxury afforded to causal manipulation in determining effects of causes. Whilst this renders the determination of causes from effects more intractable, nevertheless this is not to say that it cannot be attempted or achieved, only that it is difficult.

Morrison (2009) argues that, in seeking to identify the causes of effects, there is a need for a theoretical foundation to inform causal explanation. Possible causal explanations should be evaluated against rival theories and rival explanations, being operationalized

in considerable detail (high granularity), and tested against data that are different from those that gave rise to the causal explanation. Causal explanations should link micro- and macro-factors, include agency and intentionality as well as structural constraints, and contain a level of detail that is sufficiently high in granularity to explain the phenomenon to be explained without concealing or swamping the main points with detail overload, i.e. the researcher must be able to distinguish the wood from the trees.

The companion website to the book presents a fully worked example of working with a range of challenges in causality, for example, counterfactuals, 'before-and-after' comparisons, multiple causes, over-determination, causal forks, preceding causes, causal links, causal direction and what can and cannot be inferred about causality. We advise readers to look at that in-depth worked example.

6.13 Conclusion

In approaching causal research, then, the researcher is faced with a range of challenges, including, for example:

- focusing more on causal processes than input/output/results models of causation;
- establishing causation other than through reduction and recombination of atomistic, individual items and elements;
- regarding causation as the understanding of the emergent history of a phenomenon or a whole;
- investigating multiple and simultaneous causes and their multiple and simultaneous effects in a multiply connected and networked world;
- separating causation from predictability, and drawing the boundaries of predictability for an understanding of the frequent uniqueness of a causal sequence, which may not be repeatable, i.e. living with uncertainty and unpredictability;
- learning to work with causation in a situation in which randomness often 'trumps' causation (cf. Gorard, 2001a, p. 21);
- indicating the utility of understanding causation if it has little subsequent predictive strength;
- understanding how to investigate causation in holistic webs of connections, i.e. how is it possible to discover or demonstrate causation when looking at events holistically;
- understanding causation and causal processes in a multi-causal, multi-effect, non-linear and multiply connected world;
- identifying the causal processes at work in determining social and macro-structures from the actions and interaction of individuals (the micro-worlds) and, conversely, in determining the actions and interactions of individuals from the structures of society and its institutions (the macro-worlds), their ontologies and epistemologies.

The researcher has to decide whether the research is investigating the cause of an effect, the effect of a cause, or both, and when causation is demonstrated, given that absolute certainty is illusory. If one is investigating the effects of causes then the methodologies and approaches to be used might include experiments, action research, survey analysis, observational approaches or a combination of these (and indeed others). If one is investigating the causes of effects then, in the context of the likelihood of greater uncertainty than in establishing the causes of effects, one can employ numerical and qualitative data in backtracking from effects to causes and in testing hypothesized causes of effects. In all of these approaches, this chapter has suggested that probabilistic rather than deterministic causation is a more fitting description of the nature of the conclusions reached. It has suggested that, even if it sounds simplistic at first, nevertheless it is both important yet difficult to establish what actually constitutes a cause and an effect. The chapter has suggested that causal processes, with high granularity, are often closer to identifying the operations of causes and effects and the links between them, and that here qualitative data might hold pre-eminence in educational research. However, the chapter has also suggested that there is an important role for numerical approaches, for examining the 'regularities' that might be evidenced in survey approaches, and in the isolation and control of variables in experimental approaches. In short, the chapter is arguing for the power of mixed methodologies and mixed methods in investigating and establishing causation.

None of the preceding discussion takes us very far from the difficulty in actually defining causation. Is it, like time, space, existence, not defined in terms of previously defined concepts, hence is a 'primitive concept', irreducible to anything else?

The companion website to the book provides additional material and PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: www.routledge.com/cw/cohen.

Part 2
Research design

The planning of educational research is not an arbitrary matter; the research itself is an inescapably ethical enterprise. Nor are the planning and conduct of educational research simply a matter of cranking out recipes and following them. On the contrary, educational research is a deliberative and reflexive exercise. We place ethical issues at a very early point in the book to signal this. The research community and those using the findings have a right to expect that research is conducted rigorously, scrupulously and in an ethically defensible manner. This is thrown into sharp relief with the rise in online research, and we discuss this in a new chapter. All this necessitates careful planning, and this part introduces some key design and planning issues. It contains chapters on how to choose a research project and a comprehensive set of considerations in the design and planning of educational research, including ensuring that the research provides warrants for interpreting data and drawing conclusions. This part includes another entirely new chapter on research questions and hypotheses. The entire part contains a wide range of worked examples.

In designing research, we need to consider the issues of how to choose a research project, how to plan it, how to conduct a literature search and review, and how to ensure that the project is practicable. This part suggests several ways that researchers can approach the choice of a research project, and comments on the need for the project to be significant (and what this means), to consider its purposes and intended outcomes, feasibility, research questions, literature review and overall design.

This part also provides an augmented chapter on sampling issues, with attention to statistical power. Sampling, reliability and validity are key matters in research; without due attention to these the research could turn out to be worthless. Hence this part addresses these issues in detail. These are complex matters, and we take readers through them systematically. The chapter on sensitive educational research is included here, to underline the point that not only is the very decision to conduct research a sensitive matter, but that often access itself is difficult and sensitive, and this could be the major issue to be faced in planning research. This part sets out a range of planning possibilities so that the eventual selection of sampling procedures, together with decisions on reliability and validity, are made on the basis of *fitness for purpose*, and so that sensitivities in research are anticipated and addressed.

The ethics of educational and social research

CHAPTER 7

7.1 Introduction

Ethics concerns that which is good and bad, right and wrong. Ethical research concerns what researchers ought and ought not to do in their research and research behaviour. A cursory glance at recent literature throws up a vast field of issues in considering ethics in educational research, for example:

- informed consent;
- confidentiality and anonymity;
- identification and non-traceability;
- non-maleficence;
- beneficence and duty of care;
- responsibilities (for what and to whom);
- gaining access;
- overt and covert research;
- disclosure and public versus private knowledge and spaces;
- relationships and differential power relations in research;
- interests at stake in the research (in whose interests the research is operating);
- rights, permissions and protections;
- ownership and control of data;
- access to data (and its archiving);
- the roles and power of research sponsors and commissioners;
- sensitive research;
- gender, age, colour, (dis)ability and ethnicity issues;
- researching with children;
- avoidance of selective, partisan and skewed data analysis;
- value positions in data interpretation;
- responsibilities to different parties;
- being judgemental.

Each of these, in turn, raises many questions and considerations and we introduce them in this chapter. There are rarely easy, 'black-and-white' decisions on ethical matters. Rather, researchers must take informed decisions on a case-by-case basis. Codes of practice, ethical guidelines, ethics committees and institutional review boards, legislation, regulations and regulatory frameworks may raise issues for consideration and provide advice for researchers on what to do and not to do. However, ethical issues are rarely as straightforward as rule-following would suggest, and it is for individuals to take responsibility for the decisions that they take on ethical matters and the actions connected with those decisions (Brooks *et al*., 2014, p. 153).

Ethical decisions are contextually situated – socially, politically, institutionally, culturally, personally – and each piece of research raises ethical issues and dilemmas for the researcher. Ethical norms vary in different parts of the world, and what is acceptable in a western culture may not apply elsewhere. Ethical issues are not a once-and-for-all matter which can be decided before the research commences or when the proposal is put to an ethics committee, and then forgotten (cf. Brooks *et al*., 2014, p. 154); rather, they run throughout the entire research process. For example, Wax (1982, p. 42) makes the telling point that informed consent in many kinds of research is not a 'one-shot, once-and-for-all' affair, but has to be continuously negotiated, particularly in qualitative, emergent research. Ethics are present at every turn, and we indicate key issues to be faced at each stage.

What starts as being an apparently straightforward ethical matter quickly raises non-straightforward ethical decisions for the researcher. Each research undertaking is an event *sui generis*, and the conduct of researchers cannot be, indeed should not be, forced into a procrustean system of ethics. When it comes to the resolution of a specific moral problem, each situation frequently offers a spectrum of possibilities. Ethics are 'situated', i.e. they have to be interpreted in specific, local situations (Simons and Usher, 2000).

Each stage in the research sequence raises ethical issues. Sikes (2006) notes that ethics touch 'researchers and their research choices, research topics, methodologies and methods, and writing styles' (p. 106). Ethical issues may arise from the nature of the research project itself; the context for the research; the procedures to be adopted (e.g. creating anxiety); methods of data collection (e.g. covert observation); the nature of the

participants; the type of data collected (e.g. personal and sensitive information); what is to be done with the data (e.g. publishing in a manner that may cause participants embarrassment or harm); and reporting the data (e.g. in a way that the participants will understand) (Oliver, 2003, p. 17).

How, then, can the researcher, particularly the novice researcher, begin to address the scope of ethical issues? One way is to follow the stages of research, from initial considerations to research planning, choice of topic, design, methodologies, data collection, data analysis, interpretation, to reporting and dissemination, and this is how the chapter is organized. We review issues in the ethical field in the sequence in which they may be encountered in planning, conducting, reporting and disseminating research:

- ethical principles and the nature of ethics in educational research;
- sponsored research;
- regulatory contexts of ethics: codes of practice, ethical review boards and ethics committees, legislation, ethical frameworks and guidelines;
- choice of research topic and research design;
- ethical dilemmas in planning research: informed consent, non-maleficence, beneficence and human dignity, privacy, anonymity, confidentiality, betrayal and deception;
- gaining access and acceptance into the research setting;
- power and position;
- reciprocity;
- ethics in data analysis;
- ethics in reporting and dissemination;
- responsibilities to sponsors, authors and the research community.

These are intended to guide the reader through a maze of ethical concerns in educational research, and the foundations on which they are built. The chapter provides practical examples of ethics considerations.

7.2 Ethical principles and the nature of ethics in educational research

Ethics has been defined as 'a matter of principled sensitivity to the rights of others' (Cavan, 1977, p. 810). Educational researchers must take into account the effects of the research on participants; they have a responsibility to participants to act in such a way as to preserve their dignity as human beings. Ethical decisions are built on ethical principles, but different ethical principles may conflict with each other, and we explore this below.

Ethical problems in educational research can often result from thoughtlessness, oversight or taking matters for granted. A student whose research is part of a course requirement and who is motivated wholly by self-interest, or academic researchers with professional advancement in mind, may overlook the 'oughts' and 'ought nots'. It is unethical for the researcher to be incompetent in the area of research. Competence may require training (Ticehurst and Veal, 2000, p. 55). Indeed an ethical piece of research must demonstrate rigour and quality in the design, conduct, analysis and reporting of the research (Morrison, 1996b).

Kimmel (1988) has pointed out that it is important we recognize that the distinction between ethical and unethical behaviour is not dichotomous, even though the normative code of prescribed ('ought') and proscribed ('ought not') behaviours, as represented by the ethical standards of a profession, seem to imply that it is. Judgements about ethics lie on a *continuum* that ranges from the clearly ethical to the clearly unethical. The point here is that ethical principles are not absolute, generally speaking (though some may maintain otherwise), but must be interpreted in the light of the research context and of other values at stake.

Whilst many of the issues addressed in this chapter concern procedural ethics, ethics concerns right and wrong, good and bad, and so procedural ethics may not be enough; one has to consider how the research purposes, design, contents, methods, reporting and outcomes abide by ethical principles and practices.

A *deontological* view of ethics concerns what one has a duty or obligation to undertake, what ought to be done, i.e. there are universalizable 'categorical imperatives' (Kant's phrase) to behave in certain ways and not to behave in other ways (prescriptive and prohibitive respectively), which override the consequences of such actions. These are universalizable in the sense that it should apply to all persons, and categorical in that they must be obeyed without exception. This view involves treating people as ends in themselves – with equal respect, dignity and value – rather than as means (Howe and Moses, 1999, p. 22). As Brooks *et al*. (2014, p. 23) remark, the deontological view requires us to treat others as we would wish others to treat us, regardless of their personal characteristics, status or backgrounds. This extends to considerations such as: do no harm and do prevent harm (non-maleficence); do good (beneficence); be honest; be sincere; be grateful. We discuss these issues in detail later in the chapter.

By contrast, a *consequentialist* view of ethics concerns the outcomes of actions, for example, the utilitarian view that ethical behaviour is that which produces the greatest good (and happiness) for the greatest

number. This replaces the deontological emphasis on unexceptionable rules and what is always right with a focus on consequences. In this view a costs–benefits analysis is considered, but this is problematical, as (a) it is unclear which costs and which benefits should be factored into the analysis, and it assumes that all costs and all benefits are of the same strength (Howe and Moses, 1999, p. 23); and (b) there is disagreement on what constitutes goodness and happiness, how it will be calculated and who decides. Brooks *et al*. (2014) note that rights-based ethics concern people's liberty, and these trump consequential ethics.

From the consequentialist position, a major ethical dilemma is that which requires researchers to strike a balance between the demands placed on them as professional scientists in pursuit of truth, and the participants' rights and values potentially threatened by the research. This is known as the 'costs/benefits ratio', the essence of which is outlined by Frankfort-Nachmias and Nachmias (1992) in Box 7.1.

Deontological and consequentialist views of ethics concern actions and behaviour. By contrast, a third view is a *virtue ethics* basis which concerns people, and in which one pursues what is good simply because it is what is expected of a good and right person: 'what kind of person we ought to be' (Brooks *et al*., 2014, p. 24). A virtuous person might possess characteristics including loyalty, integrity, respect, sincerity, modesty etc., i.e. virtues. Views of what the virtues are, and what the virtuous person is, may vary by time, place, culture, society etc. For the researcher, Hammersley and Traianou (2012) identify key virtues of dedication, objectivity and independence (respecting academic freedom, professionalism and minimizing negative influences on the research) (pp. 46–51) in the disinterested pursuit of knowledge. Marshall and Rossman (2016, p. 51) note that virtue ethics concern relationships, and researchers have to consider their relationships with participants, stakeholders, sponsors, the research community, individuals, groups, the institution and so on – a complexity of relationships (cf. Ary *et al*., 2002).

These different views of ethics may not sit comfortably together; for example, a utilitarian view might argue that a person who has a healthy body and healthy organs should be killed, and his organs used to save five or six lives of those who otherwise would die, whereas a virtue ethics viewpoint (Hammersley, 2009, p. 213) would argue that this is murder and cannot be justified. Another example of values clashing is where a deontological view might argue that a failing school should be closed, whereas a utilitarian view would argue against its closure because those 2,000 students would go to an even worse school.

A source of tension in considering ethics is that generated by the competing absolutist and relativist positions. The absolutist view holds that clear, set principles should guide the researchers in their work and that these should determine what ought and what ought not to be done (see Box 7.2). To have taken a wholly absolutist stance, for example, in the case of the Stanford Prison Experiment (see Chapter 30), where the researchers studied interpersonal dynamics in a simulated prison, would have meant that the experiment should not have taken place at all or that it should have been terminated well before the sixth day. Indeed Zimbardo (1973), the author of the Stanford Prison Experiment, has stated that the absolutist ethical position, in which it is unjustified to induce any human suffering, would bring about the end of much research, regardless of its possible benefits to

BOX 7.1 THE COSTS/BENEFITS RATIO

The *costs/benefits ratio* is a fundamental concept expressing the primary ethical dilemma in social research. In planning their proposed research, social scientists have to consider the likely social benefits of their endeavours against the personal costs to the individuals taking part. Possible benefits accruing from the research may take the form of crucial findings leading to significant advances in theoretical and applied knowledge. Failure to do the research may cost society the advantages of the research findings and ultimately the opportunity to improve the human condition. The costs to participants may include affronts to dignity, embarrassment, loss of trust in social relations, loss of autonomy and self-determination, and lowered self-esteem. On the other hand, the benefits to participants could take the form of satisfaction in having made a contribution to science and a greater personal understanding of the research area under scrutiny. The process of balancing benefits against possible costs is chiefly a subjective one and not at all easy. There are few or no absolutes and researchers have to make decisions about research content and procedures in accordance with professional and personal values. This costs/benefits *ratio* is the basic dilemma residual in a great deal of social research.

BOX 7.2 ABSOLUTE ETHICAL PRINCIPLES IN SOCIAL RESEARCH

Ethics embody individual and communal codes of conduct based upon a set of explicit or implicit principles and which may be abstract and impersonal or concrete and personal. Ethics can be 'absolute' and 'relative'. When behaviour is guided by absolute ethical standards, a higher-order moral principle is invoked which does not vary with regard to the situation in hand. Such absolutist ethics permit no degree of freedom for ends to justify means or for any beneficial or positive outcomes to justify occasions where the principle is suspended, altered or diluted, i.e. there are no special or extenuating circumstances which can be considered as justifying a departure from, or modification to, the ethical standard.

Source: Adapted from Zimbardo (1984)

society. In other words, ethical absolutism over-constrains research (Hammersley and Traianou, 2012, p. 138); let not the perfect stand in the way of the good or the 'good enough'.

By an absolute principle, the Stanford Prison Experiment must be regarded as unethical because the participants suffered considerably. In absolutist principles a deontological model of research is governed, inter alia, by universal precepts such as justice, honesty and respect. In the utilitarian ethics, ethical research is judged in terms of its consequences, for example, increased knowledge, benefit for many.

Those who hold a relativist position would argue that there can be no absolute guidelines and that ethical considerations will arise from the very nature of the particular research being pursued at the time: the situation determines behaviour. Indeed they would argue that it is essential to respect the context in which the research takes place, culturally, ethnically, socio-economically, and that these should be judged in their own terms (Oliver, 2003, p. 53). This underlines the significance of 'situated ethics' (Simons and Usher, 2000; Hammersley, 2015b), where overall guidelines may offer little help when confronted with a very specific situation. From the standpoint of *situational ethics* (e.g. Simons and Usher, 2000; Oliver, 2003; Hammersley and Traianou, 2012; Hammersley, 2015b), what we should do or what is right to do depends on the situation in question, i.e. judging what to do cannot simply be determined, calculated or logically derived from principles but has to be decided in respect of the presenting situation (i.e. 'bottom-up' rather than 'top-down'): ethical principles *inform* but do not simplistically *determine*. However, this could be challenged on the grounds that it sanctions relativist ethics over absolutist principles.

There are some contexts where neither the absolutist nor the relativist position is clear-cut. Writing of the application of the principle of informed consent with respect to life history studies, Plummer (1983) says:

> Both sides have a weakness. If, for instance, as the absolutists usually insist, there should be informed consent, it may leave relatively privileged groups under-researched (since they will say 'no') and underprivileged groups over-researched (they have nothing to lose and say 'yes' in hope). If the individual conscience is the guide, as the relativists insist, the door is wide open for the unscrupulous – even immoral – researcher.
>
> (Plummer, 1983, p. 141)

He suggests that broad guidelines laid down by professional bodies which afford the researcher room for personal ethical choice offer some way out of the problem. We consider these later in this chapter.

Whilst ethical research concerns principled behaviour, as we will see in this chapter, it is often the case that the research draws on different ethical principles when considering a specific situation, i.e. ethics are situated.

7.3 Sponsored research

Sponsored research does not absolve the researcher from ethical behaviour. For example, it may be considered unethical for the sponsor to control the research or to tell the researcher: (a) how to conduct the research; (b) what results he/she should look for and what findings should be suppressed; (c) what should and should not be reported; (d) to conceal who the sponsor is; and (e) what are the purposes of the research (e.g. Hammersley and Traianou, 2012).

Sponsors may have the right to remain confidential; they may have the right to non-disclosure of who they are and the purposes and findings of the research. Further, researchers will need to consider the effects on the participants of any disclosure of who the sponsors are; for example, if they are told that the research is sponsored by a government office, how will that affect what they say and do?

Sponsors may be oriented towards certain kinds of research, for example that which is related to government policy or which has immediate or direct practical concerns or consequences, and this may suppress 'critical' or sensitive research and prefer user-friendly, policy-affirmative research, or it may exert pressure for a particular style of research to be conducted (e.g. randomized controlled trials) or quantitative research. Sponsors may wish to define the research topic, its limits and how it can or should be done, thereby rendering researchers the instruments of the sponsor. Whilst sponsored research is usually contractual between the researcher and the sponsor, and between the researcher and the participants, and whilst the research may be for the sponsor alone and not for the public, this does not privilege the sponsor in dictating how the research should be conducted and what it should find; in short, 'fixing' the study.

The researcher's responsibilities may lie only in conducting the study and providing the sponsor with a report. What happens to the report after that (e.g. whether it is released completely, selectively or not at all to the public or other parties within the sponsor's organization) is a matter for the sponsor. However, this does not absolve the researcher from decisions about the conduct of the study, and the researcher must retain the right to conduct the study as she or he thinks fit, informed by, but not decided by, the sponsor. The researcher's integrity must be absolute. It is often the case that researchers will negotiate (a) publication rights with the sponsor in advance of the research and (b) what confidentiality the researcher must respect.

The sponsor has a right to expect high-quality, rigorous and useable research. The researcher should not succumb to pressure to:

- betray the confidentiality of the respondents;
- tamper with data, their analysis or presentation to meet a particular objective;
- present selective and unrepresentative data and conclusions;
- make recommendations that do not arise from the data themselves;
- use the data for non-negotiated personal interests, agendas, purposes and advancement;
- conduct a study in which personal research objectives influence the nature, contents and conduct of the research.

The researcher has obligations to the sponsor, but not to doctor or compromise the research. Research is not the same as consultancy in that the researcher may be able to publish from the research (often with due attention to agreed confidentiality and non-traceability etc.) and the researcher owns the research, not the sponsor.

7.4 Regulatory contexts of ethics

Regulatory contexts of ethics have risen massively in influence. There have been moves from guidelines and codes of ethics which advise and inform the professional integrity of researchers and research to regulations, regulatory frameworks and increasing power and legalism to govern, control and police them in a litigious age ('ethics creep') (Haggerty, 2004).

Codes of practice, institutional review boards, university ethics committees, legislation, ethical frameworks and guidelines exist to oversee research in universities and other institutions and can constitute a major hurdle for those planning to undertake research. Ethical codes of the professional bodies and associations as well as the personal ethics of individual researchers are all important regulatory mechanisms. They have a 'gatekeeping' function, to prevent unethical research from taking place, to ensure that no harm comes to participants, and to ensure that due attention has been given by research proposers to the ethical dimensions of their research: for example, risk assessment; acceptable and unacceptable burdens on people and institutions; benefit to different parties; informed consent; confidentiality, non-traceability, privacy, disclosure and protections; control of data; beneficence and non-maleficence; appropriacy of methodology etc.

The celebrated Belmont Report (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, 1979) picks out three key ethical principles that codes of ethics are designed to protect: respect for persons, beneficence and justice (e.g. participants are not denied access to potentially beneficial interventions); as seen below, these are echoed by many organizations. Hammersley and Traianou (2012) identify key principles as: minimization of harm; respect for autonomy (and informed consent); and the protection of privacy (addressing confidentiality and anonymity) (discussed later in this chapter).

Ethical codes of practice are designed to protect the interests of individuals and institutions, to ensure suitably informed consent and to ensure that the proposed research abides by legal requirements and does not violate ethical principles. They address adherence to data protection laws, including that: (a) data will only be used in the way intended by the research and are important for, rather than superfluous to, the research; (b) data are kept securely and only for

as long as necessary; and (c) control and ownership of data are clear, with suitable attention to anonymity (Denscombe, 2014, pp. 319–20).

Professional societies and associations have formulated codes of practice which express the consensus of values within a particular group and which help individual researchers in indicating what is desirable and what is to be avoided. Of course, this does not solve all problems, for there are few absolutes and ethical principles may be open to a wide range of interpretations.

Researchers must take cognizance of ethical codes and regulations governing their practice. Failure to meet these responsibilities on the part of researchers is perceived as undermining the scientific process and may lead to legal and financial penalties and liabilities for individuals and institutions.

Brooks *et al*. (2014) note a distinction between 'foundational principles' and 'practical implications' that have been addressed in regulations, legislation and ethical review boards. The former concerns respect for persons, justice, beneficence and non-maleficence, whilst the latter concerns risk assessment, informed consent, benefits and selection of participants and projects (pp. 27–32). The authors analyse several published research guidelines and codes of practice from research associations, review boards, research sponsors and governments across the world, and note some recurrent ethics matters in them (pp. 30–1), presented here in alphabetical order:

- academic freedom;
- accountability;
- adherence to scientific standards;
- beneficence and non-maleficence (personal and social);
- compliance with the law;
- concern for welfare;
- confidentiality;
- democracy;
- duty of care;
- fairness;
- full information;
- honesty;
- impartiality;
- independence;
- integrity;
- justice;
- objectivity;
- professional competence;
- quality of research;
- reliability;
- respect for persons, including rights, dignity and diversity;
- responsibility (e.g. social, professional, personal) to researchers and others;
- voluntary participation.

Further, in an increasingly information-rich world, it is essential that safeguards be established to protect research information from misuse or abuse. The UK's Data Protection Acts of 1984 and 1998 are designed to achieve such an end. These cover principles of data protection, responsibilities of data users and rights of data subjects. Data held for 'historical and research' purposes are exempted from the principle, which gives individuals the right of access to personal data about themselves, provided the data are not made available in a form which identifies individuals. Such research data may be held indefinitely and their use for research purposes need not be disclosed at the time of data collection, notwithstanding the Freedom of Information Acts which may give the public access rights to data. Personal data (i.e. data that uniquely identify the person supplying them) shall be held only for specified and lawful purposes, and appropriate security measures shall be taken against unauthorized access to, or alteration, disclosure or destruction of, personal data and against accidental loss or destruction of personal data.

Regulatory contexts also include organizations which set legally binding regulations. For example, the United Nations Convention on the Rights of the Child (UNICEF, 1989) sets out fifty-four Articles which are legally binding standards in the fields of, inter alia: non-discrimination; development of full potential; respect for children, their dignity and their views; acting in the interests of the child; protection from harm; active and voluntary participation; and voice. These include statements that place the interests of the child as the primary consideration (Article 3.1), that the child is assured of the right to express his/her own views in matters that affect him/her and that these will be accorded due weight (Article 12.1) and that the child's freedom of expression is protected, including the freedom to 'seek, receive and impart information and ideas' in any media that the child chooses, regardless of frontiers (Article 13.1).

Echoing this, the United Nations Children's Fund (UNICEF) (Graham *et al.*, 2013) produced a wide-ranging document on *Ethical Research Involving Children* which recognizes the cultural location of research (p. 13) and places relationships 'at the core of ethical research' (p. 13). Its key principles are respect, benefit and justice, with their implications for considerations of harm and benefits (non-maleficence and beneficence), informed consent, privacy, confidentiality and payment. Its 'charter' (p. 23) includes seven key statements:

1. Ethics in research involving children is everyone's responsibility.
2. Respecting the dignity of children is core to ethical research.
3. Research involving children must be just and equitable.
4. Ethical research benefits children.
5. Children should never be harmed by their participation in research.
6. Research must always obtain children's informed and ongoing consent.
7. Ethical research requires ongoing reflection.

(Graham *et al.*, 2013, p. 23)

Many institutions of higher education have their own ethics committees, with their own codes of ethics against which they evaluate research proposals. In addition, some important codes of practice and ethical guidelines are published by research associations, for example the British Educational Research Association, the British Psychological Society, the British Sociological Association, the Social Research Association, the American Educational Research Association, the American Psychological Association and the American Sociological Association. We advise readers to consult these in detail.

The British Educational Research Association's (2011) *Ethical Guidelines for Educational Research* are devolved onto:

- *Principles*: 'all educational research shall be conducted within an ethic of respect for: the person; knowledge; democratic values; the quality of educational research; academic freedom' (p. 4).
- *Guidelines*: these address: (a) responsibilities to participants (including sections on: voluntary informed consent; openness and disclosure; rights to withdraw; children, vulnerable young people and vulnerable adults; incentives; detriment arising from participation in research; privacy; disclosure); (b) responsibilities to sponsors of research (including methods and publication); (c) responsibilities to the community of educational researchers (including sections on misconduct and authorship); and (d) responsibilities to educational professionals, policy makers and the general public.

Hammersley and Traianou (2012), writing for the British Educational Research Association, set out five ethical *principles*: minimizing harm; respecting autonomy; protecting privacy; offering reciprocity; and treating people equitably. In light of these principles they raise several issues (pp. 4–12): full and free informed consent; ethical regulation; the gravity of the ethical issues; conflicts between the ethical principles, between different interpretations of them, and how to resolve these differences; having to work with different stakeholders and groups simultaneously; the thrust towards worthwhile research; and situated ethics and judgements (pp. 4–6).

Hammersley and Traianou also include a comprehensive bibliography of many aspects of, and topics in, educational research: diverse perspectives; randomized controlled trials and experimental research; survey research; action research; researching children; Internet research; visual research; narrative and discourse analysis; relationships with funders; anonymity; archiving of data; data protection; philosophical literature on ethics (including feminist ethics and radical approaches); and literature on ethical regulation (with extensive websites). This is an extremely useful reference document, with multiple website references.

The American Educational Research Association's (2011) *Code of Ethics* is organized into principles and ethical standards:

- *Principles*: professional competence; integrity; professional, scientific and scholarly responsibility; respect for people's rights, dignity and diversity; and social responsibility.
- *Ethical standards*: scientific, scholarly and professional standards; competence; use and misuse of expertise; fabrication, falsification and plagiarism; avoiding harm; non-discrimination; non-exploitation; harassment; employment decisions; conflicts of interest; public communications; confidentiality (including privacy and electronic data storage and communication); informed consent (including deception); research planning, implementation and dissemination; authorship credit; publication process; responsibilities of reviewers; teaching, training and administering education programmes; mentoring; supervision; contractual and consulting services; and adherence to the ethical standards of the American Educational Research Association.

These standards run right through the entire research process, from planning to dissemination.

The UK's Economic and Social Research Council's (2015) research ethics framework sets out six key principles:

1. Research participants should take part voluntarily, free from any coercion or undue influence, and their rights, dignity and (when possible) autonomy should be respected and appropriately protected.

2 Research should be worthwhile and provide value that outweighs any risk or harm. Researchers should aim to maximise the benefit of the research and minimise potential risks of harm to participants and researchers. All potential risk and harm should be mitigated by robust precautions.
3 Research staff and participants should be given appropriate information about the purpose, methods and intended uses of the research, what their participation in the research entails and what risks, benefits, if any, are involved.
4 Individual research participant and group preferences regarding anonymity should be respected and participant requirements concerning the confidential nature of information and personal data should be respected.
5 Research should be designed, reviewed and undertaken to ensure recognised standards of integrity are met, and quality and transparency are assured.
6 The independence of research should be clear, and any conflicts of interest or partiality should be explicit.

(Economic and Social Research Council, 2015, p. 4)

One can note here the use of the word 'should', i.e. it has the power of an injunction, a demand (Hammersley and Traianou, 2012, p. 7). The document then provides comprehensive coverage of eleven *minimum requirements* informed by these principles, included in which is the role of Research Ethics Committees to 'protect the dignity, rights and welfare of research participants' (p. 14). The document sets out: (a) a definition of risk and how to approach risk assessment (pp. 27–9); (b) key issues in considering voluntary informed consent (pp. 29–33); and (c) issues to be addressed in an ethics review (pp. 38–9). Further, it carries an extensive list of relevant organizations and their publications on research ethics (pp. 45–9). This is a comprehensive document with useful advice to researchers in considering ethical matters.

It is important to note the references to 'principles' in these documents. Hammersley (2015c) argues that the inclusion of principles (e.g. 'general considerations') (p. 435) is helpful, as: (a) it overcomes the risk that ethics codes and guidelines could become outdated with advances coming on apace in research methodologies and topics; (b) they facilitate agreement among researchers about essential matters; (c) being at a high level of abstraction, they are likely to be inclusive of most research projects (though such abstraction might lend itself to varying interpretation); and (d) they avoid too tight a level of prescription which often encourages researchers 'to follow the letter rather than the spirit of ethical codes' (p. 434).

On the other hand, Hammersley raises the argument that principles may be 'too determinate' and prescriptive in the force of their injunctions and in seeking to derive or deduce from general principles (in a 'quasi-logical way') (2015c, p. 445) those ethical practices which obtain in a specific situation (pp. 443–8). Further, he advances the argument for 'particularism' rather than 'principlism', holding that, since researchers have to focus on specific projects, their decisions are 'situated' and their ethical decisions are taken with reference to the case in hand rather than being derived from sets of principles (p. 441) (see also Hammersley and Traianou, 2012). Whilst principles raise considerations for researchers, they do not necessarily *determine* what ethical decisions should be taken in a specific case; rather, they *inform* such decision making.

The British Psychological Society's *Code of Human Research Ethics* (2014) sets out four principles: respect for the autonomy and dignity of persons (including rights to privacy, self-determination, personal liberty and natural justice) (p. 8); scientific value; social responsibility; and maximizing benefit and minimizing harm. It also states that '[r]esearchers should respect the rights and dignity of participants in their research and the legitimate interests of stakeholders such as funders, institutions, sponsors and society at large' (p. 4). These principles inform its discussions of: risk; valid consent; confidentiality; giving advice; deception; debriefing; ethics review; safeguards for, and working with, vulnerable populations.

With regard to respecting dignity, there is the need to treat participants as equals, not as objects or as subordinate to the researcher. This may mean avoiding treating them as 'subjects' rather than as equals or participants.[1] It also means avoiding stigmatizing groups (e.g. the unemployed; the homeless; religious groups; ethnic groups; those considered deviant by virtue of their sexual orientation, dress, beliefs). The document also indicates that ethical research extends to concerns of: involvement with vulnerable groups; sensitive topics; deception; access to personal or confidential records or sensitive data from third parties (e.g. employers); the potential to induce stress, anxiety, pain humiliation; intrusive interventions that are outside the routine lives of individuals; and that which could lead to negative labelling.

From this very brief excursus into the contents of codes of ethics, it can be seen that they cover similar topics. Ethical codes are a guide, but they cannot dictate to the researcher what to do in a specific, unique situation, nor can they absolve the researcher of responsibility for action taken in the research. The issue here is that ethics are 'situated' (Simons and Usher, 2000):

> while ethics has traditionally been seen as a set of general principles invariantly and validly applied to all situations, … on the contrary, ethical principles are mediated within different research practices and thus take on different significances in relation to those practices.
>
> (Simons and Usher, 2000, p. 1)

The authors state that this implies that situated ethics are 'immune to universalization', because:

> researchers cannot avoid weighing up conflicting considerations and dilemmas which are located in the specificities of the research situation and where there is a need to make ethical decisions but where those decisions cannot be reached by appeal to unambiguous and univalent principles or codes.
>
> (Simons and Usher, 2000, p. 2)

Against ethical codes and regulation

Whilst ethics committees and regulations may be a useful safeguard, for example 'gatekeeping', Farrimond (2013) suggests that ethics committees can be too time-consuming and bureaucratic, unfairly use models from one discipline (e.g. medicine) in another (e.g. social science), are part of a wider 'audit culture', are over-concerned with protecting institutional reputation, make it difficult for researchers to challenge decisions, and lack consistency (pp. 49–51). Brooks *et al*. (2014) report that they can also undermine and discourage professional expertise and reflection. They can be unduly restrictive and lack cultural relevance. In their endeavour to protect even minimal harm from coming to individuals, they may overlook the principle of the greatest good for the greatest number. They may require socio-culturally insensitive or inappropriate ways of ensuring informed consent, for example, requiring such consent to be given on paper-copy pro formas, whereas this is inappropriate in some (e.g. non-western) cultures, and, indeed, they may require individuals to sign such forms when, in reality, in some cultures it is not the individual but the family head, the community and its leaders who should give consent (Lie and Witteveen (2017) comment on the value of filmed informed consent rather than in written form).

Further, ethics committees, codes of practice and regulations may emphasize rule-following in situations where following rules and regulations is insufficient for taking ethical decisions *in situ*. Indeed they may protect the university or institution rather than the research participants, they may prevent important sensitive research from being undertaken, and they may over-simplify complex research situations (cf. Hammersley and Traianou, 2012; Brooks *et al*., 2014, pp. 34–42).

Ethical regulation of research is often conducted by university ethics committees. Whilst the intentions here might be honourable in protecting individuals and institutions, in a blistering paper against ethical regulation by research ethics committees, Hammersley (2009, pp. 212–19) argues that:

a they are incapable of making sound or 'superior' ethical decisions, such that their work will not improve the ethical quality of research. This is because: (i) ethical issues are contentious and there is a lack of consensus among social scientists on ethical matters, principles, priorities of principles and practices, or consequences; (ii) ethical issues and practical research are complex (e.g. secrecy and deception in research); (iii) ethical answers cannot simply be cranked out, mechanistically or algorithmically, but are framed in specific contexts (which may be unknown to ethical committees); (iv) the remit of ethical committees is unclear, for example, whether to approve, prevent, control methodology or topics; (v) ethical committees only need to be persuaded that the researcher has the ethical capability to conduct the research, but this confuses ethical audit with ethical decision making and confuses substance and procedures of ethical review;

b they have no legitimacy or moral superiority/expertise to control researchers, and that this is inherent in ethical principles themselves: (i) researchers should have their autonomy respected; (ii) it is the researchers themselves – and not ethics committees – who have the responsibility for the ethical conduct of research and such responsibility cannot and should not be passed to a committee; (iii) ethics committees must apply the principle of 'informed consent' to researchers, and not just to those being researched; (iv) ethics committees operate prospectively, not only retrospectively, and this kind of prospective regulation is highly unusual in most areas of life; (v) there is almost no evidence that researchers operate unethically apart from some illegal cases, and so the processes of ethics committees are unnecessary, i.e. there is no problem which needs to be fixed;

c they lead to undesirable consequences in research: (i) the bureaucratization of research; (ii) the time and effort required to meet bureaucratic requirements will deter many researchers from proceeding; (iii) research will avoid sensitive, difficult or contested yet important areas and marginalized or powerful groups, i.e. where informed consent may

not be possible; (iv) we may not discover important data; (v) researchers will avoid important research areas because they may consider it difficult to obtain the consent of the ethics committee.

Hammersley argues that ethics committees' roles should be limited to providing advice, providing a forum for discussion on ethical matters and initiating such discussions. This echoes the comment from Howe and Moses (1999, pp. 46–5) that research ethics committees have no special expertise to judge many educational research issues about such-and-such a project, that they are bureaucratic and tend to discharge their duties in a perfunctory manner. They may provide advice and guidance, but not prospective judgements about specific research projects (Howe and Moses, 1999, p. 53).

The difficulty with, and yet the strength of, ethical codes is that they cannot and do not provide specific advice for what to do in specific situations. And the difficulty for ethics committees is that their operations are seen as impractical and, ultimately, anti-ethical, anti-research and anti-researchers. Ultimately, it is researchers themselves, their integrity and their conscience, informed by an acute awareness of ethical issues, underpinned by guideline codes and regulated practice, which should decide what to do in a specific situation, and this should be justified, justifiable, thought through and defensible.

It was observed earlier that many ethical codes and guidelines themselves avoid univalency and unambiguity, arguing, for example, that deception, covert research and the lack of informed consent may be justified. The need for polyvalency (multiple interpretations of what is worthwhile, acceptable and valuable) and situated ethics arises from the practicality of conducting research, the need for sensitivity to socio-political contexts and fairness to disadvantaged groups, and to take account of the diversity and uniqueness of different research practices. What this suggests, then, is that, whilst codes, guidelines and committees may be useful in raising issues and orienting researchers, they cannot decide what should and should not be done in a specific situation; that is for individual researchers and their informed conscience to decide.

7.5 Choice of research topic and research design

Ethical issues enter into considerations of choice of topic and the design and operationalization of the research. The decision on what to research may become a political act, deliberate or not, and the researcher has to consider whose interests are involved in, or at stake in, conducting the research. Why focus on such-and-such in proposing the research? Choice of research topic also raises issues of privacy, sensitivity and access, and we address these later in the chapter.

Here we do not rehearse the issues of 'partisan research' that we addressed in Chapter 3, though readers may find it useful to review that chapter. Rather, we address issues of the kind of research proposed. Researchers may find themselves having to defend not only their research design but their methodology in the face of, for example, questions from ethics committees or sponsors who lean towards quantitative methods and experimental approaches and away from what they perceive to be 'soft', unscientific qualitative research. This may extend to their being uncomfortable with covert research or research which, as it unfolds over time or is conducted in non-mainstream or 'different' cultures, may raise questions of informed consent or where the research will go (e.g. 'blue-skies' research) and what the research will 'deliver' (e.g. issues which routinely face ethnographic research).

The issue goes further, into instrumentation: some sponsors may not be friendly towards survey research (Brooks *et al*., 2014), particularly if it might find 'unwelcome data' (p. 72); they may either bar researchers from identifying individuals or, by contrast, positively require parties and individuals to be identified. As discussed earlier, this is illegitimate, as sponsors cannot dictate to researchers how to go about their business.

Even apparently innocuous instruments such as questionnaires broach ethical issues, as respondents typically have to answer in terms of categories already decided by the researcher, and this risks reducing the participants to data objects rather than agentic people (Hammersley and Traianou, 2012c, p. 12). Observation, participant or non-participant, intrudes into people's lives and privacy.

Researchers will also need to consider where their research will take place, for example, in classrooms, off-site (e.g. for confidentiality and 'neutral territory'), as context often influences the research. For example, interviewing children in school may be more comfortable for children than outside school or, indeed, the opposite may be the case (Morrison, 2013a). Conducting interviews in school may make students feel obliged to participate when in fact they would prefer not to participate, or might discourage them from being honest in favour of saying or doing what they think the school would require. Schools as hierarchical institutions may exert an influence on students (Brooks *et al*., 2014, p. 76).

In setting research agendas, the researcher may also face dilemmas in deciding whose agendas to serve: the insiders' (the participants, the sponsors) or the outsiders' (the researcher, the reader, the audiences of the research, the public). Whilst this may lead to some negotiation of research agendas and methodologies (e.g. in sensitive research, see Chapter 13), this is an ethical issue and the integrity of the researcher cannot be sacrificed to insider power. On the one hand it may be better not to do the research than to compromise ethical principles in deciding the agenda and the conduct, methodology and reporting of the research, how the research will be conducted and reported, and to whom. On the other hand it may be better to give ground in some quarters in order to gain ground in others: better to do some research rather than no research at all or better to make some matters public rather than no matters at all. This returns to the issue of 'situated ethics' introduced earlier: researchers have to decide how to behave ethically in each specific situation.

In identifying the research topic and the design of the research, the researcher moves to planning the conduct of the research, and this raises a huge range of issues, which we consider below. These ethical concerns need to be addressed very early on in the planning, design and conduct of the research, including: informed consent; non-maleficence; beneficence; human dignity; privacy; anonymity; confidentiality; betrayal and deception; Internet ethics; ethics and evaluative research.

Ethics and the quality of the research

The research design, and indeed the research itself, have an ethical duty to demonstrate quality. Put simply, badly designed research is a breach of ethics (Farrimond, 2013, p. 75). As Hammersley and Traianou (2012) argue, research ethics is not only about treating people correctly, i.e. procedural matters such as rights, interests and duties, but about the 'primary obligation' (p. 1) to answer worthwhile questions; to pursue, produce, test and defend valid factual knowledge (e.g. descriptions, explanations, interpretations, conclusions, theories etc.) on the basis of full evidence; and to make a significant, relevant contribution to knowledge. The fundamental purpose of research is the production of valid, relevant, worthwhile and significant knowledge. It does not have as a *necessary* goal the practicality or political attractiveness of such knowledge; there may be motives for undertaking the research but these are not the purposes of the research itself (p. 134).

Producing knowledge includes, inter alia: a rigorous and coherent research design that demonstrates fitness for purpose; appropriate sampling, methodology and instrumentation; transparency, usefulness and validity; scholarly and scientific merit; significance and advancement of the field (e.g. substantively, conceptually, methodologically); scientific value; risk assessment and minimization; and transparency. Research which does not advance the field or which is of poor quality may be a waste of time and resources, and may be literally useless, all of which violate ethics.

Ethics in educational research also affect those not directly involved in the study but who may be affected by it, for example, children and parents. Ensuring the quality of research is an ethical matter, as poor-quality educational research can cause harm, particularly if used for decision making, for example, by funding bodies, parents, governments and policy makers. In other disciplines such as medicine, poor-quality research would not pass muster and would be prevented from taking place (and this might be a legitimate role for ethics committees). In poor-quality research: the evidence is weak; it uses inappropriate designs, methods and data analysis; conclusions made do not follow from the evidence; no warrants are made to link evidence and conclusions (Gorard, 2013); reporting is biased (we discuss bias in data analysis, reporting and dissemination later in this chapter); and claims made from the research are not supported by the research and data provided. Indeed taxpayers' money is wasted.

In poor-quality research, claims concerning 'impact' are made from inappropriate sampling, lack of baseline data for enabling comparisons to be made, attrition and missing data, lack of counterfactual analysis and data, and inadequate consideration of alternative explanations of findings. Ethical researchers have a duty of care to ensure that their research is of the highest quality.

Robson (1993, p. 33) raises ten questionable practices in social research:

- involving people without their knowledge or consent;
- coercing them to participate;
- withholding information about the true nature of the research;
- otherwise deceiving participants;
- inducing them to commit acts diminishing their self-esteem;
- violating rights of self-determination (e.g. in studies seeking to promote individual change);
- exposing participants to physical or mental stress;
- invading their privacy;
- withholding benefits from some participants (e.g. in comparison groups);
- not treating participants fairly, or with consideration, or with respect.

He calls these 'questionable practices' rather than areas to be proscribed, and this indicates that they are not black and white, right or wrong matters. They constitute ethical dilemmas for the researcher.

Earlier this chapter introduced the consequentialist costs/benefits ratio. Frankfort-Nachmias and Nachmias (1992) express this as a conflict between two rights: the rights to conduct research in order to gain knowledge versus the rights of participants to self-determination, privacy and dignity. This constitutes a fundamental ethical dilemma of the social scientist for whom there are no absolute right or wrong answers. Which proposition is favoured, or how a balance between the two is struck, will depend on the background, experience and values of the individual researcher.

7.6 Informed consent

The principle of informed consent concerns autonomy, and it arises from the participant's right to freedom and self-determination. Being free is a condition of living in a democracy, and when restrictions and limitations are placed on that freedom they must be justified and consented to, as in research. Consent thus protects and respects the right of self-determination and places some of the responsibility on the participant should anything go wrong in the research. Self-determination requires participants to have the right to weigh up the risks and benefits of being involved in a piece of research, and deciding for themselves whether to take part (Howe and Moses, 1999, p. 24). As part of the right to self-determination, the person has the right to refuse to take part, or to withdraw once the research has begun (see Frankfort-Nachmias and Nachmias, 1992). Thus informed consent implies informed refusal.

Informed consent has been defined by Diener and Crandall (1978) as those procedures for individuals to choose whether or not to participate in the research, once they have been told what it is about and what it requires, i.e. all those factors which might influence their decision (p. 57). This definition involves four elements: competence, voluntarism, full information and comprehension.

'Competence' implies that responsible, mature individuals will make correct decisions if they are given the relevant information. It is incumbent on researchers to ensure they do not engage individuals incapable of making such decisions because of either immaturity or some form of impairment. The United Nations Convention on the Rights of the Child (1989) and Graham *et al*. (2013) underline the importance of involving children in decisions that may affect them, and this extends to them giving informed consent provided that they are competent to understand what is involved in the research, and in the UK it means even if this overrides their parents' wishes or if children are below their biological age for assuming maturity (Brooks *et al*., 2014, pp. 82–7).

'Voluntarism' entails ensuring that participants freely choose to take part (or not) in the research and guarantees that exposure to risks is undertaken knowingly and voluntarily.

'Full information' implies that consent is fully informed, though in practice it is often impossible or even undesirable for researchers to inform participants on everything (see section below on 'Deception') and, as we see below, on those occasions when the researchers themselves do not know everything about the investigation and how it will unfold. In such circumstances, the strategy of 'reasonably informed consent' has to be applied. Box 7.3 illustrates a classic set of guidelines used in the United States that are based on the idea of reasonably informed consent (Department of Health, Education and Welfare, 1971).

'Comprehension' refers to the fact that participants fully understand the nature of the research project, even when procedures are complicated and entail risks.

If these four elements – competence, voluntarism, full information and comprehension – are present, participants' rights will have been given appropriate

BOX 7.3 GUIDELINES FOR REASONABLY INFORMED CONSENT

1. A fair explanation of the procedures to be followed and their purposes.
2. A description of the attendant discomforts and risks reasonably to be expected.
3. A description of the benefits reasonably to be expected.
4. A disclosure of appropriate alternative procedures that might be advantageous to the participants.
5. An offer to answer any inquiries concerning the procedures.
6. An instruction that the person is free to withdraw consent and to discontinue participation in the project at any time without prejudice to the participant.

Source: US Department of Health, Education and Welfare (1971)

consideration. This also raises questions of who is the appropriate party to give informed consent, for example, an individual, a community, an institutional head, to whom such consent applies, and consent for what ('freedom from' and 'freedom for') (Hammersley and Traianou, 2012, p. 80). Further, such informed individual consent may not be a feature of, say, oppressive regimes in which participation may be mandated; does this mean that research cannot take place here? Do such people have the right not to be researched?

Further, Frankfort-Nachmias and Nachmias (1992) note that informed consent may not always be necessary (e.g. deception may be justified), but that, as a general rule, the greater the risk, the more important it is to gain informed consent. More widely, it raises the question of whether informed consent is really required and, if so, what form it should take (cf. Hammersley and Traianou, 2012, chapter 4).

Informed consent is one of the most problematic issues in educational research, as it raises a lengthy list of concerns, for example:

- Should consent be an individual, family, institutional or communitarian decision?
- Who gives consent, and for whom, for what and for how long (e.g. longevity of data storage)?
- What constitutes 'consent'?
- Who is competent to give consent, and on whose behalf?
- Can children override parents' wishes?
- What pressure (deliberate or not) on people and institutions is there to give consent?
- What does 'voluntary' really mean in 'voluntary consent'?
- In whose interests is consent given or withheld?
- How is consent given in different cultures?
- How to protect vulnerable people in giving consent.
- What degree of informality and formality is appropriate in consent giving?
- What are the possible consequences (and to whom) of consent or non-consent?
- How do power differentials affect consent giving?
- Is biological age of consent 'good enough' for giving consent?
- What are the relationships between consent and confidentiality?
- How much information is it necessary to give or withhold from participants when asking for informed consent (what does 'fully informed' mean and require)?
- Should incentives be offered to gain consent?
- How can consent be addressed in covert research?
- What tensions arise in considering consent and action research (where the researcher is the powerful teacher)?
- Is deception justified?
- How can consent be given when what happens may not be fully known in advance of the research (e.g. in exploratory research)?
- How can consent be addressed in online research?

What starts out as a simple label – 'informed consent' – raises an enormous list of concerns, and we address these in the pages below.

Whilst some cultures may not be stringent about informed consent, in others there are strict protocols for informed consent. What form should or does consent giving take? In some cultures, consent has to be given in writing; in others, such written consent is deemed to be suspicious, threatening, insulting or culturally inappropriate (cf. Hammersley and Traianou, 2012, p. 89; Farrimond, 2013, pp. 33–4), and (unrecorded) oral consent, or even a nod of a head by the appropriate person, is sufficient. Brooks *et al*. (2014) comment that there is a risk that seeking written informed consent, particularly from individuals, is 'fundamentally western and masculinist' (p. 83) and neglects communitarian requirements for giving consent, as, in some cultures, it is the community which is the gatekeeper, not the individual (cf. Howe and Moses, 1999, pp. 33–4). In other words, consent is culturally situated (Marshall and Rossman, 2016, p. 55), and the giving of informed consent differs in individualist and collectivist cultures (p. 57). Written consent might be seen as bringing a level of formality into what some cultures and communities would prefer to keep on an informal footing (Crow *et al*., 2006, pp. 88–9).

Informed consent, aver Howe and Moses (1999), is a cornerstone of ethical behaviour, as it respects the right of individuals to exert control over their lives and to take decisions for themselves. How far this extends to, for example, parents, counsellors, groups and communities is not a black-and-white matter. What happens, for example, if the researcher wishes to study child abuse at home; does she need the parents' permission? Is not the requirement for parental consent for research on children simply being too adult-centred (Brooks *et al*., 2014, p. 158)?

Informed consent often concerns access (Hammersley and Traianou, 2012), for example, to people, documents, institutions, settings and information. This, in turn, requires attention to how to secure consent and from whom (whose consent is required), for what (e.g. information, purposes and for what subsequent uses), for whom (on whose behalf and covering which

people: participants, gatekeepers, others), for how long (pp. 82–90), and how to give information (in what form or medium, and with how much formality/informality) (p. 96). It concerns what counts as 'free', under what constraints and persuasions (pp. 91–2) and whether consent is actually necessary, extending to issues of what constitutes public and private information, places and settings and how – or whether – consent relates to covert research.

Ruane (2005, p. 21) raises the question of 'how much information is enough?'. She argues that this may be an unknown, not necessarily deliberately withheld. Is it justifiable to give 'partial truths' in providing information (Hammersley and Traianou, 2012, p. 94)? Further, just as providing information may bias the results (i.e. it is important for the integrity of the research *not* to disclose its purposes or contents, e.g. the Milgram experiments, see Chapter 30), it may actually confuse the respondents. But if the researcher decides that partial information is preferable, does not this violate the principle of informed consent; is it being dishonest?

Educational research which involves children must recognize that they may not be on equal terms with the researcher (e.g. in terms of power) and it is important to keep this in mind at all stages in the research process, including the point where informed consent is sought. In this connection we refer to the important work from UNICEF (Graham *et al*., 2013) and the codes of practice introduced earlier.

There are other aspects of the problem of informed consent (or refusal) in relation to young or very young children (Greig and Taylor, 1999, pp. 143–55), not least of which is the need to abide by the requirements of legislation on working with children and on child protection. Greig and Taylor argue (p. 150) that non-therapeutic research should only be conducted with children where there is negligible risk and where the informed consent of gatekeepers (e.g. guardians and parents) has been obtained in advance, including how data will be stored (e.g. ICT-related issues), destroyed (e.g. confidential data or audio/visual recordings) upon completion of the research, how recording data may be switched off during an interview and how data will be used. For a fuller guide on ethical issues in conducting research on early childhood education, see Mukherji and Albon (2010) and the UNICEF document, *Ethical Research Involving Children* (Graham *et al.*, 2013).

Gatekeepers are in a very responsible position and they should not be overlooked. Oliver (2003, p. 39) comments that they have much more at stake – to lose – than researchers, since, whereas researchers can move on from one participant or researcher field to another, gatekeepers live with the daily consequences of the research and its effects on participants. Researchers may have an ethical obligation to seek the informed consent of gatekeepers. In turn, it must be recognized that gatekeepers also consider their own interests – protecting or promoting them – and hence may try to steer the research in certain directions, block or steer access, or try to control the dissemination of the results (Hammersley and Traianou, 2012, p. 50).

Seeking informed consent with regard to minors involves two stages. First, researchers consult and seek permission from those adults responsible for the prospective minors, and second, they approach the young people themselves. The adults in question will be, for example, parents, teachers, tutors, counsellors, youth leaders, or team coaches, depending on the research context. The point of the research will be explained, questions invited and permission to proceed to the next stage sought. Objections, for whatever reason, will be duly respected.

While seeking children's permission and cooperation is an automatic part of some research (e.g. a child cannot unknowingly complete a simple questionnaire), the importance of informed consent in some research is not always recognized. Speaking of participant observation, for example, Fine and Sandstrom (1988) say that researchers must provide a credible and meaningful explanation of their research intentions, especially in situations where they have little authority, and that children must be given a real and legitimate opportunity to say that they do not want to take part (cf. Graham *et al.*, 2013). Where participants do refuse, they should not be questioned, their actions should not be recorded and they should not be included in any book or article (even under a pseudonym). Where they form part of a group, they may be included as part of a collectivity. Fine and Sandstrom (1988) consider that such rejections are sometimes a result of mistrust of the researcher. They suggest that at a later date, when the researcher has been able to establish greater rapport with the group, those who refused initially may be approached again, perhaps in private.

Two particular groups of children require special mention: very young children and those not capable of making a decision. Researchers intending to work with pre-school or nursery children may dismiss the idea of seeking informed consent from their would-be participants because of their age, but Fine and Sandstrom (1988) and UNICEF (Graham *et al.*, 2013) would recommend otherwise. Even though such children might not understand what research is, the authors advise that the children be given some explanation. For example,

an explanation to the effect that an adult will be watching and playing with them might be sufficient to provide a measure of informed consent consistent with the children's understanding. Fine and Sandstrom (1988) and Graham *et al*. (2013) comment that children should be told as much as possible, and that steps should be taken to ensure that they understand, and that this obtains regardless of their age.

The second group consists of those children in a research project who may not meet Diener's and Crandall's (1978) criterion of 'competence' (a group of psychologically impaired children, for example – the issue of 'advocacy' applies here). In such circumstances there may be institutional or local authority or legal guidelines to follow. In the absence of these, the requirements of informed consent would be met by obtaining the permission of those acting *in loco parentis* (e.g. headteachers) or who have had delegated to them the responsibility for providing informed consent by the parents.

Two cautions: first, where an extreme form of research is planned, parents would have to be fully informed in advance and their consent obtained; and second, whatever the nature of the research and whoever is involved, should a child show signs of discomfort or stress, the research should be terminated immediately. For further discussion on the care that needs to be exercised in researching with children, we refer readers to Greig and Taylor (1999), Holmes (1998), Graue and Walsh (1998) and UNICEF (Graham *et al.*, 2013).

Informed consent applies not only to children, but to a range of vulnerable groups, for example, adults, the disabled, those who cannot speak, see or hear, those in hospital, those in care, those suffering from autism (cf. Coch, 2007; Waltz, 2007; Brooks *et al*., 2014). Oliver (2003, pp. 35–6) defines vulnerable groups as those people or categories of people who, for whatever reason, may not have sufficient understanding to be able to give informed consent to the research. In many cases ethics committees will require a full indication of how the ethics of the research will be addressed here (Crow *et al.*, 2006, p. 86).

Informed consent requires an explanation and description of several factors, including:

- the purposes, contents, procedures, reporting and dissemination of the research;
- any foreseeable risks and negative outcomes, discomfort or consequences and how they will be handled;
- benefits that might derive from the research;
- incentives to participate and rewards from participating;
- right to voluntary non-participation, withdrawal and re-joining the project;
- rights and obligations to confidentiality and non-disclosure of the research, participants and outcomes;
- disclosure of any alternative procedures that may be advantageous;
- opportunities for participants to ask questions about any aspect of the research;
- signed contracts for participation.

Brooks *et al*. (2014, p. 94) suggest that consideration can also be given to:

- the sponsors of/source of funding for the research;
- why the participants have been approached;
- how anonymity is assured;
- how data will be reported;
- contact details of the researcher(s).

Researchers who seek informed consent must ensure – check – that participants really do understand the implications of the research, not mindlessly sign a consent form. They may need time to digest the information given before consenting or not consenting. Researchers will need to decide what to include in informed consent, not least of which is the issue of volunteering. Participants may feel coerced or pressurized to volunteer (e.g. by a school principal), or may not wish to offend a researcher by refusing to participate, or may succumb to peer pressure to volunteer (or not to volunteer), or may wish to volunteer for reasons other than the researcher's (e.g. to malign a school principal or senior colleagues, to gain resources for his or her department, to gain approval from colleagues).

For example, in action research, the researcher is often the child's own teacher. Will the child really be given the right not to take part, or is the action research seen less like research and more like the carrying out of a professional duty to ensure that the best possible education is being promoted, i.e. part of the normal practice of improving curricula, teaching and learning, and hence not requiring the consent of the child or the parents?

It is important to ensure that participants are not 'railroaded' into participating, for example, by a school principal who makes the decision for the staff, or where staff are not given sufficient time to come to a decision on whether or not to participate, or where staff do not wish to appear unhelpful to researchers (who, indeed, may be friends or acquaintances of the researcher), even though they actually would rather not take part in

the research (Oliver, 2003, p. 27). The choice of whether or not to participate must be genuinely free, with no negative repercussions for not taking part, and no feelings of researchers having taken advantage of powerless participants (cf. Graham *et al.*, 2013).

Arguments against informed consent

There are some research methods where it is impossible to seek informed consent. Covert observation, for example, as used in Patrick's (1973) study of a Glasgow gang (Chapter 15), or experimental techniques involving deception, as in Milgram's obedience-to-authority experiments (Chapter 30), would, by their very nature, rule out the option. And, of course, there may be occasions when problems arise even though consent has been obtained. Burgess (1989), for example, cites his own research in which teachers had been informed that research was taking place but in which it was not possible to specify exactly what data would be collected or how they would be used. It could be said, in this particular case, that individuals were not fully informed, that consent had not been obtained and that privacy had been violated.

Some researchers advocate informed consent on the grounds that it yields better data because it is a consequence of establishing rapport and trust between researchers and participants (e.g. Crow *et al*., 2006, p. 76). Indeed it might bring better participation rates in research, as participants might be more likely to agree to being involved if they are given the 'full picture' of the research or if assurances of confidentiality are given. On the other hand, informed consent is seen less positively, as it renders some research (e.g. necessarily covert research) unresearchable, and it provides poorer participation rates where some participants may be reluctant to sign a consent form or may regard the research as too bureaucratic (p. 88), antagonistic, coercive and alienating.

Informing people of the research might provoke the Hawthorne effect (see Chapter 14) or might disturb the natural behaviour of participants (Oliver, 2003, p. 53) as they will be conscious of being watched. Hence full disclosure of the research aims and purposes might distort the research process. Whether this amounts to deception is addressed below (see section on 'Deception').

Seeking formal informed consent might lead to a narrow range of data and a neglect of the richest, most authentic data, as participants might become more guarded in what they disclose (e.g. about relationships). Indeed in some cultures, Oliver (2003, p. 103) writes, participants may find it an unusual experience to be asked to complete a questionnaire, and they may regard it as a 'test'. Howe and Moses (1999) ask how realistic it is to obtain informed consent from both parents to interview their child if the parents are separated (p. 89). The effects of all of these difficulties might lead to research only concerning itself with 'safe', easily researchable topics and to the neglect of research into vulnerable and excluded groups. By contrast, Humphreys (1975), the author of the celebrated study *Tearoom Trade* (1970), a study of homosexual meeting arrangements, wrote in his 1975 postscript on ethics that 'the greatest harm a social scientist could do to this man would be to ignore him' (p. 169).

Informed consent may not be possible in covert research, or research in which important yet sensitive issues or groups are being investigated (see Chapter 13), and it is only through covert research and perhaps deception that one can gain access to such sensitive groups or practices. It might be important to research such groups (see Mitchell's (1993) defence of secrecy in research for the public good). Similarly, in ethnographic research, the researchers may not know in advance what kind of data will be collected, from whom and how. In these circumstances Brooks *et al*. (2014) note that an 'ethics of care' might be more suitable than 'informed consent' (p. 89).

Wax (1982, p. 44) argues that informed consent offers both 'too much and too little': 'too much' in the sense that it is 'overscrupulous and disruptive', particularly in emergent situations and qualitative research where casual conversations figure highly as field notes, and 'too little' in the sense that field researchers often require much more than informed consent, for example, they seek trust, 'active assistance' from participants and 'colleagueship'. Indeed he suggests that informed consent reinforces asymmetries of power between researchers and participants, rather than equalizing them.

If the research involves participants in a failure experience, isolation or loss of self-esteem, for example, researchers must ensure that the participants do not leave the situation more humiliated, insecure, alienated and worse off than when they arrived. From the participant's point of view, procedures which involve loss of dignity or injury to self-esteem, or affect trust in rational authority, are probably most harmful in the long run and may require the most carefully organized ways of recompensing the participants if the researcher chooses to carry on with those methods.

With particularly sensitive areas, participants need to be fully informed of the dangers of serious after-effects. There is reason to believe that at least some of the obedient participants in Milgram's (1963) experiments (see Chapter 30) came away from the experience

with lower self-esteem, having to live with the realization that they were willing to yield to destructive authority to the point of inflicting extreme pain on a fellow human being (Kelman, 1967). Researchers may need to reflect attitudes of compassion, respect, gratitude and common sense without being too effusive. Participants clearly have a right to expect that the researchers with whom they are interacting have some concern for their (participants') welfare.

As a general rule, informed consent is an important principle, but, as noted above, it may not always be fully or easily applied, or desirable.

7.7 Non-maleficence, beneficence and human dignity

Non-maleficence (do not harm) is enshrined in the Hippocratic oath, in which the principle of *primum non nocere* (first of all, do no harm) is held as a guiding precept; so also with educational research. Adopting consequentialist ethics, the research should not damage the participants physically, psychologically, emotionally, professionally, personally and so on. For example, participants may find it very distressing to relive the experience of being bullied by students or other staff and researchers must decide whether or how to proceed here, with due attention to informed consent and right not to take part (cf. Oliver, 2003, p. 32).

Non-maleficence requires researchers and participants to consider carefully the possible consequences of the research on participants and the research (e.g. the negative effects on the participants and the researchers). Hammersley and Traianou (2012) argue that all research, just as everyday life, involves the risk of harm, it cannot be removed completely so the task of the researcher is to minimize it (p. 57). Further, what constitutes harm or the level of risk (small to significant) is a matter of judgement (p. 57).

Non-maleficence considers the need to avoid doing harm to participants. At first sight this seems uncontentious: of course we do not wish to bring harm to our research participants, and it is a golden rule that the research must ensure that participants are no worse off at the end of the research than they were at the start of the research. However, what constitutes 'harm' is unclear; one person's harm may be a society's benefit, and whether a little harm for a few is tolerable in the interests of a major benefit for all, or even for the person concerned, throws into relief the tension involved here.

Issues of harm and risk also raise the question of what constitutes 'worthwhile' knowledge: is the benefit worth the risk or the harm? For example, having participants recalling distressing or traumatic experiences at interview may turn out to be beneficial for them; it may be therapeutic in coming to terms with them. Harm and risk involve matters of judgement, and these involve carefully weighing complex issues and the potential degree of harm. In open-ended research or research in naturalistic settings which may be uncontrollable, for example, certain types of qualitative research, this may be unpredictable, and indeed the contexts themselves may be involving harm (Hammersley and Traianou, 2012, p. 65).

Hammersley and Traianou (2012) also identify several kinds of potential harm: (a) pain or physical injury; (b) psychological or emotional damage; (c) material damage or loss; (d) reputational or status damage or loss; (e) damage to an activity or project in which participants are involved (p. 62). Attention must be given not only to the immediate harm in (a) to (e) here, but also to 'knock-on' effects and their duration, for example, on quality of life. Attention has to be given not only to the potential degree of harm but to the degree of severity of its consequences (pp. 63–4). The authors note, for example, that visual research with children (even giving the children themselves the video cameras), in which they or their circle of contacts can be identified on video or film, in photographs or on Internet sites, poses potential risks of harm to participants or to others identified in the visual data, raising issues of whose informed consent is needed in the research, who is responsible for what and what can or cannot be foreseen (pp. 69–71).

The question here is whether the end justifies the means. It involves the 'dirty hands' dilemma: whether causing a small harm to a few is justified in terms of bringing about a greater good, for example, to society and the public good. As a general principle we advocate the application of *primum non nocere*, and, indeed, ethics regulatory boards are guided heavily by this principle. However, there could be tensions here. What do you do if you discover that the headteacher has a serious alcohol problem or is having an illicit affair with a parent? What do you do if your research shows that your teacher friend in a school has very serious weaknesses, such that their contract should be terminated in the interests of the students? Harm may also accrue to individual participants, but it does not rest there; it can extend to the researcher(s), institutions, groups and communities being researched, the researcher's own workplace and colleagues, publishers and those with whom the researcher may not have had direct personal contact.

When researchers are confronted with dilemmas such as these (however few they may be), it is generally considered that they resolve them in a manner that

avoids the extremes of, on the one hand, giving up the idea of research and, on the other, ignoring the rights of the participants. At all times, the welfare of participants should be kept in mind (cf. British Educational Research Association, 2011), even if it involves compromising the impact of the research. In the final reckoning, the decision to go ahead with a research project rests on a subjective evaluation of the costs both to the individual and society.

Bailey (1994, p. 457) suggests that there are several approaches that can be used to avoid harming research participants, including:

- using computer simulations;
- finding a situation in which the negative effects of harm already exist, i.e. where the research does not have the responsibility for having produced these conditions;
- applying only a very low level of potential harm, or for only a short period of time, so that any effects are minimal;
- informed consent (providing details of the potential negative effects and securing participants' consent);
- justifying the research on the grounds that the small amount of harm caused is much less than the harm caused by the existing situation (which the research is trying to improve);
- using samples rather than complete populations, so that fewer people are exposed to the harm;
- maintaining the privacy of participants through the use of aggregated or anonymized data.

Whilst some of these are uncontentious, others in this list are debatable, and researchers will need to be able to justify the decisions that they reach.

The complement of non-maleficence is beneficence: what benefits will the research bring, and to whom, and how? Many would-be participants could be persuaded to take part in research if it is made clear that it will, or may, bring personal, educational and social benefits. For example, it may lead to the improvement of learning, increased funding and resources for a particular curriculum area, improved approaches to the teaching of a subject, increased self-esteem for students, additional teachers in a school, increased self-awareness in the participants (Oliver, 2003, p. 35) and so on. Whilst it is sometimes worth including a statement of potential benefit when contacting schools and individuals, it may also be an actual requirement for ethics regulatory boards or sponsors.

Although it may be fanciful to believe that a single piece of research will automatically lead to improvement, the ethical question raised here – who benefits? – suggests that a selfish approach to the benefits of the research by the researcher is unethical. This point requires researchers to do more than pay lip service to the notion of treating research participants as subjects rather than as objects to be used instrumentally – research fodder, so to speak – imbuing them with self-esteem and respect.[1] One can treat people with respect but still the research may make no material difference to their lives.

Whilst it is impossible to argue against treating people with dignity and respect, it also raises the issue of the obligations and commitments of the researcher. Let us say that the researcher has been working closely in a school for one or two years; surely that researcher has an obligation to improve the lives of those being researched, rather than simply gathering data instrumentally? To do the latter would offend reciprocity (see section below on 'Reciprocity'). The issue is tension-ridden: is the research *for* people and issues or *about* people and issues? We have to be clear about our answer to the question 'what will this research do for the participants and the wider community, not just for the researcher?'

Beneficence, whilst eminently worthy, may not be the main purpose of educational research. Hammersley and Traianou (2012) make a powerful case for regarding educational knowledge as the production of valid and significant knowledge; if, in so doing, it brings beneficence then this may be a bonus, a consequence, not a purpose.

7.8 Privacy

With increasing surveillance in everyday life, with electronic storage and retrieval, privacy and its protection become a difficult and contested terrain. Further, there may be some activities or places which, by their very nature, are intensely private and to intrude into them is to break taboos. Qualitative research, in particular, has considerable potential to invade privacy. Privacy touches all aspects of the research enterprise: choice of topic, research design, foci, participants, instrumentation, questions asked, data and their collection, data analysis, reporting and dissemination.

Privacy is a primordial value, a 'basic human need' (Caplan, 1982, p. 320), which, like the right to self-determination, 'trumps' utilitarian calculations (Howe and Moses, 1999, p. 24). Its corollaries are anonymity, confidentiality and informed consent. It has been considered from three different perspectives by Diener and Crandall (1978). These are: the sensitivity of the information being given; the setting being observed; and dissemination of information. Sensitivity of

information refers to how personal or potentially threatening is the information collected by the researcher. Certain kinds of information are more personal than others and may be more threatening, for example, religion, ethnicity, sexual practices, income, values and other personal attributes such as intelligence, honesty and courage may be more sensitive items than name or age. Thus, the greater the sensitivity of the information, the stronger must be the safeguards called for to protect the privacy of the participants. These vary by culture: in one culture what is private or sensitive, what is legitimate public territory and who can have access to private matters may not be so in another, and the researcher needs to judge this. Similarly, what can and should be published (a central feature of academic research) or kept private may be contestable.

The term 'private' has different meanings (Hammersley and Traianou, 2012, pp. 111–12), for example: a 'home area' or territory (e.g. a street, a district); 'not publicly owned' (but these may still be open to the public, e.g. a shopping mall); restricted areas (who can and cannot enter them, e.g. one's home), be they publicly owned (e.g. a local authority school) or privately owned (a private school); a private activity which takes place in a public place. These, the authors note (p. 113), can be used to judge not only whether something is private, but the degree of privacy involved and the legitimacy of observing or collecting data about them with and without consent, and with varying degrees of intrusion. Indeed what counts as 'intrusion' and legitimate or illegitimate intrusion is also contestable. Private matters will affect what, how, when and where questions are asked (p. 114).

The setting being observed may vary from very private to completely public. The home, for example, is considered one of the most private settings and intrusion into people's homes without their consent is forbidden by law. As is the case with most rights, privacy can be voluntarily relinquished. Participants may choose to give up their right to privacy by either allowing a researcher access to sensitive topics or settings or by agreeing that the research report may identify them by name. The latter case at least would be an occasion where informed consent would need to be sought.

Generally speaking, if researchers intend to probe into the private aspects or affairs of individuals, their intentions should be made clear and explicit and informed consent should be sought from those who are to be observed or scrutinized in private contexts. Other methods to protect participants are anonymity and confidentiality and we examine these below.

Privacy is more than simple confidentiality (discussed below). The right to privacy means that a person has the right not to take part in the research, not to answer questions, not to be interviewed, not to have their home intruded into, not to answer telephones or emails, and to engage in private behaviour in their own private place without fear of being observed. It is *freedom from* as well as *freedom for*. This is frequently an issue with intrusive journalism. Hence researchers may have an obligation to inform participants of their rights to refuse to take part in any or all of the research, to obtain permission to conduct the research, to limit the time needed for participation and to limit the observation to public behaviour.

Individual 'right to privacy' is usually contrasted with the public's 'right to know' (Pring, 1984, 2015): what is in the public interest and serves the public good versus the individual's right to privacy. Researchers will need to decide this on a case-by-case basis: 'situated ethics'.

Chapter 8 discusses the threats to privacy introduced by online research, and we recommend researchers to consult this chapter.

7.9 Anonymity

One way of addressing privacy and protection from harm is by anonymity. Frankfort-Nachmias and Nachmias (1992) underline the need for confidentiality of participants' identities, holding that any violations of this should be made with the agreement of the participants. The essence of anonymity is that information provided by participants should in no way reveal their identity. The obverse of this is personal data which uniquely identify their supplier. A participant is considered anonymous when the researcher or another person cannot identify the participant from the information provided. For example a questionnaire might only contain a number instead of a person's name. Where this situation holds, a participant's privacy is guaranteed, no matter how personal or sensitive the information is. Thus a respondent completing a questionnaire that bears absolutely no identifying marks – names, addresses, occupational details or coding symbols – is ensured complete and total anonymity. Non-traceability is an important matter, and this extends to aggregating data in some cases, so that an individual's response is unknowable or ensuring that data cannot be combined and individuals identified (Raffe *et al*., 1989) (e.g. in a school there may be only one middle-aged male teacher of religious education).

The principal way of ensuring anonymity, then, is removing any means of identification. Further strategies for achieving anonymity have been listed by Frankfort-Nachmias and Nachmias (1992), for example, the use of: (a) aliases and pseudonyms; (b) codes for identifying

people (to keep the information on individuals separate from access to them); and (c) password-protected files. Plummer (1983), likewise, refers to life studies in which names have been changed, places shifted and fictional events added to prevent acquaintances of participants discovering their identity. In experimental research the experimenter is interested in 'human' behaviour rather than in the behaviour of specific individuals (Aronson and Carlsmith, 1969, p. 33), and the researcher has no interest in linking the person as a unique, named individual to actual behaviour, so the research data can be transferred to coded, unnamed data sheets.

Hammersley and Traianou (2012) note that if anonymity and confidentiality cannot be guaranteed, then it should not be promised (p. 129). In an age of electronic data storage, this is a reality. Further, some participants may deliberately wish to be identified, and the researcher has to consider how to take account of this. It may be that the researcher accedes to the request or denies it (e.g. if the researcher wishes to avoid any risk of libel or considers that the purpose of the research is to produce knowledge and answer research questions, not to serve individuals' or groups' interests or to give them a voice) (p. 130).

7.10 Confidentiality

One way of protecting a participant's right to privacy is through the promise of confidentiality: not disclosing information from a participant in any way that might identify that individual or that might enable the individual to be traced. It can also mean not discussing an individual with anybody else or passing on the information to others in any form that can identify individuals. This means that although researchers know who has provided the information or are able to identify participants from the information given, they will in no way make the connection known publicly; the boundaries surrounding the shared secret will be protected. The essence of the matter is the extent to which investigators keep faith with those who have helped them.

It is generally at the access stage or at the point where researchers collect their data that they make their position clear to the hosts and/or participants. They will thus be quite explicit in explaining to participants what the meaning and limits of confidentiality are in relation to the particular research project. On the whole, the more sensitive, intimate or potentially discrediting the information, the greater is the obligation on the researcher's part to make sure that guarantees of confidentiality are carried out in spirit and letter. Promises must be kept.

Kimmel (1988) notes that some potential respondents in research on sensitive topics will refuse to cooperate when an assurance of confidentiality is weak, vague, not understood or thought likely to be breached. He concludes that the usefulness of data in sensitive research areas may be seriously affected by the researcher's inability to provide a credible promise of confidentiality. Assurances do not appear to affect cooperation rates in innocuous studies, perhaps because, as Kimmel suggests, there is an expectation on the part of most potential respondents that confidentiality will be protected.

A number of techniques have been developed to allow public access to data and information without confidentiality being betrayed. These have been listed by Frankfort-Nachmias and Nachmias (1992) as follows:

- deletion of identifiers (e.g. deleting the names, addresses or other means of identification from the data released on individuals);
- crude report categories (e.g. releasing the year of birth rather than the specific date, profession but not the speciality within that profession, general information rather than specific);
- microaggregation (i.e. the construction of 'average persons' from data on individuals and the release of these data, rather than data on individuals);
- error inoculation (deliberately introducing errors into individual records while leaving the aggregate data unchanged).

Cooper and Schindler (2001, p. 117) suggest that confidentiality can be protected by obtaining signed statements indicating non-disclosure of the research; restricting access to data which identify respondents, seeking the approval of the respondents before any disclosure about respondents takes place, non-disclosure of data (e.g. subsets that may be able to be combined to identify an individual).

Confidentiality also has to respect legal requirements. For example, if a child indicates that she is considering suicide or is at risk from an abusive parent, the researcher may have a legal obligation to inform relevant authorities. The researcher will need to make this clear, for example, at the start of an interview.

7.11 Against privacy, confidentiality and anonymity

Whilst a deontological and 'virtue ethics' approach to the ethics of educational research might demand that

rights to privacy be respected, on the other hand a utilitarian, consequentialist approach might argue that privacy could be violated if it is for the public good. Lincoln (1990) suggests that privacy protects the powerful and reproduces inequalities of power, whilst Howe and Moses (1999, p. 43) give examples where privacy should not be able to cloak wrongdoing (e.g. 'an abusive teacher … a sexist curriculum').

Wiles *et al*. (2008a, p. 419) indicate some of the complexities of ethical issues in confidentiality in their discussion of whether confidentiality should be broken in the interests of public or private safety, issues of actual or predicted criminal activity, if a person is at risk (e.g. a child who reports being abused, and legislation *requires* the reporting of this), and with vulnerable groups such as children, those with special needs, the recently bereaved, children whose parents have separated or who come from violent families. In many cases the researcher makes it clear before any interview commences that any information of a legal nature may be disclosed if the interviewer thinks the interviewee is at risk or if there is a legal matter at stake. However, it is not always as simple as this, as an interviewee may reveal some information that had not been anticipated. In other cases the researcher may want to give advice to a participant about seeking counselling or therapy. (Oliver (2003) cautions that the researcher is not herself/himself a counsellor or therapist (p. 71).)

In the case of covert research, there are no guarantees of confidentiality given in the first place. At issue here is where the duty of the researcher lies – to the research, to the individual, to the public or to whom – and the possible tensions between illegality, morality and the need to bring a matter to public awareness or knowledge. For example, if one is deliberately researching criminal activity it may be necessary to ensure confidentiality (maintaining 'guilty knowledge') or else the research will not take place at all. What does the researcher do if a court order is issued that requires the release of the data?

If researchers decide to opt for confidentiality then this can place them in a difficult situation where the research is emotionally draining, because, as Wiles *et al.* (2008a, p. 421) remark, it means that researchers cannot 'offload' their difficulties onto any other person.

Walford (2005, pp. 84–5) suggests that, whilst confidentiality, anonymity and non-traceability may be accepted or desirable norms for educational research, in some cases these norms may not apply or be achievable. For example, some participants or institutions may wish, or have a right, to be identified, as it might advance their cause or institution. Schools and headteachers might welcome publicity (Oliver, 2003, p. 77). As Wiles *et al.* (2008, p. 426) remark, in an age of increasing individualization, some individuals will insist on being identified. Further, the researcher is placed in a difficult situation with regard to confidentiality if a participant comments about another person who is not in the research and/or from whom no informed consent has been sought or obtained (Crow *et al*., 2006, p. 92): does the investigator use the data? Is it fair to exclude or include data about a third party because that third party has not been approached for informed consent?

Anonymity is also a double-edged sword. Whilst it might protect people, that may not be the main question; rather the question should be 'protect them from what?', as anonymity might become a cloak behind which participants can hide whilst making a range of negative, unsupported or even slanderous or libellous comments (cf. Oliver, 2003, p. 81). Maybe confidentiality and anonymity are only confined to certain forms of research.

More problematic is the question of what confidentiality actually means if the data are to be used for the research; if data are to be confidential and cannot be used or passed on, then what is the point of collecting or having the data? In this case it is perhaps anonymity and non-traceability that should be addressed rather than confidentiality, or the *scope* of confidentiality (its boundaries) should be clarified rather than a guarantee be given of absolute confidentiality (e.g. Oliver, 2003, p. 15).

It is often simply impossible to guarantee the anonymity of a person or an institution, as people can reassemble or combine data to identify a person or an institution or an institution can be identified by the 'locals', or indeed it can be identified by entering a few simple keywords from the research into an Internet search (Walford, 2005). Oliver (2003, p. 80) writes that it is impossible to give absolute guarantees of anonymity, especially where certain individuals are in named posts (e.g. a school principal). Here the commonly used advocacy of pseudonyms is no guarantee of anonymity. Walford (2005, p. 88) argues that promises of anonymity are often used by the researcher in order to gain access, though anonymity cannot actually be guaranteed, and, hence, it is ethically questionable whether anonymity should be promised. Whilst anonymity may bring data that are richer, keener and more acute or poignant than more anodyne research data which are given without promises of anonymity, this is not necessarily a justification for making promises of anonymity that cannot be kept.

Many devices can be used in the protection of anonymity, to 'put people off the scent', for example,

using pseudonyms, reporting a different geographical location from the one in which the research is actually carried out, providing misinformation (deliberately giving incorrect details of ages or sex), concealing identifying details (cf. Howe and Moses, 1999, p. 45), i.e. moving from 'disguise' to 'distortion' (Wiles *et al*., 2008, p. 422), in short removing context and, further, not always indicating that this has been done. However, this is problematic, as not only does it smack of telling lies and dishonesty, but it actually removes some of the very contextual data that are important for the research (Walford, 2005, p. 90), particularly for ethnographic research. To omit such necessary contextual details for researchers to understand the situation gives a spurious generalizability to the research. Walford suggests that it may be important to identify institutions and individuals, but that they should be given the right to reply in the research report, though this in turn is problematic. Who has the right to reply (all the participants?); what if very different replies are given? How are transparency, frankness and trust addressed in the relations between researchers and participants? These are knotty problems.

Howe and Moses (1999, pp. 44–5) make a cogent case against privacy and confidentiality, arguing that the 'thick descriptions' of interpretive research require a level of detail that cannot be obtained if privacy, confidentiality and anonymity are required. They argue that, as descriptions move towards becoming more 'objective', they become more anodyne and lose the very richness that they are intended to demonstrate, i.e. they become 'thin'.

7.12 Deception

The use of deception in social research has attracted considerable publicity and different opinions on its acceptability (British Educational Research Association, 2011; American Educational Research Association, 2011; Economic and Social Research Council, 2015). Is it acceptable to deceive people – by commission or omission – and, if so, under what circumstances, or is deception simply 'off the agenda'?

Concealing information

Deception resides in not telling people that they are being researched (in some people's eyes this is tantamount to spying), not telling the truth, withholding some or all information about the research, telling lies, 'giving a false impression' and 'failing to correct misconceptions' (Hammersley and Traianou, 2012c, p. 97), compromising the truth or withholding opinions.

Deception is applied to that kind of experimental situation where the researcher knowingly conceals the true purpose and conditions of the research, or else positively misinforms the participants, or exposes them to unduly painful, stressful or embarrassing experiences, without the participants having knowledge of what is going on. The deception lies in not telling the whole truth. Deception is a matter of degree, and is for the researcher to judge.

Advocates of the method feel that if deception is the only way to discover something of real importance, the truth so discovered is worth the lies told in the process so long as no harm comes to the participants (see the codes of ethics introduced earlier). Deception may be justified on the grounds that the research serves the public good, that the deception prevents any bias from entering the research and that it protects the confidentiality of a third party (e.g. a sponsor). The problem from the researcher's point of view is: what is the proper balance between the interests of science and the thoughtful, humane treatment of people who, innocently, provide the data?

The pervasiveness of the issue of deception becomes even more apparent when we remember that it is even built into many measurement devices, since it is important to keep the respondent ignorant of the personality and attitude dimensions that we wish to investigate. There are many problems that cannot be investigated without deception and, although there is some evidence that most participants accept without resentment the fact of having been duped once they understand the necessity for it (e.g. the Milgram obedience-to-authority experiment, see Chapter 30), it is important to keep in the forefront of one's mind the question of whether the amount and type of deception is justified by the significance of the study and the unavailability of alternative procedures.

Kelman (1967) has suggested three ways of dealing with the problem of deception. First, it is important that we increase our active awareness that it exists as a problem. It is crucial that we always ask ourselves the question of whether deception is necessary and justified. We must be wary of the tendency to dismiss the question as irrelevant and to accept deception as a matter of course. Active awareness is thus in itself part of the solution, for it makes the use of deception a focus for discussion, deliberation, investigation and choice.

The second way of approaching the problem concerns counteracting and minimizing the negative effects of deception. For example, participants must be selected in a way that will exclude individuals who are especially vulnerable; any potentially harmful manipulation must be kept to an acceptable level of intensity;

researchers must be sensitive to danger signals in the reactions of participants and be prepared to deal with crises as soon as, or before, they arise; and at the conclusion of the research, they must take time not only to reassure participants, but also help them work through their feelings about the experience to whatever degree may be required (see the discussions of the Milgram experiments and Stanford Prison Experiment in Chapter 30). The principle that participants ought not to leave the research situation with greater anxiety or lower levels of self-esteem than they came with is a useful one (the issue of non-maleficence again). Desirably, participants should be enriched by the experience and should leave it with the feeling that they have learned something.

The third way of counteracting negative effects of research employing deception is to ensure that adequate feedback is provided at the end of the research or research session. Feedback must be kept inviolable and in no circumstances should participants be given false feedback or be misled into thinking they are receiving feedback when the researcher is in fact introducing another experimental manipulation. Debriefing (see also Chapter 30) may include (Cooper and Schindler, 2001, p. 116):

- explaining any deception and the reasons for it;
- description of the purposes, hypotheses, objectives and methods of the research;
- sharing of the results after the research;
- follow-up psychological or medical attention after the research.

Even here, however, there are dangers. As Aronson and Carlsmith (1969) indicate, debriefing a participant by exposing her/him to the truth can be harmful than no debriefing; there is 'nothing magically curative about the truth' (p. 31), and great care has to be taken to ensure that the participant does not leave more uncomfortable than at the start of the experiment. They consider that the one essential aspect of the debriefing process is that researchers communicate their own sincerity as scientists seeking the truth and their own discomfort about the fact that they found it necessary to resort to deception in order to uncover the truth. As they say, 'no amount of postexperimental gentleness is as effective in relieving a subject's discomfort as an honest accounting of the experimenter's *own* discomfort in the situation' (Aronson and Carlsmith, 1969, pp. 31–2).

Another way of dealing with the problem of deception is to ensure that new procedures and novel techniques are developed so that deception becomes unnecessary. It is a question of tapping one's own creativity in the quest for alternative methods. It has been suggested that role-playing, or 'as-if' experiments, could prove a worthwhile avenue to explore (see Chapter 30). Here the participant is asked to behave as if he/she were a particular person in a particular situation. Whatever form they take, however, new approaches will involve a different set of assumptions about the role of the participant in this type of research. They require us to *use* participants' motivations rather than bypassing them.

Kimmel (1988) claims that few researchers feel that they can do without deception entirely, since the adoption of an overtly conservative approach could render the study of important research hardly worth the effort. A study of prejudice, for example, accurately labelled as such, could affect the behaviour of the participants. Deception studies, he considers, differ so greatly that even the harshest critics would be hard pressed to state unequivocally that all deception has potentially harmful effects on participants or is wrong. Indeed whilst research associations may discourage deception in research, they also recognize that, in some cases, it may be necessary and useful – the only way possible – but this requires careful justification.

Covert research

In the social sciences, the dilemma of deception has played an important part in research where participants are not told the true nature of the research, or where researchers conceal their identities and 'con' their way into groups, for example, alien, marginal, stigmatized or oppositional groups: the overt/covert debate (Mitchell, 1993). Covert or secret participation refers to that kind of research where researchers spend an extended period of time in particular research settings, concealing the fact that they are researchers and pretending to play some other role.

Bulmer (1982) notes that there are no simple and universally agreed answers to the ethical issues that covert research produces. Hornsby-Smith (1993, p. 65) argues that covert research violates informed consent, invades personal privacy, deceives people, risks harming participants when the research is published (e.g. Scheper-Hughes, 1979) and impairs the likelihood of other researchers researching the issue in the future or, indeed, of being able to conduct research, not least when overt research might have been used instead.

Douglas (1976a), Bulmer (1982) and Mitchell (1993), by contrast, argue that covert observation is necessary, useful and revealing, and that the most compelling argument in favour of covert research is that it has produced high-quality social science and has

advanced our understanding of society, which would not have been possible without the method. Indeed that is the view often taken in published codes of ethics (discussed earlier).

Covert research may be justified, for example, if the important data gathered could not have been gathered in any other way, or if it is necessary in order to gain access to organizations which would deny access (Mitchell, 1993; British Educational Research Association, 2011; American Educational Research Association, 2011), or to uncover questionable practices that, otherwise, would not come to light (e.g. child abuse) (cf. Oliver, 2003, p. 6). The consequentialist (e.g. utilitarian) argument for covert research is powerful.

7.13 Gaining access and acceptance into the research setting

The relevance of the principle of informed consent becomes apparent at an early stage of the research project – that of access to the institution or organization where the research is to be conducted and acceptance by those whose permission is needed before embarking on the task. Early access and acceptance offers the best opportunity for researchers to present their credentials as serious investigators and establish their own ethical position with respect to their proposed research.

Investigators cannot expect access as a matter of right. They have to demonstrate that they are worthy, as researchers and human beings, of being accorded the facilities needed to carry out their investigations. The advice of Bell (1991, p. 37) is to gain permission early on, with fully informed consent, indicating to participants the possible benefits of the research.

The first stage involves the gaining of official permission to undertake one's research in the target community. This will mean contacting, in person or in writing, an appropriate official, for example, the headteacher/principal. At a later point, significant figures who will be responsible for, or assist in, the organization and administration of the research will also need to be contacted – the deputy head or senior teacher, for instance, and certainly the class teacher if children are to be involved in the research. Since the researcher's potential for intrusion and perhaps disruption is considerable, amicable relations should be fostered as expeditiously as possible. If the investigation involves teachers as participants, propositions may have to be put to the stakeholders and conditions negotiated. Where the research is to take place in another kind of institution, the approach will be similar, although the organizational structure will be different.

Achieving goodwill and cooperation is especially important where the proposed research extends over a period of time: days, perhaps months in the case of an ethnographic study, or perhaps years where longitudinal research is involved. Access does not present quite such a problem when, for example, a one-off survey requires respondents to give up half-an-hour of their time or when a researcher is normally a member of the organization in which the research is taking place (an insider), though in the case of the latter, it may be unwise to take cooperation for granted. Where research procedures are extensive and complicated, however, or where the design is developmental or longitudinal, or where researchers are not normally based in the target community, problems of access are more involved and require greater preparation.

Having identified the official and significant figures whose permission must be sought, and before actually meeting them, researchers will need to clarify in their own minds the precise nature and scope of their research. They should have a total picture of what it all entails, even if the overall scheme is a provisional one (though we have to bear in mind that this may cause difficulties later). In this respect researchers could, for instance, identify: the aims of the research and its practical applications, if any; the design, methods and procedures to be used; the nature and size of samples or groups; what tests are to be administered and how; what activities are to be observed; which participants are to be interviewed; observational needs; the time involved; the degree of disruption and intervention envisaged; arrangements to guarantee confidentiality with respect to data (where necessary); the role of feedback and how findings can best be disseminated; the overall timetable within which the research is to be encompassed; and whether assistance will be required in the organization and administration of the research.

By such planning and foresight, both researchers and institutions will have a good idea of the demands likely to be made on both participants and organizations. It is also a good opportunity to anticipate and resolve likely problems, for example, those of a practical kind. A long, complicated questionnaire, for example, may place undue demands on the comprehension skills and attention spans of a particular class of nine-year-olds, or a relatively inexperienced teacher could feel threatened by sustained research scrutiny. Once this kind of issue has been resolved, researchers will be in a stronger position to discuss their proposed plans in an informed, open and frank manner (though not necessarily too open, see below) and may thereby more readily gain permission, acceptance and support. It must be remembered that hosts will have perceptions

of researchers and their intentions and that these need to be positive. Researchers can best influence such perceptions by presenting themselves as competent, trustworthy and accommodating.

Once this preliminary information has been collected, researchers are duly prepared for the next stage: making actual contact in person, perhaps after an introductory letter, telephone call or email, with appropriate people in the organization with a view to negotiating access. If the research is university-based, they will have the support of their university (and, where relevant, their supervisor). Festinger and Katz (1966) consider that there is real economy in going to the very top of the organization or system in question to obtain assent and cooperation. This is particularly so where the structure is clearly hierarchical and where lower levels are always dependent on their superiors. They consider it likely that the nature of the research will be referred to the top of the organization sooner or later, and that there is a much better chance of a favourable decision if leaders are consulted at the outset. It may also be the case that heads will be more open-minded than those lower down, who, because of insecurity, may be less cooperative.

The authors also warn against using the easiest entrances into the organization when seeking permission; researchers may perhaps seek to come in as allies of individuals or groups who have a special interest to exploit and who see research as a means to their ends, rather than entering the situation in the common interests of all parties, with findings equally available to all groups and persons. Investigators should seek as broad a basis for their support as possible. Other potential problems may be circumvented by making use of accepted channels of communication in the institution or organization. Festinger and Katz (1966) caution that if information is limited to a single channel then the study risks becoming identified with the interests that are associated with that channel.

Following contact, there is likely to be a negotiation process. At this point researchers will give as much information about the aims, nature and procedures of the research as is appropriate. This is very important: information that may prejudice the results of the investigation may have to be withheld. Aronson and Carlsmith (1969), for instance, note that one cannot imagine researchers who are studying the effects of group pressure on conformity announcing their intentions in advance. On the other hand, researchers may find themselves on dangerous ground if they go to the extreme of maintaining a 'conspiracy of silence', because, as Festinger and Katz (1966) note, such a stance is hard to keep up if the research is extensive and lasts over several days or weeks, and trying to preserve secrecy might lead to an increase in the spread and wildness of rumours. If researchers do not want their potential hosts and/or participants to know too much about specific hypotheses and objectives, then a way forward is to present an explicit statement at a fairly general level with one or two examples of items that may not be crucial to the study as a whole, though whether this constitutes deception is, itself, an ethical dilemma.

As most research entails some risks, especially where field studies are concerned, and as the presence of an observer scrutinizing various aspects of community or school life may not be relished by all in the group, investigators must at all times manifest a sensitive appreciation of their hosts' and participants' position and reassure anyone who feels threatened by the work. Such reassurance could take the form of a statement of conditions and guarantees given by researchers at this negotiation stage. By way of illustration, Box 7.4 contains conditions laid down for the Open University students' school-based research project.

At the stage of access and acceptance, situated ethics will determine what is acceptable and what is not acceptable.

BOX 7.4 CONDITIONS AND GUARANTEES PROFFERED FOR A SCHOOL-BASED RESEARCH PROJECT

1. All participants must be given the chance to remain anonymous.
2. All data must be given strict confidentiality.
3. Interviewees should have the chance to verify statements at the stage of drafting the report (respondent validation).
4. Participants should be given a copy of the final report.
5. Permission for publication must be gained from the participants.
6. If possible, the research report should be of benefit to the school and participants.

Source: Adapted from Bell (1991)

BOX 7.5 NEGOTIATING ACCESS CHECKLIST

1. Clear official channels by formally requesting permission to carry out your investigation as soon as you have an agreed project outline.
2. Speak to the people who will be asked to cooperate.
3. Submit the project outline to the head, if you are carrying out a study in your or another educational institution.
4. Decide what you mean by anonymity and confidentiality.
5. Decide whether participants will receive a copy of the report and/or see drafts or interview transcripts. There are cost and time implications. Think carefully before you make promises.
6. Inform participants what is to be done with the information they provide.
7. Prepare an outline of intentions and conditions under which the study will be carried out to hand to the participants.
8. Be honest about the purpose of the study and about the conditions of the research. If you say an interview will last ten minutes, you will break faith if it lasts an hour. If you are conducting the investigation as part of a degree or diploma course, say so.
9. Remember that people who agree to help are doing you a favour. Letters of thanks should be sent, no matter how busy you are.
10. Never assume 'it will be all right'. Negotiating access is an important stage in your investigation. If you are an inside researcher, you will have to live with your mistakes, so take care.

Source: Adapted from Bell (1991)

A pilot study can be useful to judge the effects of a piece of research on participants (Oliver, 2003, p. 37). Where a pilot study is not feasible it may be possible to arrange one or two scouting forays to assess possible problems and risks. By way of summary, we refer the reader to Box 7.5.

Access may not be a once-and-for-all matter. For instance, in longitudinal studies, say of a school, access may become a problem if the researcher encounters new students, new parents and new staff, and access may have to be renegotiated (cf. Brooks *et al*., 2014, p. 157).

7.14 Power and position

The researcher is often seen to be, or is, in an asymmetric position of power with regard to the participants; the former may have more power than the latter, be this by status, position, knowledge, role or whatever. The researcher typically determines the agenda, the timing and duration of the research and, for example, interviews, what counts as acceptable and useful data, to whom the data are released, who might or might not be identifiable, and so on. As Brooks *et al*. (2014) remark, 'power relations are immanent in all research settings' (p. 106), and researchers may occupy different social and power positions from participants.

This is particularly the case when researching with children, as they are more vulnerable and, in many settings, more powerless than adults or researchers. For example, Morrison (2013a) reports on interviewing children in a situation in which: there were strong asymmetries of power and age; the agenda was decided by evaluators-as-interviewers; and semi-structured qualitative interviews operated in a strongly focused and question-and-answer style (pp. 320–1). He reports several strategies used to overcome the strangeness of the situation and the power differentials, to put students at ease and treat them as important, indeed to make the interviews 'a positive and enjoyable experience for the children', so that they would leave the interviews 'feeling positive about themselves and the interviews' (p. 321) (see also Chapter 25 on interviewing children).

One typical response to asymmetries of power is to try to reduce the power differentials, enabling participants to have power over decision making in the research. However, researchers have to consider the limits of this; Hammersley and Traianou (2012), for example, ask whether rapists and paedophiles should be accorded equal powers to the researcher (p. 82). Another is to establish rapport and trust, which might take the form of ensuring a match between the characteristics of the researcher and the participants (e.g. age, gender, ethnicity, language, background, biography etc.). This might be particularly important in researching minority or marginalized, excluded groups, i.e. those with limited perceived agency or power (Brooks *et al*., 2014, pp. 112–13).

Hochschild (2012) notes that 'emotion work' in research involves dealing with the emotions of others and, as part of this, requires researchers to keep their own true emotions in check, to some extent setting aside their own emotions in handling those of participants. They must be emotionally detached yet friendly and positive, and in the research situation, particularly, for example, in-depth interviews about sensitive matters, this requires an ability to be empathetic and suitably informal and yet formal. Hammersley and Traianou (2012) note that researchers may have to be prepared to tolerate behaviour, attitudes and opinions that they personally detest or find unacceptable (p. 55) in order to conduct valuable and valid research.

Researchers, then, have to be acutely aware of possible or likely asymmetries of power and take appropriate steps to address the ethical issues that such awareness raises.

7.15 Reciprocity

Reciprocity means giving or giving back something to the participants in the research in return for their participation. Researchers should never lose sight of the obligations they owe to those who are helping; an ethical matter.

Sikes (2006, p. 112) quotes the words of Lather (1986) in describing 'rape research' as 'research in which the researcher gets what they want and then clears off, giving little or nothing in return and maybe even causing damage' (see also Reinharz, 1979). This is unethical. Similarly, Laing (1967, p. 53) reminds us that 'data' are 'things that are given' – gifts – rather than 'things that are captured' (i.e. 'data' rather than '*capta*'). The researcher has some obligation to give something back to the participants.

A researcher may gain promotion, publications, a degree, research sponsorship and celebrity from a piece of research. However, the research might still leave the participants untouched, underprivileged, living and working in squalid and under-resourced conditions, under-supported and with no material, educational or other improvements brought to the quality of their lives and work. As one of Whyte's contacts remarked ruefully in his celebrated study of an Italian slum in *Street Corner Society* (1955), the locals had helped many researchers to become famous and get their doctorates, though leaving the locals' quality of life with no improvement (see also Willis and Saunders (2007, p. 96), reporting on indigenous populations who had been incessantly and minutely interrogated by outside 'experts' and left impoverished).

Baumrind (1964) warns of the possible failure on the researchers' part to perceive a positive indebtedness to their participants for their services, perhaps because the detachment which investigators bring to their task prevents appreciation of participants as individuals. This kind of omission can be averted if the researchers are prepared to spend a few minutes with participants afterwards in order to thank them for their participation, answer their questions, reassure them that they did well and generally talk to them for a time.

The issue is also raised here of whether participants should be given inducements to participate, for example, payment, gifts or the opportunity to enter a 'lucky draw'. A different kind of inducement to participate may be in the form of advice to participants or, for example, educational advice to parents. On the one hand, the argument runs that any kind of material inducement distorts a genuine relationship between the researcher and the participants, such that participants may say something or join the research because they will be paid for it, or may give perfunctory information just to be able to obtain the reward, and whose commitment is actually very small. On the other hand, participants are giving their time and effort to the research, so they should be paid for it, just as in other kinds of work (cf. Oliver, 2003, pp. 23, 59). Head (2009) notes that paying participants is widespread in medical and psychological research, indeed is ethically desirable in equalizing (power) relationships between researcher and participants, and it can apply to qualitative research as well, as it encourages participation and response rates. Payment should be commensurate with the amount of time and effort expended, and should not be coercive or corrupting (pp. 340–3).

Brooks *et al*. (2014) suggest that it may be acceptable to offer some incentives, but not to the extent that this is likely to distort the research or to have participants who join the research for the sake of receiving the incentive on offer (p. 97). On the other hand, they note that inducements may discourage participation, depending on what those inducements might be, for example, some parents may not wish to have meal vouchers as they would be seen as being in need of such vouchers and, hence, embarrassed (pp. 98–9). They also raise the question of to whom to offer the incentives, for example, the child, the parents, the school (p. 97).

7.16 Ethics in data analysis

Data analysis must be ethical. It must not mis-present findings or the phenomenon itself, and such misrepresentation can happen in many ways, for example:

- using inappropriate data-analysis techniques;
- being unfairly selective with regard to the data used;
- falsifying and making up data;
- ignoring, omitting or concealing data that do not 'fit' what the researcher wishes to show, or using data to support a preconceived or preferred view;
- being unfair to the data and what they show, for example, misrepresenting what the data are saying or showing;
- overstating and understating what the data show, and over-interpreting data and pieces of data;
- giving undue weight and priority to some data;
- projecting one's own values onto the data, and presenting the researcher's own views and own preferred frameworks for data analysis which distort the analysis;
- using inappropriate statistics, or collapsing, over-reducing and over-summarizing data;
- selecting statistics which show the situation in a better or worse light than is really the case;
- ignoring outliers;
- making the false claim that large samples prove reliability and validity;
- making false claims of causality;
- failing to exert suitable controls in the data analysis;
- breaching the ethical requirements of confidentiality and anonymity (e.g. in visual data);
- editing out items in visual data (cropping and recolouring);
- failing to give sufficient 'voice' to participants, for example, in qualitative research;
- making false, exaggerated, sensationalized, scandalized and unsubstantiated claims from the data;
- failing to consider rival interpretations and explanations of the findings;
- judging rather than analysing the data.

Whilst it is almost impossible for researchers to free themselves from their values and perspective in a post-positivist era, and indeed there may be unintentional breaches of ethics, researchers must be vigilant, very self-aware and reflexive in their data analysis. It is not true, for example, that statistics are self-justifying: the researcher has immense control over which statistics to use and what they might or might not show. Further, in mixed methods research different sample sizes may be used, and care has to be exercised not to focus too heavily on large samples to the detriment of small samples (Creswell, 2012, p. 553).

Ethics also features in discussions of ownership of the data, for example, when the ownership passes from the participants to the researcher and with what constraints, requirements, conditions and powers over the use and dissemination of the findings required by the participants (cf. Howe and Moses, 1999, p. 43; Brooks *et al*., 2014). Researchers need to be clear whether they own the data once the data have been given, or whether the participants have control over what is released and to whom; this should be agreed, where possible, before the research commences. Oliver (2003, p. 63), for example, argues that the raw data are still the property of the participants, but once the data have been analysed and interpreted, they become the property of the researcher. This is unclear, however, as it does not cover, for example, observational data, field notes and the like, which are written by the researcher, though often about other people. Negotiating ownership rights, rights to release or withdraw data, rights to control access to data, rights to verify and validate data, rights to vet data or see interim or incomplete or uncompleted reports, rights to select data and decide on their representativeness, rights to own or change the final report and rights to retain data after the research (e.g. for other purposes, as in the ongoing compilation of a longitudinal or comparative study) moves the conduct of research beyond being a mechanical exercise to being an ethical exercise (cf. Oliver, 2003, pp. 63–5).

Disclosure and data usage

The researcher will frequently find that disclosure impinges on methodological and ethical issues (Hitchcock and Hughes, 1989). They pose questions that may arise in such a situation. 'Where, for the researcher, does formal observation end and informal observation begin?' 'Is it justifiable to be open with some teachers and closed with others?' 'How much can the researcher tell the students about a particular piece of research?' 'When is a casual conversation part of the research data and when is it not?' 'Is gossip legitimate data and can the researcher ethically use material that has been passed on in confidence?' The list of questions is endless yet they can be related to the nature of both the research technique involved and the social organization of the setting being investigated. One key to the successful resolution of such questions may lie in establishing good relations, involving the development of a sense of rapport between researchers and participants that leads to feelings of trust and confidence.

Finch (1985, pp. 116–17) comments on the possibly acute political and ethical dilemmas arising from how data are used, both by the researcher and others, and the researcher has a duty of trust placed in him/her by the participants to use privileged data appropriately, not least for improvement of the condition of the participants.

BOX 7.6 ETHICAL PRINCIPLES FOR THE GUIDANCE OF ACTION RESEARCHERS

Observe protocol: Ensure that the relevant persons, committees and authorities have been consulted, informed and that the necessary approvals/permissions have been obtained.
Involve participants: Encourage potential stakeholders in the improvement to be involved in the project.
Negotiate with those affected: Take account of the responsibilities and wishes of participants, as not all of them may wish to be involved directly.

Report progress: Keep the work visible and be open to suggestions, to take account of unforeseen and unseen implications or outcomes; enable colleagues to have the opportunity to challenge or lodge a protest.
Obtain explicit authorizations: For example, if you wish to observe your colleagues and/or examine documents.

Negotiate descriptions of people's work: Always enable those described or identified in the research to challenge your accounts, for example, on grounds of fairness, relevance and accuracy.
Negotiate accounts of others' points of view (e.g. in accounts of communication): Enable participants in interviews, meetings and written exchanges to require amendments which improve fairness, relevance and accuracy.

Obtain explicit authorization before using quotations: For example, in using verbatim transcripts, attributed observations, excerpts of recordings (audio and video), judgements, conclusions or recommendations in reports.

Negotiate reports for various levels of release: Different audiences require different kinds of reports; what may suit an informal verbal report to a faculty meeting may not be suit a staff meeting, report to council, an academic article, a newspaper, a newsletter to parents; be conservative if it is not possible to control distribution.

Accept responsibility for maintaining confidentiality.
Retain the right to report your work: Provided that participants in the research are satisfied with the fairness, accuracy and relevance of accounts which pertain to them, and that these accounts do not unnecessarily expose or embarrass them, the accounts should not be subject to veto or sheltered by claims of confidentiality.

Make your principles of procedure binding and known: All those involved in the action research project must agree to the principles before the project commences; others must be aware of their rights in the project.

Source: Adapted from Kemmis and McTaggart (1981)

Box 7.6 presents a set of ethical principles specially formulated for action researchers by Kemmis and McTaggart (1981) and quoted by Hopkins (1985).

7.17 Ethics in reporting and dissemination

As with data analysis, the researcher has an ethical duty to ensure that the results of the research are reported fairly, credibly and accurately, without misrepresentation, unfair selectivity (exclusion and inclusion, or inappropriate piecemeal reporting of different parts, e.g. in different journals) (Creswell, 2012, p. 279), plagiarism, untenable claims, exaggeration or understatement, misinterpretation, bias and under-reporting or over-reporting certain findings to the detriment of a more balanced and fair view. The reporting must be honest, true, fair and in a format that the audiences of the research will be able to access and understand (e.g. lay or professional audiences). Further, potential conflicts of interest must be disclosed (many ethics committees require this).

Attention must also be given to confidentiality, anonymity and non-traceability, and this might extend to obtaining informed consent for dissemination and disclosure, which, in turn, raises issues of what informed consent should include and for how long it applies. Will an external, internal or local audience be able to identify the participants and institutions in the research, particularly if it is possible to combine data, or should deliberate attempts be made to disguise individuals and institutions, even to the point of fabricating details in order to put audiences 'off the scent'? This is particularly an issue if the research reports negative findings concerning individuals, groups, institutions and communities, i.e. where the research might cause harm.

Here, as earlier in this chapter, the researcher faces again the issue of what is in the public interest versus what respects the participants' privacy (Pring, 2015). Whilst Pring (2015) suggests that there is a prima facie case for the public's right to know – which is why research is undertaken in the first place – and whilst this breaks down the secrecy that often surrounds institutions which, in fact, should be publicly accountable, he also notes that the truth can hurt. Whose interests does the dissemination of the research protect or threaten? How are beneficence and non-maleficence interpreted and addressed? Is it acceptable for some individuals to be harmed if the greater public good is being served (i.e. the deontological view versus the utilitarian view of ethics)? The Nuremberg Code, for example, expressly argues against harming individuals in the pursuit of societal benefit (Farrimond, 2013, p. 27). Should the researcher be judgemental, and, if so, how, in whose interests and at whose expense? Should the researcher inform participants in advance of what will be disseminated and offer them the right of veto, or are the data, once given, the property of the researcher? Such issues become challenging when, for example, negative findings and divided loyalties are at stake, or if the research findings and dissemination might operate against the interests of the individual, group or community in question. As Brooks *et al*. (2014, p. 140) note, it is the researcher who stands to gain the most from the research but this does not preclude a duty of care and respect for participants and communities, and negative findings often shout louder than positive findings. This extends not only to research reports but to the data themselves, for example, written and visual data (e.g. photographs, video material which identify people).

Morrison (2006) considers the case of a school that is under-performing, poorly managed or badly led. Does not the 'consumer', indeed the state, have a right or a duty respectively to know or address this, such action typically involving the exposure to the public of a school's shortcomings, and will this not damage individuals in the school, the principal and the teachers? What 'fiduciary trust' (Mitchell, 1993) not to harm individuals (the ethical issue of 'non-maleficence') does the researcher have to the school or to the public, and how can these two potentially contradictory demands be reconciled? Should the researcher expose the school's weaknesses, which almost certainly could damage individuals but which may be in the public interest, or, in the interests of *primum non nocere*, remain silent? The pursuit of truth and the pursuit of trust may run counter to each other (Kelly, 1985, p. 147); indeed Kelly herself writes that 'I do not think we have yet found a satisfactory way of resolving this dilemma'.

In reporting and disseminating the research, the researcher needs to consider, even anticipate, who the audiences will be and the likely or possible effects on them of the reporting and dissemination. The research is only one interpretation of the findings, and the researcher has to make this clear (being reflexive), i.e. other voices might speak differently about the research. Researchers have to be mindful that once the research is in the public domain, they have no control over how it will be used.

The participants' sensibilities need also to be taken into account when the researcher comes to write up and disseminate the research. It is unacceptable for researchers to show scant regard for participants' feelings at the report stage. A related issue concerns the formal recognition of those who have assisted in the investigation, if such be the case. This can be done in a foreword, introduction or footnote. This means that the authors must consider acknowledging and thanking all who helped in the research, identifying by name those whose contribution was significant, but not if such identification jeopardizes previously agreed confidentiality and anonymity.

Personal data are defined in law as those data which uniquely identify the individual providing them. When such information is publicized with names through the media, for example, privacy is seriously violated. The more people there are who can learn about the information, the more concern there must be about privacy. This extends to the archiving of data, which should consider the removal of details which can identify individuals and institutions, as Freedom of Information Acts might permit the public to access archived data held by individuals, institutions and associations.

The term 'betrayal' is often applied to those occasions where data disclosed in confidence are revealed publicly in such a way as to cause embarrassment, anxiety or suffering to the participant disclosing the information. It is a breach of trust, in contrast to confidentiality. As Plummer comments, 'there is something slightly awry when a sociologist can enter a group and a person's life for a lengthy period, learn their most closely guarded secrets, and then expose all in a critical light to the public' (Plummer, 1983, p. 146). How does one write an honest but critical report of teachers' attitudes if one hopes to continue to work with those involved, for example, in action research (Kelly, 1989)?

Finch (1985) raises ethical issues in the consequences of reporting. In her research she worried that her reporting

> could well mean that I was further reinforcing those assumptions deeply embedded in our culture and political life that working class women (especially the urban poor) are inadequate mothers and too incompetent to be able to organize facilities that most normal women could manage.
>
> (p. 117)

Indeed she uses the word 'betrayal' (p. 118) in her concern that she might be betraying the trust of the women with whom she had worked for three years, not least because they were in a far worse economic and personal state than she herself was.

Whilst some researchers may place an embargo on having their research made available to the public (e.g. for five years) in order to protect participants (cf. Sikes, 2006, p. 111), this calls into question the values, purposes and ethical justifiability of research that cannot be disseminated and hence 'cannot contribute to the cumulativeness of knowledge' (p. 111), the latter being a signal feature of research (Pring, 2015).

7.18 Responsibilities to sponsors, authors and the research community

The researcher has responsibilities, indeed in many situations, obligations, to different parties and to legal regulation (Ary *et al*., 2002, pp. 504–7): sponsors, participants, stakeholders, authors and the research community. The researcher has to consider responsibility to the sponsors, and, again, this may pose a dilemma between what is in the public interest versus what is in the private or institutional interest or the interest of the sponsor. Sponsors may wish to restrict, prevent or censor dissemination, or control who sees what, when and in what form, and this might challenge academic freedom and fidelity to the phenomenon being researched. The sponsor may not wish to be identified or, indeed, may deliberately seek to be identified. This is a matter that should be agreed before the research commences, in order to avoid challenges arising too late in the research.

In reporting, some authors will be concerned about the order of the authors' names in, for example, an article or book. Who is the first-named, principal author? Should a research supervisor's name be included simply because he or she requires this, even though he or she has made no substantive contribution to the research, or should the supervisor's name be included in an acknowledgement (cf. Brooks *et al*., 2014, p. 148)? What are the politics involved in placing authors' names in a particular order? What are the consequences for authors (e.g. with regard to career promotion)?

The researcher also has responsibilities to the research community, for example, not to jeopardize the reputation of the research community (e.g. the university) or spoil the opportunities for further research. A novice researcher working for a higher degree might approach a school directly, using a clumsy approach, with inadequate data-collection instruments and a poor research design, and then proceed to publicize the results as though they are valid and reliable. At the very least the novice should have sought and gained advice from the supervisor, modified the research as necessary, gained approval for the research, made suitably sensitive overtures to the school and agreed rights of disclosure. Not to do so puts the researcher's (or others') institution at risk of being denied further access, of damaging the reputation of the institution, and, if word spreads, of being publicly vilified and denied the opportunity for further research to be conducted. In this case the novice researcher has behaved unethically.

Further, if a negative research report is released, will schools retrench, preventing future research in schools from being undertaken? Negative research data, such as reported evidence on deliberate grade inflation by schools in order to preserve reputation (Morrison and Tang, 2002), may not endear researchers to schools.

The researcher has a responsibility to colleagues to:

- protect their safety (e.g. in conducting sensitive research or research in dangerous locations);
- protect their well-being;
- protect their reputation;
- enable further research to be conducted;
- expect them to behave ethically;
- ensure that they adhere to correct and agreed procedures;
- protect the anonymity and confidentiality of sponsors if so agreed.

However, these may conflict with the public's right to know. The researcher, too, is a member of a research community, and this brings ethical responsibilities.

7.19 Conclusion

In this chapter we have attempted to acquaint readers with some of the ethical difficulties they are likely to experience in the conduct of research. It is not possible to identify all potential ethical questions or adjudicate on what is correct researcher behaviour. We have demonstrated that ethical principles are open to contestation, differences of interpretation and conflicts

between them; the researcher has to consider how ethical principles inform the particular research or research situation. Ethical principles help to guide researchers and only rarely definitively prescribe or proscribe research matters. In other words, whilst the knowledge of ethical principles help in all aspects and stages of the research, nevertheless ethics are 'situated' and particular to a specific situation. It is for the researcher to decide how to address and apply ethical principles in coming to a decision on how to act in the

BOX 7.7 ETHICAL PRINCIPLES FOR EDUCATIONAL RESEARCH (TO BE AGREED *BEFORE* THE RESEARCH COMMENCES)

Responsibility to research

The researcher should be competent and aware of what is involved in conducting research.

The research must be conducted rigorously and with the correct procedures – avoid misuse of procedures at all stages.

Report procedures accurately and publicly (rigour).

Don't jeopardize future research(ers).

Report clearly and make data available for checking.

Tell the truth (do not tell lies or falsify data, avoid being unfairly selective, e.g. to support a case, do not misrepresent data).

Maintain the integrity and autonomy of the research, for example, avoid censorship of, or interference with, the research by sponsors/those who give permission for the research to be undertaken.

Responsibility to participants and audience(s)

Gain fully informed consent where appropriate (usually in writing), in order to respect self-determination and autonomy; provide information on all aspects of the research and its possible consequences.

Decide whether, and how, overt or covert research is required/justified.

Decide whether, and how, deception is required/justified; be honest or justify dishonesty.

Ensure non-maleficence (no harm, hurt or suffering to be caused to participants and those who might be affected by the research); be humane.

Ensure beneficence (the research will bring benefit to the participants or will contribute to the welfare of participants).

Ensure that participants do not leave the research worse off than when they started it.

Respect people's rights and dignity and interests, and be respectful – research participants are subjects, not objects to be exploited. Treat people as subjects, not objects.

Agree individual's rights to privacy.

Ensure participants have the right to withdraw at any time.

Inform participants about who will have access to the data/report, i.e. the audiences of the research, how public it will be, when it will become public and how it will be disseminated; negotiate levels of release (i.e. who will see which parts of the research).

Ensure anonymity/confidentiality/non-traceability; if these are not possible then tell participants in advance.

Indicate how anonymity will be addressed (e.g. by confidentiality, aggregation of data).

Inform participants how data will be collected and how files/questionnaires/audio data/video data/computer files will be stored during the research and destroyed after use.

Ensure sensitivity to people (e.g. age, ethnicity, gender, culture, religion, language, socio-economic status etc.).

Gain permission from all relevant parties (e.g. parents/guardians, school, principals etc.) for access.

Respect vulnerability (e.g. in interviewing children/those without power).

Agree respondent validation.

Agree ownership of the data (and when ownership passes from participants to researcher).

Allow time for review.

Avoid causing unnecessary offence. Thank the participants.

Ensure that participants and sponsors have the right to dissent/distance themselves from the research.

Demonstrate social responsibility and obligations.

Consider indemnification, liabilities and disclaimers.

Don't abuse your position/power as a researcher.

Don't use dangerous methods.

specific research in question. Such decisions almost inevitably involve compromises.

Although no code of practice can anticipate or resolve all problems, there is a sixfold advantage in fashioning a personal code of ethical practice. First, such a code establishes one as a member of the wider scientific community having a shared interest in its values and concerns. Second, a code of ethical practice makes researchers aware of their obligations to their participants and also to those problem areas where there is a general consensus about what is acceptable and what is not. In this sense it has clarificatory value. Third, when one's professional behaviour is guided by a principled code of ethics, it is possible to consider that there may be alternative ways of doing the same thing; ways that are more ethical or less unethical should one be confronted by a moral challenge. Fourth, a balanced code can be an important organizing factor in researchers' perceptions of the research situation, and as such may assist them in their need to anticipate and prepare. Fifth, a code of practice validated by their own sense of rightness will help researchers to develop an intuitive sensitivity that will be particularly helpful to them in dealing with the unknown and the unexpected, especially where methods such as ethnography and participant observation are concerned. And sixth, a code of practice will bring discipline to researchers' awareness. Here Box 7.7 raises considerations to be borne in mind in planning, conducting and reporting research.

Box 7.7 raises issues and suggestions, not solutions or decisions. These latter two have to be decided by each researcher in respect of the particular situation he or she faces. Ethics are 'situated'. For a summary of ethical principles for social research and other ethical issues explored in this chapter, we refer readers to the companion website.

Note

1 The word 'subjects' is ambiguous: contrasted with 'objects' it could be positive, according equal status and respect to the participants; on the other hand it could be negative in that participants are subjected to the wishes of the researchers ('subject' literally means 'thrown under' or 'thrown below').

Companion Website

The companion website to the book provides additional material and PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Ethics in Internet research

CHAPTER 8

The rise of Internet-based research, online research and virtual worlds has created a new site in which interactions take place between individuals and communities from ethically plural cultures and backgrounds. This raises many ethically ambiguous and contested issues which we introduce here. Many issues that we raise in Chapter 7 apply to Internet research, and we advise readers to review that chapter.

The following pages will explore:

- what Internet research is
- key ethical issues in Internet research
- informed consent
- public and private matters
- confidentiality and anonymity
- ethical codes for Internet research

8.1 What is Internet research?

Internet research is defined by Buchanan and Zimmer (2012) as that which uses the Internet to collect data using an online tool, or comprises studies of Internet use and how people use it, or which uses online datasets, databases or other materials (p. 2). Similarly the Association of Internet Researchers (2012) indicates that Internet research is that which:

a utilizes the Internet to collect data or information, e.g., through online interviews, surveys, archiving, or automated means of data scraping;
b studies how people use and access the Internet, e.g., through collecting and observing activities or participating on social network sites, listservs, websites, blogs, games, virtual worlds, or other online environments or contexts;
c utilizes or engages in data processing, analysis, or storage of datasets, databanks, and/or repositories available via the Internet;
d studies software, code, and Internet technologies;
e examines the design or structures of systems, interfaces, pages, and elements;
f employs visual and textual analysis, semiotic analysis, content analysis, or other methods of analysis to study the web and/or Internet-facilitated images, writings, and media forms;
g studies large-scale production, use, and regulation of the Internet by governments, industries, corporations, and military forces.

(Association of Internet Researchers, 2012, p. 3)

The British Psychological Society (2013) defines Internet research as 'any research involving the remote acquisition of data from or about human participants using the Internet and its associated technologies' (p. 3), which addresses both reactive and unobtrusive research. To assume homogeneity in Internet-based research is to misrepresent its diversity (Madge and O'Conner, 2005; Orton-Johnson, 2010).

Orton-Johnson (2010) and Jones (2011) note that the Internet is a tool, a means, a medium, a locale (a place to acquire and keep data), an object for research and a distribution channel for research. It includes data-collection instruments, web pages, chat rooms, blogs, email, discussion boards, virtual worlds, forums, social networking sites and pages, and so on – the list expands exponentially over time. It can enable unobtrusive research (where people do not know that their data are being collected, e.g. 'big data'; Beneito-Montagut, 2017) and intrusive research (where people are canvassed for their participation and/or data).

Whilst the Internet is global and not bounded by countries and territories, it operates differently in different jurisdictions and is regulated by differing laws in different parts of the world. Internet usage in research has exposed fissures in traditional conceptions of public and private spaces, and these, in turn, raise ongoing and emergent ethical questions. Indeed ethics has to play 'catch-up' in terms of online research (Convery and Cox, 2012).

8.2 What are key ethical issues in Internet research?

Internet research covers three main types (Farrimond, 2013): passive (the researcher is non-participant, e.g. studying data and sites on the Internet), active (researcher

is a participant, e.g. in an online community) and online traditional forms (e.g. surveys). Eysenbach and Till (2001) set out many key areas for ethical consideration in studying Internet communities: intrusiveness, perceived privacy, vulnerability, potential harm, informed consent, confidentiality and intellectual property rights. However, this is only a starting point, as Internet researchers must address the many issues that we raise below.

What do conventional conceptions of privacy, confidentiality, anonymity, ownership of intellectual property, vulnerability, harm, authenticity and informed consent really mean in a borderless world in which people are traceable yet never seen face-to-face, their data are tracked, recorded, aggregated, combined, stored indefinitely and interrogated without their knowledge, and where their private, even intimate, thoughts, communications and pictures are open to the public?

Buchanan and Ess (2009), surveying over 700 US ethics review boards, note that they were primarily concerned with matters of privacy, informed consent, confidentiality, security of data, and recruitment procedures. However, the field is wider than this. The Association of Internet Researchers (2012), Farrimond (2013), Barnes *et al*. (2015), Busher and James (2015), James and Busher (2015), Kontopoulou and Fox (2015), Roberts and Allen (2015), Stevens *et al*. (2015) suggest that ethical issues in Internet research have a huge embrace, here presented in alphabetical order:

- agency and the 'other' in online research (Busher and James, 2015, p. 170);
- beneficence and benefits (and for whom);
- blurring of online and real worlds: demarcation matters for privacy;
- combining online and face-to-face aspects of data collection, and the relationship between online and offline situations for participants and the researcher (Busher and James, 2015; James and Busher, 2015);
- conflicts of interest (where the researcher is a participant in an Internet group);
- consideration of online research by ethics committees;
- deontological and utilitarian issues;
- disclosure, data quality (e.g. representativeness of the sample) and veracity;
- ethical appraisal and approvals;
- the ethics of 'forced responses' (e.g. when a participant cannot proceed in a survey until all the questions on a screen have been answered);
- fairness;
- identity construction and protection, self-representation, authenticity, credibility and authentication;
- inapplicability of some traditional ethical guidelines and the rise of emergent challenges;
- informed consent, permissions and ensuring that participants know what they are consenting to, and the age of consent;
- keeping promises (fidelity);
- micro-celebrity status (Ramírez and Palu-ay, 2015, p. 146);
- opportunity for one participant to send in multiple completed online surveys;
- ownership of data and copyright concerns;
- power distribution, asymmetries of power and the need for justice;
- privacy, confidentiality and anonymity (e.g. the tracking of individuals online);
- private and public domains;
- privatized, deprivatized, semi-privatized, public, semi-public domains;
- questioning what counts as evidence;
- rapport in online research;
- reflexivity and transparency;
- representation;
- respondent validation;
- risk management, duty of care and protecting participants from harm and malicious intent;
- security;
- tensions between, and ambiguity in, private and public spheres;
- transparency;
- use of incentives;
- use of quotations that might be able to identify individuals through an internet search;
- uses of social media for research;
- virtual public spaces;
- visual data and their use.

These issues are addressed in our discussions that follow.

A twin guiding principle in Internet research, as with conventional research, is the avoidance of harm to people (non-maleficence) and the promotion of beneficence. The researcher must operate in what he or she considers are the best interests of participants. In this respect the rights of participants trump the rights or threats to the integrity of the research.

8.3 Informed consent

Informed consent is not straightforward in online research. For example, the researcher may not know who the actual person is who is answering, say, an online survey, and whether the details that they enter are honest and correct. How can informed consent be

gained from someone who is unseen and when there are no checks on whether the participant has understood the implications? Does one need consent from minors or their parents in online research? Can participants subsequently have their data withdrawn if they wish to withdraw from the research (Brooks *et al*., 2014, p. 93)? What if a person does not complete an online survey or withdraws from an ongoing piece of research: does the informed consent cease? And, anyway, how can the researcher trace which participants have given which data online?

Marshall and Rossman (2016, p. 183) note that researchers considering informed consent in Internet research face issues such as: whether, how much and in what sense and domains the data are public or private (who constitutes the research community); how sensitive the topics are; how much interaction will be required; the vulnerability of participants; and whether consent is actually necessary.

Seeking informed consent might come as an intrusive shock or a disruption to some participants, who had not realized that their data (e.g. from chat rooms, forums, social networking sites) were being monitored or collected. On the other hand, as with non-electronic research, covert research and deception might be justified in certain circumstances (Glaser *et al*., 2002), for example, where it is essential not to have informed consent for fear of 'blowing one's cover'. Indeed Denscombe (2014), reporting on Glaser's *et al*.'s (2002) study, notes that 'the respondents' statements were made in a public forum.… [T]he deception was absolutely necessary … and respondents' identities were carefully protected' (p. 322).

How easy, possible or realistic is it to obtain informed consent, and, if so, from whom (participants, parents, gatekeepers etc.)? How do we know that informed consent has really been given (Buchanan and Zimmer, 2012), when, for how long (e.g. in archived data), for what (use, and release, of data) and on whose behalf? It might be assumed that participants who complete an online survey, for example, are thereby giving consent, but have they really been informed about what they are consenting to and what might happen with the data? It may be that informed consent for Internet-based research has to be negotiated and renegotiated with participants over time as the research unfolds, and this may put off some participants.

Further, a researcher may not be able to identify a participant, such as, for example, in a survey conducted with non-disclosure of identifying details by the participant. Here informed consent is not possible, raising the question of whether the researcher uses or does not use the data (e.g. from chat rooms, forums, blogs, social networking sites)?

Ensuring informed consent may be obtained by requiring the researcher to provide information and asking participants to check an 'I accept' box, but this is akin to asking people to read the fine print of all the software that they download before checking the 'I accept' box, which typically they don't read. Some online research might ask participants to complete an 'I accept' box in a step-by-step staged process, whereby they are given some information on one sub-element or screen, to which they agree, and then later given information about the next sub-element or screen, to which they agree, and so on; this prevents the participant from being overwhelmed with too much information at once, but it may risk the participants dropping out if they are frequently having to check an 'I accept' box. Care must be taken to avoid long statements of information before checking a consent box, as participants may not read them. Some online research will place the consent box at the very end of, for example, the survey, so that participants know that they can draw back from sending data.

8.4 Public and private matters

Online ethical issues also arise in the context of 'big data'. With the rise of big data and online networking, data collection, storage and retrieval, tracing and tracking, the boundary between what constitutes public and private is called into question. Whilst it may bring benefits, big data also bring risks and problems as they touch almost every aspect of life (Mayer-Schönberger and Cukier, 2013; Beneito-Montagut, 2017). Using big data raises many ethical questions: privacy; traceability; ethics and accountability; surveillance; individual human agency, free will (e.g. in opting out of being traced) and responsibility; informed consent; the use and re-use of data that are stored about us; ownership of data; the threats to anonymity from re-identification of people by combining data; and the dangers of propensity analysis in judging risk and in making predictions, fair judgements and decisions about individuals (Collmann and Matei, 2016). As Mayer-Schönberger and Cukier (2013) remark, big data can 'paralyze privacy' (p. 152).

On the one hand, big data are useful (Beneito-Montagut, 2017). For example, data sets on school and student performance, attendance, grade retention and repetition, dropout, student evaluations of teaching, added value, socio-economic indicators and so on are widely used. On the other hand, this raises major questions of privacy and confidentiality, which we explore below (see also the Council for Big Data, Ethics and Society: http://bdes.datasociety.net).

It is not only in the sphere of big data that issues of ethics and privacy are raised. The Internet has spawned a raft of issues concerning privacy in research, and we introduce these here. The matter does not stop at the level of individuals. As metadata, social networking and social networking analysis are increasingly being used in research, individuals, groups, institutions and a range of other parties are caught in the debate about what constitutes legitimate and illegitimate use of electronic data. Here we focus on issues of privacy.

Solove (2004) notes that, with the rise of 'digital dossiers' and electronic data storage in many forms, the issue of privacy has come into prominence, that 'privacy is dead' (p. 73) and that people should no longer expect it in many areas that previously had been deemed private (p. 225). Indeed he quotes the CEO of Sun Microsystems as saying that there is 'zero privacy. Get over it' (p. 224) and that a new legal architecture is required to address the new, non-privacy environment. Nonetheless, privacy must still be respected, and he sets out several ways of addressing it.

Van den Hoven (1997) identifies key issues in 'privacy moral wrong-doing in an information age' (p. 33), which include: (a) the *tension between privacy, anonymity and the public good* in panoptic technologies; (b) the risk of *harm* from access to, and use of, personal information; (c) the issue of *inequality*, wherein when people use ICT they divulge not only personal information but data which are useful to organizations but to the use of which the person has not consented (van den Hoven gives an example in that each time a customer buys something they also have something to sell, namely, purchasing information (p. 35)); (d) *injustice* (e.g. discrimination and loss of agency in educational opportunity based on information from medical data stored electronically); and (e) *encroachment on moral autonomy* which occurs when privacy is compromised (or indeed shared in social networking) even with data protection laws in place.

Solove (2006) sets out a 'taxonomy of privacy' which can be applied to Internet research:

- information collection: surveillance; interrogation (probing for information);
- information processing: aggregation (combining data about a person); identification; insecurity (improper access and information leaks); secondary use (information collected for one purpose being used without consent for another purpose); exclusion (failure to inform the person that data on them is held by others and failure to involve the person in the use of such data);
- information dissemination: breach of confidentiality; disclosure (of information that affects how others judge a person's character); exposure (e.g. of bodily functions, nudity, grief); increased accessibility; blackmail (threat to disclose information); appropriation (use of a person's identity to serve the purposes or interests of another person); distortion (spreading false or misleading information about a person);
- invasion: intrusion (into a person's solitude or tranquillity); decisional interference (governmental incursion into a person's decision on private matters).

As this taxonomy indicates, the boundaries between public and private spaces are blurred in online research (e.g. Rosenberg, 2010; Brooks *et al*., 2014), and this creates challenges for informed consent. Bruckman (2004) notes that public/private spaces are not a simple binary matter – one or the other – but are a question of degree. Indeed different cultures have different conceptions of what constitutes 'public' and 'private' (Association of Internet Researchers, 2012). This links closely to the issue of informed consent. Are postings, blogs and social networking data public or private? For example, Denzin (1999) suggests that postings on bulletin boards are automatically public and so do not need informed consent for use by researchers, but is this so, and does this extend to traceability, and, if so, should not informed consent be obtained? Is the expropriation of online data for research purposes acceptable simply because it has been posted online?

How private should documents and data be, and is it ethical to use data that were not originally posted for research or public usage, for example, blogs, web pages, discussion forums, chat rooms (Denscombe, 2014, p. 321); has copyright been breached (p. 323)? Hudson and Bruckman (2005, p. 298) suggest that 'people in public, online environments often act as if these environments were private', and that they feel that their privacy has been violated if data from public chat rooms are used for research purposes, even though the data cannot not be traced back to participants.

Some data are unproblematically public, for example, national archives, publications, etc. Some may require passwords and this may require researchers to agree to 'cookies' being deposited on their computer, rendering them traceable. However, it is unclear whether other places are public or private. Is a chat room a private or a public place, or, perhaps, a semi-private space? Is an online forum a private space for members of the 'community' in question or a public space?

Rosenberg (2010) suggests that public data are those which can be accessed freely by anyone through the Internet and private if 'they are perceived as private by participants' (p. 24), in which latter case they may not be intended for public use, even if the public can access them. Like a public park, a virtual place (e.g. a cafe) can appear to be a public place, but it may be a parochial place (used by groups) or even a private place (e.g. used by clubs or parties, couples for a private conversation etc.) (cf. Rosenberg, 2010, pp. 33–4).

The researcher, then, has to decide how the participants view the space and what expectations and intentions they may have for privacy (cf. Denscombe, 2014, p. 321): public, private or somewhere in between. Simply because it is a public place does not make what happens in it completely public, in terms of both access to, and release of, information (and who is the audience of such data), and simply appropriating content because it happens to be public or accessible is ethically questionable.

Is a private communication 'fair game' for public access or researcher use, without consent? What constitutes 'private information' is blurred in Internet research. For example, it may be that in which a person can reasonably expect the context to be such that no observation, recording, monitoring or data collection is taking place or in which the individual can reasonably expect the information not to be made public (e.g. medical or financial records). However, the Internet and the tracking and searching, indeed hacking, which may accompany it pose threats to this conception of private information. Social networking sites are clear instances of this ambiguity: the data are publicly viewable, so does this mean that they are no longer private information, or only for 'friends', or for researchers, unseen or visible?

James and Busher (2007) argue that online research poses difficult issues of confirming the authenticity of respondents and responses, and of protecting the privacy of vulnerable groups, confidentiality and anonymity, particularly if emails are being used, as these are susceptible to others' viewing them either deliberately or accidentally (e.g. if mails are forwarded or shared). Further, there is a possibility that online correspondents may or may not distort their stated views, or, indeed, withhold them (p. 107), in ways that may not be so likely in face-to-face research. People may not be honest in reporting personal details; they may create avatars that have little relationship to their true selves.

Privacy and its protection include confidentiality of data and people, and this is particularly the case in sensitive Internet research or research which may bring harm or embarrassment to individuals if their identities are disclosed (and cyber-bullying and cyber-stalking are examples of this). Indeed privacy is a matter of legislation in many jurisdictions.

Privacy can be addressed by, for example, scrubbing data to remove all personal identifying material, or by providing restricted access and anonymity in the data-collection process, or by using pseudonyms, or by using encryption techniques (though some jurisdictions consider encryption to be illegal). However, as the network is not owned by, or under the control of, the researcher, scrubbing out and stripping out all potential identifiers to ensure anonymity and confidentiality may still not give an absolute guarantee that people may not be traced (Ohm, 2009). Using pseudonyms may not guarantee anonymity, not least as people use pseudonyms that describe themselves.

If researchers feel that the participants expect the data to be private, then this may raise requirements of confidentiality, anonymity, privacy and what may be made public. Just because a participant wants the data to be kept private, should those data be kept private? This raises the issue of the importance of establishing rapport and trust between the researcher and the participants. Lewis (2006), for example, took five months to establish such a relationship of trust, and he developed this relationship with his participants as a member of an online community before he approached them to participate in his research.

Whilst data protection is subject to legislation, the issue for Internet research is that, as data can be accessed from different jurisdictions, that legislation may not apply in countries outside those in which the data are generated or stored; this is a familiar issue in the protection of intellectual property.

8.5 Confidentiality and anonymity

Privacy, confidentiality and anonymity are linked in Internet research. Anonymity is where not even the researcher knows who the person is, and confidentiality is where the researcher knows but nobody else knows or is allowed to know. Researchers must consider whether, and how, to address confidentiality and anonymity in Internet research. On the one hand, not to acknowledge data sources could be deemed an infringement of copyright, even theft of intellectual property, but on the other hand such disclosure might breach participants' important right to protection from harm (Barnes, 2004).

Given that data and IP addresses are stored on networks and clouds which are not owned or controlled by the researcher but for which the researcher has a

duty of 'stewardship' (Buchanan and Zimmer, 2012), it may be impossible to guarantee anonymity and confidentiality. Indeed, combining data may relatively easily enable individuals to be 're-identified' (Ohm, 2009; Association of Internet Researchers, 2012) even in would-be anonymized data. Further, some online data-collection instruments indicate, for example, in the introductory statements to the software, that the provider owns the data, and many people do not read the small print before checking the 'I agree' or 'I accept' box. As data are held in electronic form, the software used may not permanently destroy deleted data, as 'the system' automatically keeps a digital record, which is, for example, in the permanent or semi-permanent records held by Internet companies of searches performed by individuals, or data that are entered on 'cloud' computing sites. The implications here are that it may be incorrect to promise that the data will be permanently destroyed, or, indeed, that hackers may not be able to break into the data (Marshall and Rossman, 2016, p. 182).

As it may not be possible to guarantee complete confidentiality and anonymity, and as traceability may be possible in the Internet, it is important to ensure that permissions, where required, have been given for data to be used. For example, Zimmer (2010) reports a study where, despite many precautions taken in good faith to protect ethics of consent, privacy, confidentiality, non-identifiability, personal information, non-traceability and access, including clearance by institutional review boards, nevertheless identification was uncovered easily and quickly.

In going online, there is the risk that participants may be prey to predatory Internet users. How is the protection from maleficence addressed? Researchers may need to consider how to protect participants from cyber-bullying or too-public disclosure.

A related issue in online research concerns the recruitment of participants. There is a need for researchers to establish not only their own bona fide status but that of their correspondents. This raises issues of authenticity and how to judge it (James and Busher, 2007) and the authentication of the participant's identity (a particular challenge if minors are involved, as this raises matters of legality and informed consent and the age of consent, which may differ in different jurisdictions). Further, it raises issues of anonymity, privacy and confidentiality, who is actually involved in the research (for example, is the same person completing an entire survey), or whether the research participants are operating in the environment with similar levels of control. Some software sites for research (e.g. surveys) may store cookies onto IP addresses, and this reduces the protection of privacy and confidentiality.

8.6 Ethical codes for Internet research

Many organizations have produced codes of ethics for online and Internet research. These also complement and refer to legal regulations and requirements. We give some examples below, interspersed with references to other studies on relevant ethical matters.

An early statement of research ethics, as indicated in Chapter 7, was the Belmont Report (National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, 1979), which identified three key principles: respect for persons, beneficence and justice. Buchanan and Zimmer (2012) note that the focus of much computer security research concerns the prevention of harm to humans (p. 6). But what, exactly, is meant by a human subject (see also the Association of Internet Researchers, 2012), as the Internet, as mentioned earlier, enables people to assume different identities, to create avatars and virtual persons?

The British Psychological Society's (BPS) *Ethics Guidelines for Internet-mediated Research* (British Psychological Society, 2013) identifies four key principles (p. 5):

- respect for the autonomy and dignity of persons (covering the public/private distinction, confidentiality and anonymity, copyright, valid consent, withdrawal and debriefing);
- scientific value (including levels of control);
- social responsibility (including disrupting social structures);
- maximizing benefits and minimizing harm.

The BPS, whilst recognizing that there is a blurring of the public/private domains, and that there are differing opinions on what the boundaries of these are, those data which are readily accessible by anyone, or those data in which there is no expectation of privacy, can be considered public and no consent may be justifiable. However, where there is ambiguity, the researcher must consider the possible damaging effects on participants of undisclosed observations or those without informed consent and this may require consent, confidentiality and/or anonymity.

'Valid consent', the BPS document contends, should be obtained where it cannot be reasonably assumed that the data are public (2013, p. 8), and it recognizes that this might be problematic if the data are anonymous

(e.g. questionnaires, though completing a questionnaire might be a fair proxy for consent). Consent statements with a check box can be used, and radio buttons can be used to try to ensure that participants have read and consented (though this is no guarantee that they have read such statements). Similarly, 'exit' and 'withdraw' radio buttons can be used, and these can link to a debriefing button once the participant has completed, exited or withdrawn.

The BPS recognizes that it may be impossible to guarantee confidentiality, as researchers do not have control over the network, and email, particularly unencrypted email, is not secure. Further, as mentioned earlier, it is possible to track down an individual's IP address from forums, chat rooms, blogs, postings and verbatim quotations. Indeed researchers must ask themselves whether they need consent to use or publish such verbatim quotations. 'Consequential risk' (Williams, 2012) of harm from, say, using quotations from people should be considered, and even identifying and publishing websites might be risky to individuals or communities (p. 18).

With regard to 'scientific value', the BPS notes that researchers must address issues of control: who has access to participate; the 'environmental conditions under which the participants are responding' (2013, p. 14); participants' feelings and reactions; and variations in the research brought about by different hardware and software that the participants are using. This echoes Williams (2012), who argues that lack of controls is a serious problem for researchers, including knowing who is completing the online survey (and whether it is the same person throughout) (p. 2). Control must also be in place to prevent repeat submissions (some online survey software already builds in such checks and preventions). Similarly, with regard to maximizing benefits and minimizing harm, the researcher must take steps to ensure the protection of minors (e.g. in informed consent) and verifying identity. Williams (2012) notes that often it is teenagers who not only use social networking most but are most at risk from being harmed and traced by it, not least because they may not realize that they are being monitored unobtrusively; they may also be subject to cyber-bullying (pp. 3–4). It may be necessary to avoid situations where researcher controls are so few that there is a real risk of harm to participants.

'Social responsibility' concerns beneficence and the betterment of society. This extends to covert research, and Orton-Johnson (2010) notes that it is relatively easy to conduct covert research on the Internet. The researcher has to decide whether to use covert research (non-disclosure that he/she is a researcher, see Chapter 7). For example, some researchers may join online communities without disclosing the fact that, actually, they are doing so in order to obtain research data (Reynolds and de Zwart, 2010). Is this ethical? Should they disclose their intentions and seek permission to participate and make data public?

'Maximizing benefits and minimizing harm' requires a risk assessment and an identification of the nature, duration, degree, severity, intensity, discomfort of risk and harm (physical, emotional, psychological, social etc.), how to address it, and how to balance it with possible benefits. We refer readers to the considerable discussion of this in Chapter 7. As mentioned in Chapter 7, the research must not leave participants worse off at the end of the research than they were at the beginning (non-maleficence); indeed maybe their own and others' lives should have been improved by participation (beneficence).

Ess and the Association of Internet Researchers (2002) set out ethical guidelines for researchers using the Internet for data collection and research, including:

- Do not assume that emails are secure.
- Ensure that nobody is harmed by the research.
- Enable participants to correspond in private if they wish.
- Indicate the steps taken to ensure privacy.
- Check where the communication comes from.
- Determine the most suitable online method of requesting and receiving informed consent.
- The greater the acknowledged publicity of the venue, the less obligation there may be to protect individual privacy, confidentiality and rights to informed consent.
- The greater is the vulnerability of the researcher to the participant, the greater is the obligation of the researcher to protect the participant.
- Indicate clearly how material will be used and whether or how it will be attributed, and whether data will be used verbatim, aggregated or summarized.
- Work within the framework of legal obligations of protection (e.g. data protection, privacy, copyright and libel laws).
- Indicate who has access to the communication, and whether it is private.
- Consider the possible outcomes to individuals if private data are made public.

Similarly, Gwartney (2007) argues for professional ethics to be respected, and she indicates websites that can provide guidance to researchers on this (p. 53), including codes of conduct, informed consent,

confidentiality, privacy, avoidance of harassment, email solicitation, active agent technology (e.g. behind-the-scenes data mining), installing software and setting cookies or hard-to-uninstall software, codes and standards for minimal disclosure, unsolicited telephone calls and setting up 'Do Not Call' lists, professional responsibilities in working with people. Additionally, Gwartney (2007) reproduces some of these ethical guidelines (pp. 57–69).

More recently, the Association of Internet Researchers (2012) provides a comprehensive set of guiding principles for ethical Internet research. These recognize the situated, contextual nature of ethical decision making, such that there may be no single set of judgements (no 'one-size-fits-all'; p. 4) which is universally applicable. Rather, researchers have to take ethical decisions on a case-by-case, casuistic basis (p. 7) (see the discussion of this in Chapter 7). The Association's 'key guiding principles' include:

- The greater the vulnerability of the community/author/participant, the greater the obligation of the researcher to protect the community/author/participant.
- Because all digital information at some point involves individual persons, consideration of principles related to research on human subjects may be necessary even if it is not immediately apparent how and where persons are involved in the research data.
- When making ethical decisions, researchers must balance the rights of subjects (as authors, as research participants, as people) with the social benefits of research and researchers' rights to conduct research. In different contexts the rights of subjects may outweigh the benefits of research.
- Ethical issues may arise and need to be addressed during all steps of the research process, from planning, research conduct, publication, and dissemination.
- Ethical decision-making is a deliberative process, and researchers should consult as many people and resources as possible in this process, including fellow researchers, people participating in or familiar with contexts/sites being studied, research review boards, ethics guidelines, published scholarship (within one's discipline but also in other disciplines), and, where applicable, legal precedent.

(Association of Internet Researchers, 2012, pp. 4–5)

The Association also recognizes that key considerations of potential harm, vulnerability, beneficence and respect for people apply throughout the research process (2012, p. 5). In keeping with its advocacy of a case-by-case approach to ethics, the Association raises some eighty questions that researchers can address in considering the ethics of their Internet research, including:

- How is the context defined?
- How is the content (venue/participants/data) being accessed?
- Who is involved in the study?
- What is the primary object of study?
- How are data managed, stored, and represented?
- How are texts/persons/data being studied?
- How are findings presented?
- What are the potential harms or risks associated with this study?
- What are the potential benefits associated with this study?
- How are we recognizing the autonomy of others and acknowledging that they are of equal worth to ourselves and should be treated so?
- What particular issues might arise around the issue of minors or vulnerable persons?

(Association of Internet Researchers, 2012, pp. 8–11)

The Association's document also provides a useful chart of types of data, venues and contexts, and commonly asked questions concerning ethical practice.

The UK's Economic and Social Research Council (2015) argues that risk assessment must include research involving 'social media and participants recruited or identified through the Internet, in particular when the understanding of privacy in these settings is contentious where sensitive issues are discussed' (p. 10). Further, whilst it defines differences between public and private domains, the former being those 'forums or spaces on the Internet that are intentionally public' (p. 12), it also argues that

> the public nature of any communication or information on the Internet or through social media should always be critically examined, and the identity of individuals protected, wherever possible, unless it is critical to the research, such as statements by public officials.
>
> (p. 12)

It also notes that social media users must abide by any regulations set out by those social media and data providers, and it offers a cautionary note that children and others 'may not understand the implications of what they are doing, and those harvesting data may also uncover illegal images or activities' (p. 12). Researchers, they comment, must consider issues of anonymity

in social media and place themselves in the shoes of the participants in considering whether the data from social media are in the public or private domains (p. 26).

8.7 Conclusion

An overriding principle is the double issue of non-maleficence and beneficence. It is easy to use the phrase 'do no harm'. However, as seen in this chapter and in Chapter 7, it is neither easy to define nor easy in practice, particularly where individual privacy may conflict with the public good. We have also noted the importance of addressing legal requirements and constraints. Further, this chapter has suggested that it is important for Internet researchers to take defensible decisions on many issues (e.g. Watson *et al*., 2007; Association of Internet Researchers, 2012; British Psychological Society, 2013), for example:

- decide whether the participants themselves consider the virtual community to be a public or private space and online data to be public or private, and to what degree. This might be informed by consideration of membership and membership access (e.g. whether it is open or restricted, a private, intimate group, stable membership). Give serious consideration to participants' expectations and perceptions;
- decide how to respect the autonomy and dignity of individuals;
- decide how to ensure the scientific value and control of the online research;
- decide whether or how much the research is overt, covert, obtrusive, unobtrusive, intrusive or non-intrusive, socially disruptive or non-disruptive, and justify the decision;
- decide the ethics of access to people and data (e.g. covert, overt, deception, intrusion, non-intrusion, intrusiveness, unobtrusiveness);
- decide whether and how to verify authenticity and identity;
- decide how to address privacy, confidentiality, anonymity and non-traceability;
- decide on removal of identifying data;
- decide the vulnerability of the group and the potential risk of harm to the participants (including minors and vulnerable people);
- decide how to address non-maleficence, beneficence and the minimization of harm;
- decide whether informed consent is required. If so, from whom, when, for what (from access to publication), for how long (including archived data), what constitutes 'valid consent' and 'informed', and how the consent will be obtained. If informed consent is not required, then such a decision must be defensible;
- decide how to address data removal if participants withdraw;
- decide how to address debriefing;
- decide how to establish a relation of trust with online contacts where appropriate (e.g. in ethnographic research);
- decide who owns the data, and for how long, and what are the intellectual property rights and responsibilities;
- decide how data will be stored and archived securely, and with what protections;
- decide how to report, disclose and disseminate the research ethically, with appropriate protections.

As can be seen, many of the issues listed above rehearse ethical challenges in everyday research, i.e. they are not exclusive to Internet and online research. However, careful attention needs to be given to these and how they are applied and interpreted in online research.

Companion Website

The companion website to the book provides PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Choosing a research project

CHAPTER 9

This chapter provides key decision points of reference on which researchers can reflect and plan, including:

- how to choose a research project
- the importance of the research
- the purposes of the research
- ensuring that the research can be conducted
- research questions
- the scope of the literature review
- a summary of key issues in choosing a research topic or project

This chapter concerns the selection of the research and initial, practical matters that researchers can address when choosing and deciding the project on which to work. It is the first of six consecutive chapters that concern the planning of research. This chapter concerns the selection of the research and the initial matters to address, whilst the subsequent chapters unpack several of these in greater detail. We draw not only from relevant literature but from our own experiences of supervising several hundred research students. Research is a practical activity, and the advice that we give here is practical. This is not a simplistic recipe or low-level 'tips for researchers'; rather it is the distillation of key features of practicable research and issues on which to deliberate, and to help to ensure that the research provides relevant and useful findings.

9.1 Introduction

Choosing a research project is normally the decisive feature of successful research. Many novice students and researchers start with an over-ambitious project. The task of a mentor or supervisor is to help the novice researcher to narrow and hone down the research field in order to render the research practicable, useful and workable. Indeed part of the discipline of choosing and conducting a piece of research is fining it down to manageable/researchable proportions, to enable rigour (e.g. fitness for purposes and methodological soundness) to be inserted into the research. Rigour in planning and doing research lies in choosing a project that is sufficiently tightly framed. A research topic is only one small aspect of the field of the subject, and careful boundaries must be drawn around the topic: what it will and will not do.

For novice researchers, a piece of educational research often starts by wanting to be their life story or the opportunity to give their personal opinions some grounding in literature and empirical study that support their opinions or prejudices. This is not the task of research. The task of research is to find out, to investigate, to develop, to test out (e.g. a theory), to address questions such as: 'what if', 'how', 'why', 'how well', 'what' and 'where'.

9.2 What gives rise to the research project?

Several points can give rise to a research topic. For example, for many teachers it may be a problem that they encounter in their day-to-day work: they may want to find out the causes of the problem and how to solve it; they may want to plan an intervention to see how well it addresses or solves the problem. Examples of these might be: 'How can teachers improve students' learning of algebra in lower secondary schools?'; 'How to maximize the learning of students with Asperger's syndrome in mainstream schooling'; 'How to conduct a music lesson with many musical instruments, without the lesson descending into chaos and noise'; 'How to teach speaking a foreign language in large, mixed-ability classes'.

Some research projects may begin with an area of interest or personal experience that researchers may have been wanting to investigate, for example: 'What is the long-term effect on employment of early school dropout?'; 'How effective is early identification of behaviour disorders on educational provision for such students?'; 'How can teachers improve students' motivation to learn a second language?'; 'Why do young teachers leave teaching and older teachers stay?'

Some research topics may begin with a recognized area of importance or topical concern in the field, for example: 'How to maximize primary students' learning

using ICT'; 'What is the effect of frequent testing on students' stress?'; 'How can developments in brain research and cognitive neuroscience impact on pedagogy?'; 'What is the predictive validity of personality tests or learning styles inventories on the success of first-time employees' applications for employment?'; 'Do interactive teaching methods produce higher test scores in university students than lecture-based teaching?' Such importance may arise from coverage of the topic in the press, articles, conference papers and journals.

Some research is conducted as part of a sponsored research project, in which the field and purposes of the research must be spelled out very clearly in order for the sponsorship to be obtained. For example in the UK the Economic and Social Research Council (www.esrc.ac.uk/research/research-topics), the Leverhulme Trust (www.leverhulme.ac.uk), Nuffield Foundation (www.nuffieldfoundation.org) and the Joseph Rowntree Foundation (www.jrf.org.uk) require detailed applications to be completed, and in the United States the Social Science Research Council (www.ssrc.org) requires similarly high levels of detail. Such funding might also need to fit the categories of research set out by the funding agencies.

A decision on what to research can arise from several wellsprings of the researcher's own motivation:

- a problem encountered in the researcher's everyday work or outside her/his everyday work (e.g. conceptual, theoretical, substantive, practical, methodological);
- an issue that the researcher has read about in a journal, book or other media;
- a problem that has arisen in the locality, perhaps in response to government policy or practices or to local developments;
- an area of the researcher's own interest;
- an area of the researcher's own experience;
- a perceived area of importance;
- an interesting question;
- a testable guess or hunch;
- a topical matter;
- disquiet with a particular research finding that one has met in the literature or a piece of policy (e.g. from the school, from a government), and a wish to explore it further;
- an awareness that a particular issue or area has been covered only partially or selectively in the literature, and a wish to plug the gap;
- a wish to apply a piece of conceptual research to actual practice, or to test a theory in practice;
- a wish to rework the conceptual or theoretical frameworks that are often used in a specific area;
- a wish to revise or replace the methodologies that are often used in researching a specific area;
- a desire to improve practice in a particular area;
- a desire to involve participants in research and development;
- a desire to test out a particular methodology in research;
- an interest in seeing if reported practice (e.g. in the literature) holds true for the researcher's own context (e.g. a comparative study);
- an interest in investigating the causes of a phenomenon or the effects of a particular intervention in the area of the phenomenon;
- a wish to address an issue or topic that has been under-researched in the literature;
- a priority identified by funding agencies;
- an issue identified by the researcher's supervisor or a project team of which the researcher is a member;
- a wish to explore further or to apply an issue or topic that one has encountered, for example, in the literature.

The long list above concerns the motivation that leads a researcher to consider doing a particular piece of research. Add to this a salutary point for researchers, which is that the study on which they might embark will probably take weeks, months and maybe years. Sustaining interest and momentum in the researcher(s) are important considerations. Researchers should ask themselves whether they really have the interest in studying the issue in question or in conducting the research for a long period of time. If the answer is 'no' then, if they have the luxury of not having to do this particular piece of research, they may wish to consider an alternative area that will enable them to sustain interest in, and motivation for, the research. A piece of research that is conducted by an unwilling or bored researcher could easily become unimpressive.

Beyond the *motivation* for the research are the *sources* of the research in question: where does research come from? For example, the research may derive from:

- a practical concern (e.g. 'why do females have higher scores than males in international tests of reading at age 14?') or a practical need (Leong *et al*., 2012);
- a literature review (though Andrews (2003) observes that if the research question derives from the literature review then there is a risk that there is no research question to initially drive the literature review (p. 18), i.e. the literature review could lack direction, purpose and boundaries). A literature

search (including specialist literature in the field, primary and secondary sources) helps the researcher to understand the existing field and the real-world implications of the research (Alvesson and Sandberg, 2013);
- the identification of a gap in the literature or field of study (gap filling) (Alvesson and Sandberg, 2011, 2013);
- the identification of where the research can build on existing literature (Alvesson and Sandberg, 2011);
- a theoretical concern, enabling theories to be generated and tested (e.g. 'how significant is performance-related pay in motivating senior managers of schools?', in which the 'theory' to be tested is that performance-related pay is a necessary but not sufficient motivator of senior staff (Pink, 2011));
- policy concerns (e.g. 'how effective is such-and-such in attracting females to take STEM subjects?');
- concerns in the media and blogs (including the Internet);
- society, empirical data (Alvesson and Sandberg, 2013, p. 16);
- personal experience, interest or observation (Leong *et al*., 2012);
- colleagues and contacts (ibid.);
- experts and practitioners in the field (ibid.);
- conferences and conventions (ibid.);
- faculty seminars, research groups, discussion groups and workshops (ibid.);
- students (ibid.);
- societies, associations, research bodies and special interest groups;
- spotting where areas are neglected, for example, overlooked/under-researched;
- existing studies and influential theories (Alvesson and Sandberg, 2013, p. 17);
- challenge to, or problematization of, an assumption, agenda or existing theory (Alvesson and Sandberg, 2013);
- a novel idea which challenges existing ideas or practices;
- funding bodies and/or project directors;
- spotting where applications may lie;
- spotting where confusions need to be clarified;
- spotting where new methodologies and research methods might be applied;
- other starting points – the list is endless.

It is essential that the research and the questions it asks should address something that is worth asking: asking the right question (Leong *et al*., 2012, p. 121). In turn this means that the research itself must be worth doing – it must make a significant contribution to the field. Behind the many features of effective research questions lies the need to ensure that the research itself, i.e. in principle, is interesting. In this respect there is an overlap in the literature between research areas and research questions, i.e. what some authors would place under the category of 'research questions' could just as easily be placed in the category of 'research areas' or 'fields of research', or 'research topics'. This harks back to the seminal work of Davis (1971) (see also Chapter 4), who provides a formidable list of twelve factors that make social science, and hence research and research questions, 'interesting'.

More recently, Alvesson and Sandberg (2011, 2013) argue that much research is 'gap filling', and that, whilst worthy, this risks being over-confined to the status quo, conservative, under-problematizing or over-problematizing matters, derivative and non-interesting because, since it builds on or around existing literature, it does not challenge assumptions in the literature, does not sufficiently problematize assumptions and agendas, and does not generate really new ideas or innovatory, creative thinking. It reinforces rather than challenges consensus (Alvesson and Sandberg, 2011, p. 250). Gap spotting, they observe, might be easy, uncontroversial and resonant with the idea of cumulative research, but it does not question received wisdoms and research perspectives.

Rather, Alvesson and Sandberg (2011, 2013) argue for the problematization of issues and the development of new ideas – *challenging* assumptions, agendas and theories – in order to create 'interesting' and 'influential' research and research questions (2013, p. 45). Problematization and questioning assumptions, they suggest, is a powerful methodology for generating interesting research questions and questioning of received truths, i.e. disruptive of existing theory, practices, paradigms and ideologies, and it is faithful to the uncertain nature of scientific 'truths' (p. 50). The aim of problematization, they argue, is to 'disrupt rather than build upon and extend an established body of literature' (2011, p. 248).

Of course, gap filling, building on existing research and problematization for the creation of new ideas are not mutually exclusive. All can generate 'interesting' research; as the authors remark (Alvesson and Sandberg, 2011, p. 266), there are good reasons for gap spotting as this can enable research to supplement and enrich existing studies, and clarify issues, for example, where there are disagreements among researchers. Innovative, high-impact research questions, they suggest (Alvesson and Sandberg, 2011, 2013), stem from the questioning of assumptions that underlie existing theories in significant ways. They set out a methodology

for problematization to produce 'interesting' research and research questions which constitutes one of Davis's (1971) features of 'interesting' research: what appear to be matters or phenomena that can coexist actually cannot, and vice versa (p. 4). Alvesson's and Sandberg's (2011, p. 256) methodology for generating 'interesting' research through 'dialectical interrogation' of assumptions requires researchers to:

Step 1: Identify a domain of literature;
Step 2: Identify and articulate the assumptions that underlie that domain;
Step 3: Evaluate the assumptions that underlie that domain;
Step 4: Develop an alternative assumption ground;
Step 5: Consider this alternative assumption ground in relation to its audience;
Step 6: Evaluate the alternative assumption ground.

Essentially the task is to expose and evaluate existing 'in-house' assumptions (e.g. in the literature, in 'theories'), i.e. those assumptions which are regarded as unproblematic and which are accepted by their advocates (p. 254), thence to challenge those assumptions (e.g. problems with them, their shortcomings and oversights) (p. 267), and develop and evaluate an 'alternative assumption ground' that will generate 'interesting' theory, taking the latter into account in relation to the audience, i.e. the wider intellectual, social and political situation of the research community and their possible reactions to the challenges posed (p. 258), and check to see if the alternative assumption ground is obvious, interesting or, indeed, absurd (p. 259).

Alvesson and Sandberg argue, for example, that rather than trying to develop research and research questions solely from a literature review, it might be more 'interesting' (and they use Davis's (1971) word here) to ask how a particular field becomes the target of investigation, to evaluate and challenge the *assumptions* (unchallenged, accepted and shared schools of thought), *ideologies* (e.g. values, politics, interests, identifications, moral and ethical views), *paradigms* (ontological, epistemological and methodological assumptions, world views), *root metaphors* (images of a particular area) and *field assumptions* (broader sets of assumptions about specific subject matter which are shared by schools of thought within, across a paradigm or discipline) (2011, p. 255) that underlie a theory. From there, the researcher seeks to develop and evaluate the 'alternative assumption ground' which, thereby, is 'more disruptive' and 'less reproductive' (Alvesson and Sandberg, 2013, p. 122). Challenging in-house assumptions is regarded as a minor level of problematization (Alvesson and Sandberg, 2011, p. 255); questioning root metaphors constitutes a middle-ground challenge; and challenging ideology, paradigms and field assumptions constitutes a more fundamental form of problematization (p. 255).

Leong *et al*. (2012, pp. 128–9) suggest that research and its research questions can be framed which: (i) discover a new effect; (ii) extend an established effect (e.g. to new domains); (iii) demonstrate mediation of factors (interaction), i.e. the mechanisms that lead to an effect; and (iv) moderation of an established effect (modelling for which groups of people/situations the effects hold true or not true). Whilst discovering a new effect may be for seasoned researchers, they note that extending an established effect may be suitable for novice researchers. They comment that moving beyond 'gap filling' to novel research is uncomfortable because it takes us out of our familiar, sedimented, deeply ingrained ways of thinking. They suggest that making the opposite assumptions, exposing hidden assumptions, casting doubt on existing assumptions and scrutinizing meanings of key concepts is unsettling (pp. 126–7).

Alvesson and Sandberg (2011, 2013) are arguing that effective, high-impact research and research questions derive from high-impact research proposals that move beyond 'gap filling' to disrupting conventions, modes of thinking and examining a phenomenon. This echoes Leong *et al*. (2012) who argue that creative, innovative, worthwhile research may be unclear at the outset and that if it is too clear too early on then it may not be focusing on anything new or important (p. 122); as the authors say, if it is too predictable, why do it? Indeed they write that an innovative research question is one that generates ambiguity rather than certainty, and they suggest that effective research questions are those which: are unclear on their outcomes; can generate answers; and discriminate between theories, each of which leads to different predictions (p. 122).

9.3 The importance of the research

Whatever research area or topic is identified, it is important for it to be original, significant, non-trivial, relevant, topical, interesting to a wider audience and to advance the field. For example, I may want to investigate the use of such-and-such a textbook in Business Studies with sixteen-year-olds in Madagascar, but, really, is this actually a useful research topic or one that will actually help or benefit other teachers or educationists, even though it yields original data?

Or I might conduct research that finds that older primary children in a deprived area of Aberdeen,

Scotland prefer to have their lunch between 12 noon and 1.00 p.m. rather than between 1.00 p.m. and 2.00 p.m., but, really, does anybody actually care? The topic is original and, indeed, the data are original, but both are insignificant and maybe not worth knowing.

In both of these examples, the research brings about original data, but that is all. Research needs to go beyond this, to choose a significant topic that will actually make an important contribution to our understanding and to practice. Originality alone is not enough. Rather, the research should move the field forward, perhaps in only a small-scale, piecemeal, incremental way, but nevertheless to advance it such that, without the research, the field would be poorer. Hence it is important to consider how the research takes the field forwards not only in terms of data, but also conceptually, theoretically, substantively and/or methodologically. At issue here is not only the contribution to knowledge that the research makes, but the *impact* of that knowledge; indeed funding agencies typically require an indication of the impact that the research will make on the research community and more widely, and how that impact will be assessed and known. What will be the impact, uptake and effects of the research, and on whom?

It is also useful for the researcher to identify what benefit the research will bring, and to whom, as this helps to focus the research and its audience. Fundamental questions are 'what is the use of this research?' 'What is the point of doing this research?' 'Who benefits?' 'Is this research worth doing?' If the answer to the last question is 'no', then the researcher should abandon it, otherwise it ceases to be useful research and becomes an indulgence of the dilettante.

Many novice researchers may not know whether the research is original, significant, important, complex, difficult, topical and so on. Here it is important for such a novice to read around the topic, to conduct a literature search, to conduct an online search, to attend conferences on the topic, to read newspaper reports on the topic; in short, to review the state of the field before coming to a firm decision on whether to pursue research in that field. In this respect, if the researcher is a student, it is vital to discuss the proposed topic with a possible supervisor, to receive expert feedback on the possible topic.

Before a researcher takes a final decision on whether to pursue a particular piece of research, it is useful to consider selecting a topic that interests the researcher, reading through background materials and information and compiling a list of keywords, clarifying the main concepts and writing the topic as a statement (or a hypothesis). Whilst incomplete, nevertheless this provides a useful starting point for novice researchers contemplating what to research.

9.4 The purposes of the research

Implicit in the previous section is the question 'why do the research?' This is ambiguous, as 'why' can refer to reasons/causes and purposes, though the two may overlap. Whereas the previous section concerned reasons, this section concerns purposes: what we want the research to achieve. It is vital that the researcher knows what she or he wants the research to 'deliver', i.e. to answer the question 'what are the "deliverables" in the research?' In other words, what do we want to know as a result of the research that we did not know before the research commenced? What do we want the research to do? What do we want the research to find out (which is not the same as what we want the results to be: we cannot predict the outcome, as this would be to 'fix' the research; rather, the kind of information or answers we want the research to provide)?

In this respect it is important for the researcher to be very clear on the purposes of the research, for example:

- to demonstrate that such-and-such works under a specified set of conditions or in a particular context (experiment; action research);
- to increase understanding and knowledge of learning theories (literature-based research);
- to identify common features of successful schools (research synthesis; descriptive research);
- to examine the effects of early musical tuition on general intelligence (meta-analysis; multilevel research);
- to develop and evaluate community education in rural and dispersed communities (participatory research; evaluative research; action research);
- to collect opinions on a particular educational proposal (survey);
- to examine teacher–student interactions in a language programme (ethnography; observational research);
- to investigate the organizational culture of the science faculty in a university (ethnography; survey);
- to identify the relative strengths of a range of specified factors on secondary school student motivations for learning (survey; observational study; multiple regression analysis; structural equation modelling);
- to see which of two approaches to teaching music results in the most effective learning (comparative study; experiment; causal research);
- to see what happens if a particular intervention in setting homework is introduced (experiment; action research; causal research);

- to investigate trends in social networking in foreign language teacher communities (network analysis);
- to identify key ways in which teachers in a large secondary school view the leadership of the senior staff of the school (personal constructs; accounts; survey);
- to interrogate government policy on promotion criteria in schools (ideology critique; feminist critique);
- to see the effects of assigning each student to a mentor in a university (survey; case study; causal research);
- to examine the long-term effects of early student dropout from school (survey; causal or correlational research);
- to see if repeating a year at school improves student performance (survey; generalization; causal or correlational research);
- to chart the effects of counselling disruptive students in a secondary class (case study; causal or correlational research);
- to see which catches richer survey data on student drug usage: questionnaires or face-to-face interviews (testing instrumentation; methodology-related research);
- to examine the cues that teachers give to students in question-and-answer classroom episodes (discourse analysis);
- to investigate vandalism in schools (covert research; informer-based research);
- to investigate whether case studies or surveys are more effective in investigating truancy in primary school (comparative methodology);
- to run a role-play exercise on communication between a school principal and senior teachers (role-play);
- to examine the effects of resource allocations to under-performing schools (ideology critique; case study; survey; causal research);
- to understand the dynamics of power in primary classrooms (ethnography; interpretive research);
- to investigate the demise of the private school system in such-and-such a town at the end of the nineteenth century (historical research);
- to understand the nature of trauma and its treatment on primary-aged children living in violent households (case study; action research; grounded theory; ex post facto research);
- to generate a theory of effective use of textbooks in secondary school physics teaching (grounded theory);
- to clarify the concept of 'the stereotype activation effect' for investigating the effect of sex stereotyping on reading in young teenagers (survey; case study; experiment; causal research);
- to test the hypothesis/theory that increasing rewards loses effect on students over time (experiment; survey; longitudinal research; causal or correlational research).

As can be seen in these examples, different purposes suggest different approaches, so 'fitness for purpose' takes on importance in planning research (see Chapter 10). One can also see that there is a range of purposes and types of research in education. The researcher cannot simply say that he or she likes questionnaires, or is afraid of numbers, or prefers to conduct interviews, or feels that it is wrong to undertake covert research so no covert research will be done. That is to have the tail wagging the dog. Rather, the research purposes determine what follow in respect of the kind of research, the research questions, the research design, the instruments for data collection, the sampling, whether the research is overt or covert (the ethics of research), the scope of the research, and so on.

9.5 Ensuring that the research can be conducted

Many novice researchers, with the innocence and optimism of ignorance, may believe that whatever they want to do can actually be done. This is very far from the case. There is often a significant gulf between what researchers want to do and what actually turns out to be what they can do.

A formidable issue to be faced here is one of *access*. Many new researchers fondly imagine that they will be granted access to schools, teachers, students, parents, difficult children, students receiving therapy, truants, dropouts, high performers, star teachers and so on. This is usually NOT the case: gaining access to people and institutions is one of the most difficult tasks for any researcher, particularly if the research is in any way sensitive (see Chapter 13). Access problems can kill the research, or can distort or change the original plans for the research.

It is difficult to overstate the importance of researchers doing their homework before planning the research in any detail, to see if it is actually feasible to gain access to the research sites or people they seek. If the answer is 'no' then the research plan either stops or has to be modified. It is not uncommon for the researcher to approach organizations (schools, colleges, universities, government departments) with some initial, outline plans of the research, to see if there is a possibility, likelihood or little or no chance of doing the research.

Nor is it enough to be clear on access; supplementary to this is 'access to what?'. It is of little use to be given access to a school by the school principal if the teachers have not been consulted about this, or if they are entirely uncooperative (see the discussion of informed consent in Chapter 7). One of the authors recalls an example of a Master's student who wanted to study truancy; the student had the permission of the school principal and turned up on the day to commence the research with the school truants, only to find that they had truanted, and were not present! The same is true for sensitive research. For example, let us suppose that one wished to research child abuse in primary school students. The last people to consent, or even to be identified and found, might be the child abusers or the abused children; even if they *were* identified and found, why should they agree to being interviewed by a stranger who is conducting research? Or, let us suppose that one wished to investigate the effects on teachers of working with HIV-positive children in hospital; those teachers might be so traumatized or emotionally exhausted at the end of a day's work that the last thing they want to do is to talk about it further with an outside researcher whom they have never met before; they simply want to go home and 'switch off'. These are real issues. The researcher has to check out the situation before embarking on a fully worked-out plan, because the plan might come to nothing if access is not possible.

It is not only the people with whom the researcher is working who have to be considered; it is the researcher herself/himself. For example, does the researcher have the right personality, dispositions, sympathies, interpersonal skills, empathy, emotional intelligence, perseverance and so on to conduct the research? For instance, it would likely be a disaster if a researcher were conducting a piece of research on student depression and tacitly believed that students were just lazy or work-shy and that they used 'feeling down' (as the researcher might put it) as an excuse, i.e. the researcher refused to recognize the seriousness of depression as a clinical condition or as a pathological disorder. Equally, it would be an unwise researcher who would choose to conduct a longitudinal study if she had limited perseverance or if she knew that she was going to move overseas in the near future.

Researchers themselves will also need to decide whether they have sufficient expertise in the field in which they want to do the research. It could be dangerous to the researcher and to the participants if the researcher were comparatively ignorant of the field of the proposed research, as this could mean that direction, relevance, prioritization or even safety might be jeopardized. This is a prime reason for the need for researchers to conduct a literature review, to demonstrate that they are sufficiently well-versed in the field to know what to do, what to look for, and where, when and how to proceed.

Researchers will also have a personal commitment to the research; it may help to further their specialist interest or expertise; it may help to establish their reputation; it may make for career advancement or professional development. These considerations, though secondary, perhaps in choosing a piece of research, nevertheless are important features, given the commitment of time and effort that the research will require.

In addition to access, there are issues of time to be considered. Part of the initial discipline of doing research is to choose a project that is manageable – can actually be done – within the time frames that the researcher has at her/his disposal. It would be ridiculous for a researcher to propose a longitudinal study if that researcher only has maybe six or nine months to plan, conduct and report the entire research project. The time frames may prevent certain types of research from being conducted.

Similarly, the time availability of the researcher has to be considered: many researchers are part-time students who may not have much time to conduct research, and often their research is a lonely, one-person affair rather than a group affair with a team of full-time researchers. This places a practical boundary around what can and cannot be done in the research. Again, these are real issues. The availability of the researcher features in ensuring that the research can be conducted, and this applies equally to the participants: are they willing and able to give up their time in participating in the research, for example, in being interviewed, in keeping diaries, attending follow-up debriefings, participating in focus groups and writing reports of their activities?

Whilst access and time are important factors, so are resources (e.g. human, material). For example, if one is conducting a postal survey there are costs for printing, distribution, mail-back returns and follow-up reminders. If one is conducting a questionnaire survey on a large, dispersed university campus then one will need the cooperation of academic and administrative staff to arrange for the distribution, collection and return of the questionnaires. If one is conducting an online survey of teachers' views of, for example, government assessment policy, can it be assured that all teachers will have access to the online facilities at times that are convenient for them, and that poor connectivity, slow speed and instability of the system will not end in them abandoning the survey before it is completed?

If one is conducting an analysis of trends in public education in early-twentieth-century Scotland, then one needs to have time to search and retrieve public records (and this may involve payment), maybe visit geographically dispersed archives, and sit in front of microfiche readers or computers in public record offices and libraries.

A further consideration in weighing up the practicalities of the research is whether, in fact, the research will make any difference. This is particularly true in participatory research. Researchers may wish to think twice before tackling issues about which they can do nothing or over which they may exert little or no influence, such as changing an education or schooling system, changing the timetabling or the catchment of a school, changing the uses made of textbooks by senior staff, changing a national or school-level assessment system. This is not to say that such research cannot or should not be done; rather it is to ask whether the researcher's own investigation can do this, and, if not, then what the purposes of the research really are or can be.

Many researchers who are contemplating empirical enquiries will be studying for a degree. It is important that they will be able to receive expert, informed supervision for their research topic. Indeed, in many universities a research proposal will be turned down if the university feels that it is unable to supervise the research sufficiently. This will require the student researcher to check out whether his/her topic can be supervised properly by a member of the staff with suitable expertise, and, indeed, many students find this out before even registering with a particular university. It is a sound principle.

A final feature of practicality is the scope of the research. This returns to the opening remarks of this chapter, concerning the need to narrow down the field of the study. We advise that a single piece of research be narrow and limited in scope in order to achieve manageability as well as rigour. As the saying goes, 'the best way to eat an elephant is one bite at a time'! Researchers must put clear, perceptible, realistic, fair and manageable boundaries round their research. If this cannot be done straightforwardly then maybe the researcher should reconsider whether to proceed with the planned enterprise, as uncontrolled research may wander everywhere and actually arrive nowhere. Part of the discipline of research is to set its boundaries clearly and unequivocally. In choosing a piece of research, the manageability of setting boundaries is important; if these cannot be set, then the question is raised of the utility of the proposed endeavour.

For example, if one were to investigate students' motivations for learning, say, biology, this would involve not only identifying a vast range of independent variables, but also handling likely data overload, and ensuring that all the theories of motivation were included in the research. This quickly goes out of control and becomes an impossible task. Rather, one or two theories of motivation might be addressed, within a restricted, given range of specified independent variables (unless, of course, the research was genuinely exploratory), and with students of a particular age range or kind of experience of biology.

Small samples, narrowly focused research, can yield remarkable results. For example, Axline's *Dibs in Search of Self* (1964) study of the restorative and therapeutic effects of play therapy focused on one child, and Piaget's (1932) seminal theory of moral development, in *The Moral Judgement of the Child*, focused on a handful of children. In both cases, the detailed carefully bounded research yielded great benefits for educationists.

Practical issues, such as those mentioned here, often attenuate what can be done in research. They are real issues. The researcher is advised to consider carefully the practicability of the research before embarking on a lost cause in trying to conduct a study that is doomed from the very start because insufficient attention has been paid to practical constraints and issues.

9.6 Considering research questions

The move from the aims and purposes of a piece of educational research to the framing of research questions – the process of operationalization of the research – is typically not straightforward, but an iterative process. The construction of careful research questions is crucial and we devote an entire chapter to this (Chapter 10). We refer the reader to that chapter and indicate in it that research questions typically drive and steer much research.

It is the answers to the research questions that can provide some of the 'deliverables' referred to earlier in the present chapter. A useful way of deciding whether to pursue a particular study is the clarity and ease in which research questions can be conceived and answered. As mentioned in more detail in Chapter 10, research questions turn a general purpose or aim into specific questions to which specific, data-driven, concrete answers can be given. Questions such as 'what is happening?', 'what has happened?', 'what might/will/should happen?' open up the field of research questions. Chapter 6 also mentioned causal questions; here 'what are the effects of such-and-such a cause?' and 'what are the causes of such-and-such an effect?' are two such questions, to which can be added the frequently

used questions 'how?' and 'why?'. These questions ask for explanations as well as reasons.

As we mention in Chapter 10, the research may have one research question or several. Andrews (2003, p. 26) suggests that the research should have only one main research question and several supporting questions: 'subsidiary' questions which derive from and are necessary, contributory questions to the main research question (see Chapter 10 of the present volume). He notes that it is essential for the researcher to identify what is the main question and how the subsidiary questions relate to it. For example, he suggests that a straightforward method is to put each research question onto a separate strip of paper and then move the strips around until the researcher is happy with the relationship between them as indicated in the sequence of the strips (p. 39). This implies that the criteria for identifying the relationship have to be clear in the researcher's mind (e.g. logical/chronological/psychological, general to specific, which questions are subsumed by or subsidiary/subordinate/superordinate to others, which questions are definitional, descriptive, explanatory, causal, methodological etc., which question emerges as the main question). This process, he notes (p. 41), also enables the researcher to identify irrelevant questions and to refine down, to delimit the research; many novice researchers may have many research questions, each of which merits its own substantial research in itself, i.e. the research questions are unrealistically ambitious.

Chapters 1 and 2 drew attention to numerical, non-numerical and mixed methods research questions. Some research questions might need to be answered by gathering only numerical data, others by only qualitative data. However, we recommended in Chapter 2 that, for mixed methods research, attention should be paid to the research questions such that they can *only* be answered by mixed – combined – types of data, or by adopting mixed methodologies, or by having a set of purposes that can only be addressed by mixed methods, or by taking mixed samples, or by having more than one researcher on the project (mixed researchers), in short, by building a mixed methods format into the very heart of the research. So, a research question in this vein might combine 'how' and 'what' into the same research question, or 'why' and 'who' might be combined in the same question, or description and explanation might be combined, or prediction, explanation and causation might be combined, and so on. We provide examples of these in Chapter 2.

It has been suggested (e.g. Bryman, 2007b) that, in mixed methods research, the research question has considerable prominence in guiding the research design and sampling, yet it is often more difficult to frame research questions in mixed methods research than in single paradigm research (e.g. quantitative or qualitative) (Onwuegbuzie and Leech, 2006a, p. 477). This is because it requires quantitative and qualitative matters to be addressed within the same research questions. Onwuegbuzie and Leech provide examples of mixed methods research questions, such as 'What is the relationship between graduate students' levels of reading comprehension and their perceptions of barriers that prevent them from reading empirical research articles?' (pp. 483–4). Here both numerical and qualitative data are required in order to provide a complete answer to the research question (e.g. numerical data on levels of reading comprehension, and qualitative data on barriers to reading articles) (p. 484). They provide another example of mixed methods research questions thus: 'What is the difference in perceived classroom atmosphere between male and female graduate students enrolled in a statistics course?' (p. 494). This could involve combining measures with interviews.

Here is not the place to discuss the framing of research questions (Chapter 10 addresses this). Here we draw attention to research questions per se, in particular their clarity, ease of answering, comprehensiveness, comprehensibility, specificity, concreteness, complexity, difficulty, contents, focus, purposes, kinds of data required to answer them and utility of the answers provided, to enable researchers to decide whether the particular piece of research is worth pursuing. This will require researchers to pause, generate and reflect on the kinds of research question(s) required before they decide whether to pursue a particular investigation. This argues that researchers may wish to consider whether they really wish to embark on an inquiry whose research questions are too difficult or complex to answer within the scope or time frames of the study. Many of the most useful pieces of research stem from complex issues, complex research questions and 'difficult-to-answer' research questions. They move from Alvesson's and Sandberg's (2013) 'gap filling' to problematization, new ideas and areas, innovatory thinking and the elements that make for Davis's (1971) 'interesting' research, mentioned in Chapter 4.

9.7 The literature search and review

A distinction has to be drawn between a literature search and a literature review. The former identifies the relevant literature; the latter does what it says: reviews the literature selected. If the researcher knows in advance what are the research purposes, issues and research questions then this can make the literature

search efficient, directed and selective; they determine what to look for. But this is not always the case. It is frequently the case that the researcher does not have an exact or clear picture of the field or what is relevant, and is relying on the literature review to provide such clarity and exactitude. In this situation, the literature search risks being somewhat aimless, too wide or too unfocused. In Chapter 11 we provide detailed guidance on how and where to conduct a literature search. Among other kinds of written or online materials, a sound literature search (and indeed review) will include up-to-date information from materials such as: books, articles, reports, research papers, newspaper articles, conference papers, theses, dissertations, reviews and research syntheses, government documents, databases and Internet sources, primary and secondary sources and so on.

A literature review is an essential part of many kinds of research, particularly if the research is part of a thesis or dissertation. It serves many purposes, for example:

- it ensures that the researcher's proposed research will not simply recycle existing material (reinventing the wheel), unless, of course, it is a replication study;
- it gives credibility and legitimacy to the research, showing that the researcher has 'done his/her homework' and knows the up-to-date, key issues and the theoretical, conceptual, methodological and substantive problems in the field in which the research is being proposed;
- it clarifies the key concepts, issues, terms and the meanings of these for the research;
- it acts as a springboard into the study, raising issues, showing where there are gaps in the research field, and providing a partial justification or need for the research. It makes clear where new ground has to be broken in the field and indicates where, how and why the proposed research will break that new ground;
- it indicates the researcher's own critical judgement on prior research or theoretical matters in the field and, indeed, provides new theoretical, conceptual, methodological and substantive insights and issues for research;
- it sets the context for the research and establishes key issues to be addressed;
- it enables the researcher to raise questions that still need to be answered in the field, how to move the whole field forward, and how to look differently at the field;
- it establishes and justifies the theoretical and conceptual frameworks of the research and the research design (see also Chapter 4).

We provide more details on conducting the literature search and review in Chapter 11. A literature review must be useful, not only to show that the researcher has read some relevant materials, as this is a trivial, self-indulgent reason, but that this actually informs the research. A literature review must be formative and lead into, or give rise to, all aspects of the research: the field, the particular topic, the theoretical grounding and framework, the methodology, the data analysis and implications for future research.

The researcher who is contemplating conducting a particular piece of research will need to give careful consideration to the necessary size and scope of the literature review, as this has implications for time, manageability, practicability and decision making on whether the project is too large, unfocused, diffuse, general or difficult to have justice done to it in the time and resources available. It is a determinant of whether to opt for a particular piece of research.

9.8 Summary of key issues in choosing a research topic or project

This chapter has set out several practical considerations in choosing a research topic. We advise researchers, both novice and experienced, to approach the selection of, and decision making on, a research topic with caution, going into it 'with their eyes open', aware of its possible pitfalls as well as its benefits and implications. We summarize the points discussed in the chapter in Box 9.1.

BOX 9.1 ISSUES TO BE FACED IN CHOOSING A PIECE OF RESEARCH

1. Make the topic small. Think small rather than big.
2. Limit the scope and scale of the research: think narrow rather than broad.
3. Keep the focus clear, limited, bounded and narrow.
4. Don't be over-ambitious.
5. Be realistic on what can be done in the time available, and whether, or how much, this might compromise the viability or worth of the research.
6. Make it clear what has given rise to the research – why choose this topic/project.
7. Choose a topic that might enable you to find your niche or specialism in the research or academic world or which might help to establish your reputation.
8. Decide why the research is important, topical, interesting, timely, significant, original, relevant and positively challenging.
9. Decide what contribution the research will make to the conceptual, practical, substantive, theoretical and methodological fields.
10. Decide whether your research is mainly to 'fill a gap' or to break new ground, to be innovatory.
11. Choose a research project that will be useful, and decide how and for whom it will be useful.
12. Decide why your research will be useful and who will/might be interested in it.
13. Decide what might be the impact of your research, and on whom.
14. Choose a topic that is manageable and practicable.
15. Choose a topic that will enable rigour to be exercised.
16. Choose a topic that has clear boundaries or where clear, realistic, fair boundaries can be set.
17. Decide what the research will 'deliver'.
18. What will the research do?
19. What will the research seek to find out?
20. Choose a topic for which there is a literature.
21. Decide whether you will have the required access and access to what/whom in order to be able to conduct the research.
22. Decide what can and cannot be done within the time and timescales available.
23. Decide what can and cannot be done within the personal, people-related, material, effort-related, financial and scope of the research.
24. Consider the likely clarity, scope, practicability, comprehensiveness, ease of answering, framing, focus, kinds of data required, comprehensibility of the research questions and their combination.
25. Consider whether the research will influence, or make a difference to, practice, and, if not, why it might still be important.
26. Consider whether you have the right personality, characteristics, experience and interpersonal behaviour to conduct the proposed piece of research.
27. Consider whether the research will sustain your creativity, imagination, positive attitude and motivation over time.
28. Choose a topic for which you know you will able to receive expert, informed supervision.
29. Be clear on why you – personally, professionally, career-relatedly – want to do the research, and what you personally want out of it, and whether the research will enable you to achieve this. How will the research benefit you?
30. How will the research benefit the participants?
31. How will the research benefit the world of education?
32. Choose a topic that will sustain your interest over the duration of the research.
33. Consider whether you have sufficient experience, skills and expertise in the field in which you want to conduct the research for you to be able to act in an informed way.
34. Consider whether it is advisable to embark on a piece of research that deliberately does not have research questions.
35. Consider the necessary complexity (where it exists) of the research phenomenon, scope and conduct of the research, and the difficulty of the research issues, foci and conduct.
36. Consider how future research will be able to build on your research, i.e. that the research opens up possibilities rather than closes them down.

Companion Website

The companion website to the book provides PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Research questions

CHAPTER 10

This chapter will explore:

- the purpose of research questions and where they come from
- different kinds of research questions
- devising your research question(s)
- making your research question answerable
- how many research questions you should have

10.1 Why have research questions?

Research design includes a concrete and specific statement of the aims and objectives of the research as set out in the overall research purposes. There is a move in the research design from the general to the specific and concrete. From these specific, concrete objectives the researcher can formulate direct, concrete, specific research questions that the research will answer specifically and concretely and, thereby, address the objectives of the research. Research questions get to the heart of the research issue.

For many kinds of research, the framing of the research question(s) is critical; it focuses, centres, shapes, steers and drives the entire research and it is the answers to the research questions in which the researcher is interested. As Alvesson and Sandberg (2013) remark, research questions concern the direction of a study and what it is about (p. 2). They strive to 'tame curiosity' (White, 2013, p. 213) and to shape and direct the research (Agee, 2009), to make the research topic tractable. Research questions might raise a problem and shape it into a testable question or hypothesis and enable the results to be reported; they inform the direction of the research in substantive, contextual, theoretical and methodological terms; in other words, they indicate what the research is really about and what it must address.

Research questions are not the start of the research; typically they stem from the overall research purposes, objectives and design. They are the concrete questions, carefully composed in order to address the research objectives, to constitute a fair operationalization and embodiment of a valid set of indicators for addressing the research objectives, providing answers which address the research purposes with warranted data. Research questions render research aspirations, in principle, researchable and able to be investigated scientifically and rigorously, and answered empirically or by appropriate non-empirical means. We say 'in principle' because other factors, for example, practical matters such as access, permissions, finances and resources (human, material, temporal, administrative), may obstruct the research progress. Research questions take the purposes and objectives of the research and narrow them down into specific, concrete areas of focus; they narrow the boundaries of the research and help the researcher to decide where to go in the research.

This chapter does not distinguish between qualitative and quantitative research, as the issues raised apply to both. It is invidious to suggest that certain issues apply only to quantitative research and that others apply only to qualitative research; the issues apply to both types, and, indeed, mixed methods research demonstrates this very clearly, drawing on different kinds of research and data in order to answer a particular research question. For example, Simon (2011) notes that qualitative research questions tend to be exploratory and open in nature (p. 1), but there is no reason why this cannot apply to quantitative research.

Research questions typically precede the specification of research designs, methodologies, data types, methods of data collection, instrumentation and sampling, i.e. the logistical aspects of the research and which follow from the research questions.

10.2 Where do research questions come from?

Research questions stem from the aims, purposes and objectives of the research. Research questions turn a general purpose or aim into specific questions to which specific, data-driven, concrete answers can be given. This is the process of operationalization of the aims and purposes into research questions. Researchers must ensure that there is an alignment between the aims and objectives of the research and the research questions,

such that the latter serve the former. The research questions must yield data that provide warrantable evidence to address the research purposes and objectives and to draw conclusions. They must follow logically from the research purposes and objectives, and the data used in answering them must be reliable and valid indicators of the evidence needed to answer the research purposes and objectives.

It is the answers to the research questions that can provide some of the 'deliverables' referred to in Chapter 9. A useful way of deciding whether to pursue a particular study is to ascertain the clarity and ease with which research questions can be conceived and answered. Leong *et al*. (2012) argue that, in constructing research questions, it is important to have: (i) knowledge of the literature on the topic (research literature, theoretical literature); (ii) an awareness of the implications, practicability and limitations in conducting the research; and (iii) an integration of (i) and (ii). Whereas the overall research identifies the *field*, the *main topic* and *direction* of the research, the research question asks for specific, explicit answers from the outcomes of the research (p. 34).

For example, take the issue 'why do females have higher scores than males in international tests of reading at age 14?'; here the research questions might ask: (a) 'what are the test scores of females and males in such-and-such an international test of reading comprehension at age 14 in such-and-such a country?'; (b) 'how consistent among different sub-groups of females and males are the scores in such-and-such an international test of reading comprehension at age 14 in such-and-such a country?'; (c) 'how much variation is there in the scores of females and males in the scores in such-and-such an international test of reading comprehension at age 14 in such-and-such a country?'; and (d) 'what reasons do the test designers and data give for the answers to (a), (b) and (c)?'. Here the initial single overall question generates several research questions; this is common, as one of the purposes of a 'good' research question is to take a particular objective of the research and render it concretely researchable and practicable (White, 2009, p. 34).

10.3 What kinds of research question are there?

Questions such as 'what is happening?', 'what has happened?' 'what might/will/should happen?' open up the field of research questions. Chapter 6 also mentioned causal questions; 'what are the effects of such-and-such a cause?' and 'what are the causes of such-and-such an effect?' are two such questions, to which can be added the frequently used questions 'how?' and 'why?'. These questions ask for explanations as well as reasons. De Vaus (2001, p. 1) notes that there are two fundamentals of research questions: 'what is going on?' (description) and 'why is it going on?' (explanation). These are useful pointers when starting to think about research questions.

A useful approach to framing different kinds of research questions can be to ask questions that start with: what; what if; who; when; where; which; whence; whither; why; and how. There are many categories or types of research question. An early typology of these stem from Dillon (1984) who identified seventeen types of research question, which he refined into four main types: descriptive, explanatory, comparative and normative. His 'first order' type addresses 'properties' (p. 330): existence, identification, affirmation, substance, definition, character, function and rationale. His 'second order' type concerns 'comparisons': concomitance, conjunction and disjunction, equivalence and difference. His 'third order' type concerns 'contingencies': relations, correlations, conditionality (consequence and antecedence) and causality. His 'extra order' type concerns deliberation (normative questions), and other attributes. He arranges these in a hierarchy, with causal questions at the apex, being closest to the purpose of scientific inquiry.

Flick (2009) differentiates questions concerning describing states (what they are, how they came about, how they are sustained) from those describing processes (how and why something develops or changes) (p. 102). He also distinguishes between those questions which seek to confirm existing hypotheses or assumptions and those which seek to discover or allow new assumptions or hypotheses (p. 102), the latter being Strauss's (1987) 'generative questions', which are those that 'stimulate the line of investigation in profitable directions; they lead to hypotheses, useful comparison, the collection of certain classes of data, even to general lines of attack on potentially important problems' (Strauss, 1987, p. 22).

Agee (2009, p. 433) reports four kinds of research question: exploratory, explanatory, descriptive and emancipatory. Denscombe (2009a) identifies six types, articulated with their concern: description, prediction, explanation, evaluation, development-related and empowerment. De Vaus (2001) adds 'comparison' to these. Research questions can concern, for example:

- prediction ('what if' and 'what will' types of question), understanding, exploration, explanation (reasons for: 'why-type' questions; 'how-type' questions), description ('what-type' questions) and causation;

- testing and evaluation;
- comparisons/relations/correlations (between variables, people, events);
- processes, functions and purposes; stages of something;
- factors, structures, properties and characteristics of something;
- classification, types of something, trends and patterns;
- how to achieve certain outcomes; how to do, achieve, improve and develop something; alternatives to something;
- empowerment (of individuals and groups).

White (2009, pp. 42–4) argues that 'metaphysical questions' (those which cannot be answered completely through empirical research and observation) and 'normative questions' (those concerning judgements of values, what 'should' or ought to be the case or should happen, ethical and moral matters: what is desirable, good, bad, right, wrong, defensible) are typically beyond the scope of empirical social science, being 'deliberative' questions (p. 43) to which there are multiple answers deriving from people's opinions. Similarly, Hammersley (2014) comments that such questions are out of court for social scientists. Social science, he avers, should concern itself with factual data (descriptions and explanations), and social scientists have no more authority than others to determine what is good or bad (pp. 94, 144).

10.4 Devising your research question(s)

Research questions should enable the researcher to make a significant and innovative contribution to the field of study, say something new and interesting and contribute to the concerns and current topics in the academic community (see Chapter 4). Researchers should check that their research question will yield useful, relevant and significant data on matters that recipients (widely defined) of the research will care about (the 'so what?' criterion). It is also useful to consider whether the research question is 'gap filling', 'neglect filling', a new formulation of an existing idea or an entirely new idea, and how the facts which the answers to the research yield will match relevant theory.

Researchers need to decide exactly what they need to know about the matter in hand and make sure that, together, the research questions address all the required scope of the research. Though it sounds like common sense, it is important to check that it is possible to answer the research questions and that the answers to the research questions stem from data. The research questions must be manageable, practicable and answerable, fully operationalized, with a clear delineation of their scope and boundaries, and that they can be answered within the time frame and scope of the research.

With regard to the formulation of the research questions there are several points to make:

- Make sure that the types of research questions are fit for purpose (e.g. descriptive, explanatory, causal, evaluative, exploratory etc.) and that the research questions suggest an appropriate methodology. Where relevant, ensure that your research questions will be amenable to formulating hypotheses.
- Make your research questions as brief, clear, specific, concise and precise as possible (no more than a single sentence) (White, 2009, pp. 66–70), ensuring that they address (a) the focus: the 'what'; (b) the persons: the 'who' (the population and the sample as appropriate); (c) the location (the 'where'); and (d) the timing (the 'when' or the (historical) period studied) of the research (pp. 71–2).
- If you have more than one research question, make clear the relationship (e.g. logical) between them and the relative status of each question (is one question more important than another, and, if so, why or do they have equal status?) (cf. Andrews, 2003, p. 35).
- If you have one research question with several subsidiary questions (discussed later in this chapter), make clear the relationship (such as logical, chronological, empirical) not only between the subsidiary questions but between them and the main research question. Identify the main research question and the contributing subsidiary research questions (if there are any) (cf. Andrews, 2003).
- Check whether some of your research questions are more general/specific than others, and, if so, why. Check the scope of the research question: make sure your research questions are very focused, neither too narrow nor too broad. Avoid questions that require a simply binary response (yes/no). Avoid personal pronouns in the research questions.

Lipowski (2008, p. 1669) suggests that researchers can examine the four s's of research questions in order to determine their importance: size (the magnitude of an effect); scope (the overall effect on existing practice); scalability (how the findings may have expanded – wider – impact); and sustainability (long-term effects and support). It is useful to ask a colleague to review one's research questions and to give feedback on them.

White (2009) provides some useful cautions in constructing research questions:

- Only ask one question at a time (p. 37). Avoid putting two questions into the same single question, as it is important to see which answer refers to which part of the question. For example, avoid putting into the same research question a 'what' and 'why' question; they are asking for two different kinds of response/data, for example, 'what are the test scores of females and males in such-and-such an international test of reading comprehension at age 14 in such-and-such a country and how can we account for such findings?'. Combining descriptive, explanatory, causal, comparison, correlational, evaluative or other types of question into a single research question builds in questionable ambiguity. However, as discussed in Chapter 2, mixed methods research often suggests combining more than one question in a research question.
- Avoid 'false dichotomies' (p. 37). For example, in the question 'is a country's centralized university entrance examination a narrowing of the curriculum or a fair basis for comparing student performance?', neither or both statements may be true, partially true, irrelevant, or, indeed, there may be a less polarized position.
- Avoid making false assumptions (p. 38). For example, in the question 'why do males prefer multiple choice questions to essay questions in public English language examinations at age 16?', there are suppressed assumptions that such a preference exists, that multiple-choice questions are all of a single type (and the same applies to essay questions), that English language examinations are of a single type, and so on – many questionable assumptions and ambiguities underlie the research question. Whilst it may be impossible, because language and terminology inherently carry ambiguities, to render research questions unambiguous, nevertheless the researcher should avoid making false assumptions; in other words, the assumptions made should be warrantable.
- Avoid tautological questions (p. 40), i.e. those questions which say the same thing in more than one way. For example, in the question 'why do so many wealthy students study in elite universities?', one of the criteria (among others, of course) for a university to be regarded as 'elite' is that it recruits from among the wealthy groups in society. In other words, the research question here could be rewritten as 'why do so many wealthy students study in universities which recruit mainly wealthy students?' As White (2009, p. 41) remarks, this type of question is redundant because it already supplies its answer.

One can add to these cautions:

- Avoid making the research question too broad. For example, a research question such as 'what are the effects of such-and-such an intervention on students?' is far too broad, and could be replaced by, for example: 'how does such-and-such an intervention relate to sixteen-year-olds' examination performance in mathematics?'.
- Avoid making research questions too simple. For example, 'how are schools addressing student under-achievement?' could be answered by a simple Internet search, whereas a more complex question could be 'what are the effects of such-and-such an intervention in upper primary schools on the achievement of students at age 11?'.
- Avoid biased and leading questions (Agee, 2009), avoid 'can'/'how can' questions, as these are hypothetical and limitless (Andrews, 2003, p. 34).
- Avoid making your research question your questionnaire question; the former is overall and the latter is specific (Andrews, 2003, p. 69).

Some authors set out a linear process of devising research questions (cf. Alvesson and Sandberg, 2013, pp. 21–2), for example:

Step 1: Identify the field of study/subject area.
Step 2: Identify a specific topic within the field of study.
Step 3: Identify the purpose of the particular study.
Step 4: Formulate a research question that relates to the specific topic which is of both theoretical and practical interest/concern.

Leong *et al*. (2012, p. 127) suggest an alternative sequence:

Step 1: Define the domain of the research.
Step 2: Identify the main factors in, attributes of, conceptual frameworks of, influences on, and practical implications of, the topic in question.
Step 3: Plan how to cover these main factors/attributes/influences/conceptual frameworks/implications in formulating your research question, including which ones to address or leave aside.
Step 4: Operate a convergent exercise in bringing steps (1) to (3) into a researchable question (the authors recommend mixed methods in preference to either quantitative or qualitative methods, as this is consistent with their advocacy of 'multiple and convergent operationalism').

However, Alvesson and Sandberg (2013) suggest that, in reality, the formulation of a research question is much more iterative, interactive and evolutionary than that which is set out in a simple linear approach, and includes greater reference to literature, current debates and policy concerns. Leong *et al*. (2012) advocate brainstorming ideas, from which practicable, interesting and novel research questions can be selected; this might involve connecting ideas that may not have previously been connected ('novel links') (p. 120) and trying to look at a phenomenon as an outsider might view it. In this respect, mixed methods may possess greater potential for effective research questions than mono-methods approaches (see Chapter 2).

Similarly, researchers should evaluate their research questions and be prepared to modify them either before or during the research (if appropriate). As research progresses, matters may arise which indicate that the initial research question was too broad, or that the focus needs to shift, or that a more specific question needs to be asked. Research questions can change over time, as the researcher becomes more immersed in the research and as the research unfolds over time. This is commonplace and is almost to be expected: as the research becomes more refined, so the research questions will become more refined. The point here is that, at the start of the research it is not always clear where the research will go, and this means that the research question(s) could well change over time as the phenomenon in question is unpacked.

Similarly, what the researcher initially planned or wished to do in the research may have to be modified as the actual research is negotiated or unfolds. As Chapter 13 makes clear, this is not uncommon in sensitive research, but it is not confined to that: what the researcher wishes to do and what he/she can do in reality are not the same, and this may affect the research questions. A range of practical constraints, such as time, resources, access, scope can lead to research questions being modified over time. Further, as the research unfolds, unforeseen avenues for important exploration may open up, or what the researcher had initially thought was the 'correct' research question may turn out to need modification in order to get to the heart of the matter. This, too, is not uncommon; indeed in some kinds of research (e.g. ethnographic and qualitative research) it may even be expected to occur.

Some research – often qualitative (Bryman, 2007b) – may not have research questions. Similarly, it is important to recognize that research methods are not always driven by the research questions (p. 18), and that one should avoid the 'dictatorship of the research questions' (p. 14) in steering the design and conduct of the enquiry. Nevertheless, in many kinds of research the research questions figure significantly, and hence the chapter moves to considering their importance.

Some kinds of research (e.g. ethnography) might not begin with research questions but, in their closing stages, might use the open-ended research (e.g. an ethnography, interviews, focus groups) to raise research questions for further study in subsequent investigations. Such research, being exploratory in nature, might not wish to steer the inquiry too tightly, and indeed one of the features of naturalistic research (see Chapter 15) is that it endeavours not to disturb the everyday, natural setting for the participants. However, for many kinds of research, one of the early considerations that researchers can address in choosing a project is the research questions that the study might generate (or indeed should, as they derive from the overall purposes of the research).

In considering the proposed research, a useful approach is to brainstorm the possible areas of the field, moving from a general set of purposes to a range of specific, concrete issues and areas to be addressed in the research, and, for each, to frame these in terms of one or more research questions (or indeed in terms of a thesis to be defended or a hypothesis to be tested).

10.5 Making your research question answerable

There are many different kinds of research questions that derive from different purposes of the research. For example, research questions may seek:

- to describe what a phenomenon is and what is, or was, happening in a particular situation (e.g. in ethnographies, case studies, complexity theory-based studies, surveys);
- to explain why something happened;
- to predict what will happen (e.g. in experimentation, causation studies, research syntheses);
- to investigate what should happen (e.g. in evaluative research, policy research, ideology critique, participatory research);
- to examine the effects of an intervention (e.g. in experimentation, ex post facto studies, case studies, action research, causation studies);
- to examine perceptions of what is happening (e.g. in ethnography, survey);
- to compare the effects of an intervention in different contexts (experimentation, comparative studies);
- to test a theory or hypothesis;
- to develop, implement, monitor and review an intervention (e.g. in participatory research, action research).

In all of these the task of the researcher is to turn the general purposes of the research into actual practice, to operationalize the research. We discuss the process of operationalization in Chapter 11. In the present chapter we note that operationalization in terms of research questions means moving from very general, broad questions to very specific, concrete, practicable questions to which specific answers can be given. Thus the researcher breaks down each general research purpose or general aim into more specific research purposes and constituent elements, continuing the process until specific, concrete questions have been reached to which specific answers can be provided. This is not unproblematic; for example, Leong *et al*. (2012) note that operationalization, whilst valuable, may be prone to rendering issues biased or simplistic, and that, to overcome this, it is important to consider multiple perspectives on, and methodologies for researching, the topic (triangulation) (p. 127). Two examples of operationalization are provided below.

Let us imagine that the overall research aim is to ascertain the continuity between primary and secondary education (Morrison, 1993, pp. 31–3). This is very general, and needs to be translated into more specific terms. Hence the researcher might deconstruct the term 'continuity' into several components, for example, experiences, syllabus content, teaching and learning styles, skills, concepts, organizational arrangements, aims and objectives, ethos, assessment. Given the vast scope of this, the decision is taken to focus on continuity of pedagogy. This is then broken down into its component areas: the level of continuity of pedagogy; the nature of continuity of pedagogy; the degree of success of continuity of pedagogy; the responsibility for continuity; record-keeping and documentation of continuity; resources available to support continuity.

The researcher might take this further into investigating: the *nature* of the continuity (the provision of information about continuity); the *degree* of continuity (a measure against a given criterion); the *level of success* of the continuity (a judgement). An operationalized set of research questions, then, might be:

- How much continuity of pedagogy is occurring across the transition stages in each curriculum area? What kind of evidence is required to answer this question? On what criteria will the level of continuity be decided?
- What pedagogical strategies operate in each curriculum area? What are the most frequent and most preferred? What is the balance of pedagogical strategies? How is pedagogy influenced by resources? To what extent is continuity planned and recorded? On what criteria will the nature of continuity be decided? What kind of evidence is required to answer this question?
- On what aspects of pedagogy does planning take place? By what criteria will the level of success of continuity be judged? Over how many students/teachers/curriculum areas will the incidence of continuity have to occur for it to be judged successful? What kind of evidence is required to answer this question?
- Is continuity occurring by accident or design? How will the extent of planned and unplanned continuity be gauged? What kind of evidence is required to answer this question?
- Who has responsibility for continuity at the transition points? What is being undertaken by these people?
- How are records kept on continuity in the schools? Who keeps these records? What is recorded? How frequently are the records updated and reviewed? What kind of evidence is required to answer this question?
- What resources are there to support continuity at the point of transition? How adequate are these resources? What kind of evidence is required to answer this question?

It can be seen that these questions, several in number, have moved the research from simply an expression of interest (or a general aim) into a series of issues that lend themselves to being investigated in concrete terms. This is precisely what we mean by *operationalization*. The questions above also deliberately avoid the precision that one might be seeking in some research questions, such as the delineation of the locale of the research and the schools in question.

It is now possible to identify not only the specific questions to be posed, but also the instruments that might be needed to acquire data to answer them (e.g. semi-structured interviews, rating scales on questionnaires, or documentary analysis). By operationalization we thus make a general purpose amenable to investigation, be it by measurement or some other means. The number of operationalized research questions is large here, and may have to be reduced to maybe four or five at most, in order to render the research manageable.

Take another example of operationalizing a research question: 'do students work better in quiet rather than noisy conditions?' Here it is important to define who are the 'students', what is meant by 'work better', 'quiet' and 'noisy'. 'Students' might be fifteen-year-old males and females in school, 'work better' might mean 'obtain a higher score on such-and-such a mathematics test', 'quiet' might mean 'silence', and 'noisy' might mean 'having moderately loud music playing'. Hence the fully operationalized research questions might be 'do fifteen-year-old male and female students in school obtain a

higher score on such-and-such a mathematics test when tested when there is silence rather than when there is moderately loud music playing?' Now we have defined – and thereby narrowed – the scope, terms, field, focus, location, participants, indicators (a measurable score) and the conditions (silence and moderately loud music).

In this example the process of operationalization is to break down the constructs (or abstract terms) in question into component variables (categorical, continuous, dependent and independent), which, as the term suggests, can vary, and which are describable, observable and, in this case, measurable.

Hypotheses

An alternative way of operationalizing research questions takes the form of hypothesis raising and hypothesis testing. A 'good' hypothesis has several features:

- It is clear on whether it is directional or non-directional: a directional hypothesis states the kind or direction of difference or relationship between two conditions or two groups of participants (e.g. students' performance increases when they are intrinsically motivated). A non-directional hypothesis simply predicts that there will be a difference or relationship between two conditions or two groups of participants (e.g. there is a difference in students' performance according to their level of intrinsic motivation), without stating whether the difference, for example, is an increase or a decrease. (For statistical purposes, a directional hypothesis requires a one-tailed test whereas a non-directional hypothesis uses a two-tailed test; see Part 5.) Directional hypotheses are often used when past research, predictions or theory suggest that the findings may go in a particular direction, whereas non-directional hypotheses are used when past research or theory is unclear or contradictory or where prediction is not possible, i.e. where the results are more open-ended.
- It is written in a testable form, that is, in a way that makes it clear how the researcher will design an experiment or survey to test the hypothesis (e.g. 'fifteen-year-old male and female students in school obtain a higher score on such-and-such a mathematics test when tested when there is silence rather than when there is moderately loud music playing'). The concept of interference by noise has been operationalized in order to produce a testable hypothesis.
- It is written in a form that can yield measurable results.

Here it is a small step from a research question to a research hypothesis. Both specify and manipulate variables. In the example above, converting the research question into a hypothesis leads to the following hypothesis: *people work better in quiet rather than noisy conditions*. The fully operationalized hypothesis might be *fifteen-year-olds obtain a higher score on a mathematics test when tested when there is silence rather than when there is music playing.* One can see here that the score is measurable and that there is zero noise (a measure of the noise level).

In conducting research using hypotheses, one has to be prepared to use several hypotheses (Muijs, 2004, p. 16) in order to catch the complexity of the phenomenon being researched, and not least because mediating variables have to be included in the research. For example, the degree of 'willing cooperation' (dependent variable) in an organization's staff is influenced by 'professional leadership' (independent variable) and the 'personal leadership qualities of the leader' (mediating variable) which needs to be operationalized specifically.

There is also the need to consider the null hypothesis and the alternative hypothesis (discussed in Part 5) in research that is cast into a hypothesis testing model. The *null hypothesis* states that, for example, there is *no* relationship between two variables, or that there has been *no* difference in participants' scores on a pre-test and a post-test of history, or that there is *no* difference between males and females in respect of their science examination results. The *alternative hypothesis* states, for example: there *is* a correlation between motivation and performance; there *is* a difference between males' and females' scores on science; there *is* a difference between the pre-test and post-test scores on history. The alternative hypothesis is often supported when the null hypothesis is 'not supported': if the null hypothesis is not supported then the alternative hypothesis is. The two kinds of hypothesis are usually written thus:

H_0: the null hypothesis
H_1: the alternative hypothesis

We address hypothesis-testing fully in Part 5, particularly Chapters 38 and 39.

Contrary to statements that hypotheses are the province of only quantitative methods, we hold that hypotheses can be developed and tested in both quantitative and qualitative research; we see no reason why not. Nor do we concur with the view that a 'variable' is not a property of qualitative research. Theories and hypotheses can be tested in both qualitative and quantitative research, singly and together, and variables can comfortably be found and explored in both types (cf. White, 2013, p. 231). There is no exclusivity.

10.6 How many research questions should I have?

Whilst there are no hard and fast rules, a general principle is to have as few as necessary, but no fewer. Some researchers suggest having only one central research question with or without several subsidiaries (e.g. Andrews, 2003; Simon, 2011; Creswell, 2012). Others suggest no more than three or four (e.g. White, 2009); Creswell (2012) also suggests five to seven in qualitative research, whilst yet others (e.g. Miles and Huberman, 1994) extend this into double figures.

Andrews (2003) is very clear that there should be only one main research question, though a main research question may require 'subsidiary questions' (which are more specific and contribute to the answer to the main research question; p. 26) and 'ancillary questions' (which may not answer the main research question but which may be a consequence of, lead on from or broaden out the main research question; p. 81). Subsidiary questions, he avers (p. 43), are those that are '*on the way*' (his italics) to answering the main research question, whilst ancillary questions (those that provide useful but not strictly necessary material to answer the main research question) flow from, rather than contribute to, the main research question (p. 81). He cautions against having more than one main research question and, indeed, against having too many subsidiary questions, as these risk making the study too broad or ambitious in scope.

Whether one has several research questions or one research question with one or more subsidiary questions, Andrews (2003, p. 80) makes the important point that it is essential to establish the relationship (e.g. logical, chronological) between them and to identify which are the main questions and which questions are closely related or more distantly related to each other (p. 80), and how and why. His suggestion of having only one main research question is useful in identifying and focusing on the key purpose of the research.

Answering 'how many research questions do I need?' concerns the purposes of the research, the research design, the scope and magnitude of the research and each research question (and, where relevant, its subsidiaries and ancillaries) and, hence, its manageability. If the researcher wishes to avoid Andrews' suggestion of only a single, main research question, a general guide might be to have no more than four main research questions (though some would suggest that this is too many) with only two or three subsidiaries for each, but this is highly contestable and others would argue for fewer. If you have too many research questions then this might indicate that the scope of the research is too broad and ambitious, is impractical, lacks focus, lacks precision and specificity, is poorly operationalized and is insufficiently thought through. In our experience, many novice researchers have maybe three research questions, but this is very fluid.

Many studies may have one research question that asks for descriptive data, together with another that asks for explanations (causal – why – or 'how' questions), together with a third that asks for the implications/recommendations that derive from the answers to the preceding two research questions, moving from description to analysis/explanation to evaluation/implications/recommendations, i.e. three research questions (cf. Gorard, 2013, p. 37). Or the research questions may comprise: (i) a question that asks for descriptive data (what, who, where, when); followed by (ii) a question that requires comparisons, differences, relations to be drawn; followed by (iii) a question that asks 'so what?' (implications and recommendations).

10.7 A final thought

Researchers may wish to ponder on whether they want to embark on investigations that have no clearly defined research questions (cf. Andrews, 2003, p. 71) or indeed any research questions, for example an ethnography, a naturalistic observational study, studies in the humanities and arts (p. 71), or qualitative research (Bryman, 2007b). A research question may lead to a subsequent hypothesis, but that is an open question.

Companion Website

The companion website to the book provides PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Research design and planning

CHAPTER 11

This chapter sets out a range of key issues in planning research, including:

- research design and methodology
- approaching research planning
- a framework for planning research
- conducting and reporting a literature review
- searching for literature on the Internet
- how to operationalize research questions
- data analysis
- presenting and reporting the results
- a planning matrix for research
- managing the planning of research
- ensuring quality in the planning of research

It also provides an extended worked example of planning a piece of research.

Research design has to take account of the context of research and constraints on it, as these will inform orienting decisions. Such decisions are strategic; they set the general nature of the research. Here, questions that researchers may need to consider are:

- Who wants the research?
- Who will receive the research/who is it for?
- Who are the possible/likely audiences of the research?
- What powers do the recipients of the research have?
- What are the general aims and purposes of the research?
- What are the main priorities for and constraints on the research?
- Is access realistic?
- What are the timescales and time frames of the research?
- Who will own the research?
- At what point will the ownership of the research pass from the participants to the researcher and from the researcher to the recipients of the research?
- Who owns the data?
- What ethical issues are to be faced in undertaking the research?
- What resources (e.g. physical, material, temporal, human, administrative) are required for the research?

Decisions here establish some key parameters of the research, including some political decisions (e.g. on ownership and on the power of the recipients to take action on the basis of the research). At this stage the overall feasibility of the research will be addressed.

11.1 Introduction

A research design is a plan or strategy that is drawn up for organizing the research and making it practicable, so that research questions can be answered based on evidence and warrants. Some researchers argue that a research design should go into considerable detail on data-collection instruments and data types; others argue that this is a logistical rather than a logical matter, and that a design comprises only, or mainly, a logical argument in which all the elements of the argument cohere (e.g. issues of research questions, methodologies/kinds of research suitable to answer the research questions). As Labaree (2013) remarks, the research design

> refers to the overall strategy that you choose to integrate the different components of the study in a coherent and logical way, thereby, ensuring you will effectively address the research problem; it constitutes the blueprint for the collection, measurement, and analysis of data.
>
> (p. 1)

There is no single blueprint for planning research. Research design is governed by 'fitness for purpose'. The purposes of the research determine the design of the research which, in turn, informs the methodology. For example, if the purpose of the research is to map the field, or to make generalizable comments, then a survey design might be desirable, using some form of stratified sample; if the effects of a specific intervention are to be evaluated then an experimental or action research design may be appropriate; if an in-depth study of a particular situation or group is important then an ethnographic design might be suitable.

It is possible to identify a set of issues in design that researchers need to address, regardless of the specifics

of their research. This chapter indicates those matters which need to be addressed in practice so that an area of research interest can become practicable and feasible. The chapter indicates how research can be operationalized, i.e. how a general set of research aims and purposes can be translated into a practical, researchable topic.

It is essential to try as far as possible to plan every stage of the research. To change the 'rules of the game' in midstream once the research has commenced is a sure recipe for problems, though sometimes matters arise which necessitate this. The terms of the research and the mechanism of its operation must be ironed out in advance as far as possible if it is to be credible, legitimate and practicable. Once they have been decided, the researcher is in a positive position to undertake the research. The setting up of the research is a balancing act, for it requires the harmonizing of *planned possibilities* with *workable, coherent practice*, i.e. the resolution of the difference between what could be done/what one would like to do and what will actually work/what one can actually do, for, at the end of the day, research has to work. In planning research there are two phases – a divergent phase and a convergent phase. The divergent phase will open up a range of possible options facing the researcher, whilst the convergent phase will sift through these possibilities, see which ones are desirable, which ones are compatible with each other, which ones will actually work in the situation, and move towards an action plan that can realistically operate. This can be approached through the establishment of a framework of planning issues.

11.2 Approaching research planning

What the researcher does depends on what the researcher wants to know and how she or he will go about finding out about the phenomenon in question. The planning of research depends on the kind(s) of questions being asked or investigated. This is not a mechanistic exercise, but depends on the researcher's careful consideration of the purpose of the research (see Chapter 10) and the phenomenon being investigated (see Table 11.1).

Chapters 1 and 2 set out a range of paradigms which inform and underpin the planning and conduct of research, for example:

- positivist, post-positivist, quantitative, scientific and hypothesis-testing
- qualitative
- interpretive, naturalistic, phenomenological and existential, interactionist and ethnographic, qualitative
- experimental
- ideology critical
- participatory
- feminist
- political
- evaluative
- mixed methods.

It was argued that these paradigms rest on different ontologies (e.g. different views of the essential nature or characteristics of the phenomenon in question) and different epistemologies (e.g. theories of the nature of knowledge, its structure and organization, and how we investigate knowledge and phenomena: how we know, what constitutes valid knowledge, our cognition of a phenomenon). For example:

- a positivist paradigm rests, in part, on an objectivist ontology and a scientific, empirical, hypothesis-testing epistemology;
- a post-positivist paradigm rests on the belief that human knowledge is conjectural, probabilistic, influenced by the researcher and the theoretical lenses being used (i.e. there are no absolute truths or value-free enquiry), and that the warrants used to

TABLE 11.1 PURPOSES AND KINDS OF RESEARCH

Kinds of research purpose	*Kinds of research*
Does the research want to test a hypothesis or theory?	Experiment, survey, action research, case study
Does the research want to develop a theory?	Ethnography, qualitative research, grounded theory
Does the research need to measure?	Survey, experiment
Does the research want to understand a situation?	Ethnographic and interpretive/qualitative approaches
Does the research want to see what happens if…?	Experiment, participatory research, action research
Does the research want to find out 'what' and 'why'?	Mixed methods research
Does the research want to find out what happened in the past?	Historical research

support conjectures are mutable. Like positivism, it holds to a realist ontology and, unlike positivism, it holds to a conjectural, falsificationist epistemology;

- an interpretive paradigm rests, in part, on a subjectivist, interactionist, socially constructed ontology and on an epistemology that recognized multiple realities, agentic behaviours and the importance of understanding a situation through the eyes of the participants;
- a paradigm of ideology critique rests, in part, on an ontology of phenomena as organized both within, and as outcomes of, power relations and asymmetries of power, inequality and empowerment, and on an epistemology that is explicitly political, critiquing the ideological underpinnings of phenomena that perpetuate inequality and asymmetries of power to the advantage of some and the disadvantage of others, and the need to combine critique with participatory action for change to bring about greater social justice;
- a mixed methods paradigm rests on an ontology that recognizes that phenomena are complex to the extent that single methods approaches might result in partial, selective and incomplete understanding, and on an epistemology that requires pragmatic combinations of methods – in sequence, in parallel, or in synthesis – in order to fully embrace and comprehend the phenomenon and to do justice to its several facets.

Researchers need to consider not only the nature of the phenomenon under study, but also what are or are not the ontological premises that underpin it, the epistemological bases for investigating it and conducting the research into it. These are points of reflection and decision, turning the planning of research from being solely a mechanistic or practical exercise into a reflection on the nature of knowledge and the nature of being.

On the other hand some researchers argue against the need for the articulation of research paradigms in conducting research. For example, Gorard (2012) remarks:

> [i]in buying a house we would not start with epistemology, and we would not cite an 'isms' or Grand Theory. Nor would we need to consider the 'paradigm' in which we were working.… We would collect all available and any evidence available to us as time and resources allow, and then synthesize it quite naturally and without considering mixed methods as such.
>
> (p. 6)

Having a paradigm as a whole approach to research is, for him, simply a 'red herring' (p. 7); this is contestable.

11.3 Research design and methodology

Having a rigorous research design is crucial in the research process. In planning research, the researcher commences with the overall purposes of the research and then constructs a research design to address these. De Vaus (1999) contends that a research design functions to ensure that the evidence that research obtains enables them to 'answer the initial question as unambiguously as possible' (p. 9) and to indicate the kind of evidence required to answer the research questions.

Research design is, as White (2013, p. 221) notes, a logical rather than a logistical matter, i.e. concerned with the overall blueprint – the architecture – rather than the 'nuts and bolts' of how to carry out that plan (the implementation of the plan and the building materials to be used). The 'logic' here is the sequence which connects the data (typically empirical data) to the research questions and its conclusions (Yin, 2009, p. 26). It ensures that evidence is linked to research questions and conclusions and it makes clear the logic which connects the data to the evidence.

The research design identifies the evidence needed to address the research purposes, objectives and questions, i.e. the logic that underpins the connections between purposes, objectives, questions, data and conclusions drawn. Evidence requires an indication of the warrants that will be used to support the case made from the findings of the research. In other words, the research design connects the idea and the conclusions with the evidence; it sets out the 'chain of reasoning' and the warrants that link together these elements (White, 2009, p. 112). A claim about, or conclusion from, the research needs not only an evidence base but also a logical warrant that renders the evidence a fair defence of the claim or conclusion. A warrant, then, provides the link, the 'backing' between the evidence and the proposition under study (Andrews, 2003, p. 30). Imagine a court of law: a case is made for such-and-such, and the evidence is brought to support that case. The evidence is a defensible selection of the data available.

A research design includes research questions and the nature of, and warrants for, the evidence required to answer those questions. Research design does not dictate the kinds of *data* (de Vaus, 1999, p. 9), but it indicates the kinds of *evidence* (see also Gorard, 2013, p. 6). Research design precedes decisions on data types.

Evidence is not the same as data. Data are neutral, an unsorted collection of any information or facts. Evidence is what you derive from those data, i.e. once selected, processed, organized and brought into the service of supporting a claim, argument, interpretation, proof, theory, conclusion or answer to a question, then data become evidence. Data require a warrant in order to become evidence. A warrant is

> an argument leading from the evidence to the conclusion.… [It is] the form in which people furnish rationales as to why a certain voice … is to be granted superiority … on the grounds of specified criteria.… The warrant of an argument can be considered to be its general principle – an assumption that links the evidence to the claim made from it.
>
> (Gorard, 2002, p. 137)

Data/Information + Warrant (criteria for an evidential relationship) → Evidence.

Data are just facts, states of affairs, or propositions expressing facts; data become evidence once they enter into evidential relationships; and evidential relationships are typified by *prediction*, *confirmation/refutation* and *explanation*. Suppose we have our hypothesis H, and then there are many data/propositions available; let us call them D1, D2, D3, D4 etc. Data D3 will enter into an evidential relationship with H (will be 'evidential' with respect to H), which, if true, would: *predict* that D3 would occur; be supported (*confirmed*) or *disconfirmed* (refuted, falsified) by D3; *explain* why D3 occurs (cf. Mayo, 2004, p. 79). Data are evidential by a theoretical connection made between the hypothesis and data, and this theoretical connection 'warrants' the data; it gives the data this particular kind of normative power termed 'evidential'. Hence theory is important.

An example of using a warrant might be as follows, simplified for ease of understanding. Imagine that a research study focuses on male and female student performance in the upper end of secondary schools, and finds that upper secondary school males outperform females in mathematics. The researcher concludes that teachers are responsible for the differential mathematics achievement of upper secondary school males and females. How are the data connected to the conclusion drawn? What is the warrant linking the evidence to the conclusion, and how sound is the warrant?

The data are, for example, examination results, classroom observations and interviews. The warrant here might be that teachers operate a self-fulfilling prophecy in their differential expectations of males and females and that this self-fulfilling prophecy is the major factor responsible for the differential mathematics performance. But other warrants/acceptably justified and defensible explanations are also possible, for example: (a) student motivation exerts a major influence on mathematics performance; (b) teachers' pedagogical strategies exert a major influence on mathematics performance; (c) home conditions for study exert a major influence on mathematics performance; (d) parental influence tracks males and females into different subject preferences; (e) students' intended careers track/steer males and females into according differential significance to mathematics and so on. The list of possible warrants/defensible explanations is endless, and so it is incumbent on the researcher to demonstrate that the warrant chosen – the operation of the self-fulfilling prophecy and teacher expectation – trumps the other rival warrants. Applying the logic of the present warrant will need to show that it pulls its weight in offering a more defensible explanation than other warrants. In turn, this may require additional data and evidence not only to support the warrant given but to demonstrate that rival warrants (e.g. (a) to (e) above) are not supported, or are less well supported, by relevant evidence. Gorard (2002) provides useful examples of faulty warrants in published research.

A research design will include items such as:

- the research purposes;
- the research questions;
- the problem, issue, phenomenon, matter to be addressed and the focus of the research;
- the kind of research to be undertaken (methodology(ies)), for example, longitudinal, experimental, action research, survey, ethnographic, case study, mixed methods, together with a justification for the kind chosen;
- the timing and duration of the research;
- the content of the research (which may lie on a continuum from interventionist to non-interventionist);
- the people, groups/sub-groups or cases involved and how these are decided;
- how to ensure reliability and validity in the kinds of evidence needed to meet the requirements of the warrants required (i.e. why should we believe that the answers given to the research questions provide us with fair evidence or conclusions; how convincing are the answers; how does the evidence, the findings of the research, lead to the conclusions drawn, and how safe is this, e.g. in comparison to possible alternative conclusions and interpretations);
- addressing the ethical issues in the research;
- the organization of the research.

Creswell (2012) adds to these elements of research design the data collection, analysis and reporting procedures to be used (p. 20), though this implies that the design will move beyond statements of evidence to statements of data types and instrumentation (see also Wellington, 2015), i.e. it moves towards logistical as well as logical matters. Similarly, Ragin (1994a, p. 191) and Flick (2009) note that a research design includes fine detail that ranges from data collection to techniques of data analysis.

There appears to be little consensus on the level of detail or scope of what to include in the research design, particularly in respect of whether it should include instrumentation for data collection, data types and methods of data analysis. Whether a design should include logistical rather than simply logical matters is an open question; there are powerful arguments to support and counter both views (cf. Gorard, 2013).

There are many different kinds of design, and we introduce several of these in this book, for example: experimental, survey, ethnographic, action research, case study, longitudinal, cross-section, causal, correlational. None of these indicate data types, and indeed each or all of these might use questionnaires, observational data, interviews, documents, tests, accounts and so on.

11.4 From design to operational planning

If the preceding comments are strategic then decisions in this field are tactical; they establish the practicalities of the research, assuming that, generally, it is feasible (i.e. that the orienting decisions have been taken). Decisions here include addressing such questions as:

- What are the specific purposes of the research?
- Does the research need research questions?
- How are the general research purposes and aims operationalized into specific research questions?
- What are the specific research questions?
- What needs to be the focus of the research in order to answer the research questions?
- What is the main methodology of the research (e.g. a quantitative survey, qualitative research, an ethnographic study, an experiment, a case study, a piece of action research etc.)?
- Does the research need mixed methods, and if so, is the mixed methods research a parallel, sequential, combined or hierarchical approach?
- Are mixed methods research questions formulated where appropriate?
- How will validity and reliability be addressed?
- What kinds of data are required?
- From whom will data be acquired (i.e. sampling)?
- Where else will data be available (e.g. documentary sources)?
- How will the data be gathered (i.e. instrumentation)?
- Who will undertake the research?

11.5 A framework for planning research

Planning research depends on the design of the research which, in turn, depends on: (a) the kind of questions being asked or investigated; (b) the purposes of the research; (c) the research principles informing how one is working, and the philosophies, ontologies and epistemologies which underpin them. Planning research is not an arbitrary matter. There will be different designs for different types of research, and we give three examples here.

For example, a piece of quantitative research that seeks to test a hypothesis could proceed thus:

> Literature review → generate and formulate the hypothesis/the theory to be tested/the research questions to be addressed → design the research to test the hypothesis/theory (e.g. an experiment a survey) → conduct the research → analyse results → consider alternative explanations for the findings → report whether the hypothesis/theory is supported or not supported, and/or answer the research questions → consider the generalizability of the findings.

A qualitative or ethnographic piece of research could have a different sequence, for example:

> Identify the topic/group/phenomenon in which you are interested → literature review → design the research questions and the research and data collection → locate the fields of study and your role in the research and the situation → locate informants, gatekeepers, sources of information → develop working relations with the participants → conduct the research and the data collection simultaneously → conduct the data analysis either simultaneously, on an ongoing basis as the situation emerges and evolves, or conduct the data analysis subsequent to the research → report the results and the grounded theory or answers to the research questions that emerge from the research → generate a hypothesis for further research or testing.

One can see in the examples that for one method, the hypothesis drives the research, whilst for another the

hypothesis (if, in fact, there is one) emerges from the research, at the end of the study (some qualitative research does not proceed to this hypothesis-raising stage).

A mixed methods research might proceed thus:

> Identify the problem or issue that you wish to investigate → identify your research questions → identify the several kinds of data and the methods for collecting them which, together and/or separately, will yield answers to the research questions → plan the mixed methods design (e.g. parallel mixed design, fully integrated mixed design, sequential mixed design) (see Chapter 2) → conduct the research → analyse results → consider alternative explanations for the findings → answer the research questions → report the results.

These three examples proceed in a linear sequence; this is beguilingly deceptive, for rarely is such linearity so clear. The reality is that:

- different areas of the research design influence each other;
- research designs, particularly in qualitative, naturalistic and ethnographic research, change, evolve and emerge over time rather than being a 'once-and-for-all' plan that is decided and finalized at the outset of the research;
- ethnographic and qualitative research starts with a very loose set of purposes and research questions, indeed there may not be any;
- research does not always go to plan, so designs change.

In recognition of this, Maxwell (2005, pp. 5–6) develops an interactive (rather than linear) model of research design (for qualitative research), in which key areas are mutually informing and shape each other. The five main areas of his model are:

1. *Goals* (informed by perceived problems, personal goals, participant concerns, funding and funder goals, and ethical standards);
2. *Conceptual framework* (informed by personal experience, existing theory and prior research, exploratory and pilot research, thought experiments and preliminary data and conclusions);
3. *Research questions* (informed by participant concerns, funding and funder goals, ethical standards, the research paradigm);
4. *Methods* (informed by the research paradigm, researcher skills and preferred style of research, the research setting, ethical standards, funding and funder goals, and participant concerns); and
5. *Validity* (informed by the research paradigm, preliminary data and conclusions, thought experiments, exploratory and pilot research, and existing theory and prior research).

At the heart of Maxwell's model lie the research questions (3), but these are heavily informed by the four other areas. Further, he attributes strong connections between goals (1) and conceptual frameworks (2), and between methods (4) and validity (5). The links between conceptual frameworks (2) and validity (5) are less strong, as are the links between goals (1) and methods (4). His model is iterative and recursive over time; the research design emerges from the interplay of these elements and as the research unfolds.

Though the set of issues that constitute a framework for planning research will need to be interpreted differently for different styles of research, nevertheless it is useful to indicate what those issues might be. These are outlined in Box 11.1.

BOX 11.1 THE ELEMENTS OF RESEARCH DESIGN

The elements of research design

1. A clear statement of the problem/need that has given rise to the research;
2. A clear grounding in literature for construct and content validity: theoretically, substantively, conceptually, methodologically;
3. Constraints on the research (e.g. access, time, people, politics);
4. The general aims and purposes of the research;
5. The intended outcomes of the research: what the research will do and what the 'deliverable' outcomes are;
6. Reflecting on the nature of the phenomena to be investigated, and how to address their ontological and epistemological natures;
7. How to operationalize research aims and purposes;

8 Generating research questions (where appropriate) (specific, concrete questions to which concrete answers can be given) and hypotheses (if appropriate);
9 Statements of the warrants for the research (the rationale that links evidence and conclusions);
10 The foci of the research;
11 Identifying and setting in order the priorities for the research;
12 Approaching the research design;
13 Focusing the research;
14 Research methodology (approaches and research styles, e.g.: survey; experimental; ethnographic/naturalistic; longitudinal; cross-sectional; historical; correlational; *ex post facto*);
15 Ethical issues and ownership of the research (e.g. informed consent; overt and covert research; anonymity; confidentiality; non-traceability; non-maleficence; beneficence; right to refuse/withdraw; respondent validation; research subjects; social responsibility; honesty and deception);
16 Politics of the research: who is the researcher; researching one's own institution; power and interests; advantage; insider and outsider research;
17 Audiences of the research;
18 Instrumentation, e.g.: questionnaires; interviews; observation; tests; field notes; accounts; documents; personal constructs; role-play;
19 Sampling: size/access/representativeness; type – probability: random, systematic, stratified, cluster, stage, multi-phase; non-probability: convenience, quota, purposive, dimensional, snowball;
20 Piloting: technical matters: clarity, layout and appearance, timing, length, threat, ease/difficulty, intrusiveness; questions: validity, elimination of ambiguities, types of questions (e.g. multiple choice, open-ended, closed), response categories, identifying redundancies; pre-piloting: generating categories, grouping and classification;
21 Time frames and sequence (what will happen, when and with whom);
22 Resources required;
23 Reliability and validity:
validity: construct; content; concurrent; face; ecological; internal; external;
reliability: consistency (replicability); equivalence (inter-rater, equivalent forms); predictability; precision; accuracy; honesty; authenticity; richness; dependability; depth; overcoming Hawthorne and halo effects;
triangulation: time; space; theoretical; investigator; instruments;
24 Data analysis;
25 Verifying and validating the data;
26 Reporting and writing up the research.

A possible sequence of consideration is:

Preparatory issues	→	*Methodology*	→	*Sampling and instrumentation*	→	*Piloting*	→	*Timing and sequencing*
Ontology, epistemology, constraints, purposes, foci, ethics, research question, politics, literature review	→	Approaches Reliability and validity	→	Reliability and validity Pre-piloting	→		→	

Clearly this need not be the actual sequence; for example, it may be necessary to consider access to a possible sample at the very outset of the research.

These issues can be arranged into four main areas:

1 orienting decisions;
2 research design and methodology;
3 data analysis;
4 presenting and reporting the results.

These are discussed later in this chapter. Orienting decisions are those decisions which set the boundaries or the constraints on the research. For example, let us say that the overriding condition of the research is that it has to be completed within six months; this will exert an influence on the enterprise. On the one hand it will 'focus the mind', requiring priorities to be settled and data to be provided in a relatively short time. On the other hand it may reduce the variety of possibilities

available to the researcher. Hence questions of timescale will affect:

- the research questions which might be answered feasibly and fairly (e.g. some research questions might require a long data-collection period);
- the number of data-collection instruments used (e.g. there might be enough time for only a few instruments to be used);
- the sources (people) to whom the researcher might go (e.g. there might be enough time to interview only a handful of people);
- the number of foci which can be covered in the time (e.g. for some foci it will take a long time to gather relevant data);
- the size and nature of the reporting (there might be time to produce only one interim report).

By clarifying the timescale a valuable note of realism is injected into the research, which enables questions of practicability to be answered.

Let us take another example. Suppose the overriding feature of the research is that the costs in terms of time, people and materials for carrying it out must be negligible. This, too, will exert an effect on the research. On the one hand it will inject a sense of realism into proposals, identifying what is and what is not manageable. On the other hand it will reduce, again, the variety of possibilities which are available to the researcher. Questions of cost will affect:

- the research questions which might be feasibly and fairly answered (e.g. some research questions might require: (a) interviewing, which is costly in time both to administer and to transcribe; (b) expensive commercially produced data-collection instruments, e.g. tests, and costly computer services, which may include purchasing software);
- the number of data-collection instruments used (e.g. some data-collection instruments, such as postal questionnaires, are costly for reprographics and postage);
- the people to whom the researcher might go (e.g. if teachers are to be released from teaching in order to be interviewed then cover for their teaching may need to be found);
- the number of foci which can be covered in the time (e.g. in uncovering relevant data, some foci might be costly in researcher's time);
- the size and nature of the reporting (e.g. the number of written reports produced, the costs of convening meetings).

Certain timescales permit certain types of research, for example, a short timescale permits answers to short-term issues, whilst long-term or large questions might require a long-term data-collection period to cover a range of foci. Costs in terms of time, resources and people might affect the choice of data-collection instruments. Time and cost will require the researcher to determine, for example, what will be the minimum representative sample of teachers or students in a school, as interviews are time-consuming and questionnaires are expensive to produce. These are only two examples of the real constraints on the research which must be addressed. Planning the research early on will enable the researcher to identify the boundaries within which the research must operate and what are the constraints on it.

Further, some research may be 'front-loaded' whilst other kinds are 'end-loaded'. 'Front-loaded' research is that which takes a considerable time to set up, for example to develop, pilot and test instruments for data collection, but then the data are quick to process and analyse. Quantitative research is often of this type (e.g. survey approaches) as it involves identifying the items for inclusion on the questionnaire, writing and piloting the questionnaire, and making the final adjustments. By contrast, 'end-loaded' research is that which may not take too long to set up and begin, but then the data collection and analysis may take a much longer time. Qualitative research is often of this type (e.g. ethnographic research), as a researcher may not have specific research questions in mind but may wish to enter a situation, group or community and only then discover – as they emerge over time – the key dynamics, features, characteristics and issues in the group (e.g. Turnbull's (1972) notorious study of the descent into inhumanity of the Ik tribe in their quest for daily survival as *The Mountain People*). Alternatively, a qualitative researcher may have a research question in mind but an answer to this may require a prolonged ethnography of a group (e.g. Willis's (1977) celebrated study of 'how working class kids get working class jobs, and others let them'). Between these two types – 'front-loaded' and 'end-loaded' – are many varieties of research that may take different periods of time to set up, conduct, analyse data and report the results. For example, a mixed methods research project may have several stages (see Table 11.2).

In example one in Table 11.2, in the first two stages of the research, the mixed methods run in sequence (qualitative then quantitative), and are only integrated in the final stage. In example two, in the first two stages the quantitative and qualitative stages run in parallel, i.e. they are separate from each other, and they only combine in the final stage of the research. In example

TABLE 11.2 THREE EXAMPLES OF PLANNING FOR TIME FRAMES FOR DATA COLLECTION IN MIXED METHODS RESEARCH

Example one	*Example two*	*Example three*
Qualitative data to answer research questions in total or in part, or to develop items for quantitative instruments (e.g. a numerical questionnaire survey)	Quantitative data and qualitative data in parallel to answer research questions in total or in part, or to identify participants for qualitative study	Quantitative and qualitative data together to answer research questions in total or in part and to raise further research questions
↓	↓	↓
Quantitative data to answer research questions in total or in part, or to identify participants for qualitative study (e.g. interviews)	Quantitative and qualitative data in parallel to answer research questions in total or in part	Quantitative and qualitative data to answer research questions in total or in part
↓	↓	↓
Quantitative and qualitative data to answer one or more research questions	Quantitative and qualitative data to answer one or more research questions	Quantitative and qualitative data to answer research questions in total or in part

three, the mixed methods are synthesized – combined – from the very start of the research.

The researcher must look at the timescales that are both required and available for planning and conducting the different stages of the research project.

Let us take another important set of questions: is the research feasible? Can it actually be done? Will the researchers have the necessary access to the schools, institutions and people? These issues were explored in the previous chapter. This issue becomes a major feature if the research is in any way sensitive (see Chapters 5 and 13).

11.6 Conducting and reporting a literature review

Before one can progress very far in planning research it is important to ground the project in validity and reliability. This is achieved, in part, by a thorough literature review of the state of the field and how it has been researched to date. Chapters 9 and 10 indicated that it is important for a researcher to conduct and report a literature review. A literature review should establish a theoretical framework for the research, indicating the nature and state of the theoretical and empirical fields and important research that has been conducted and policies that have been issued, defining key terms, constructs and concepts, and reporting key methodologies used in other research into the topic. The literature review also sets out what the key issues are in the field to be explored, and why they are, in fact, key issues, and it identifies gaps that need to be plugged in the field. All of this contributes not only to the credibility and validity of the research but to its topicality and significance, and it acts as a springboard into the study, defining the field, what needs to be addressed in it, why, and how it relates to – and extends – existing research in the field. The literature review, then, leads into, and is a foundation for, all areas and stages of the research in question: purpose, foci, research questions, methodology, data analysis, discussion and conclusions.

A literature review may report contentious areas in the field and why they are contentious, contemporary problems that researchers are trying to investigate in the field, difficulties that the field is facing from a research angle, new areas that need to be explored in the field.

A literature review synthesizes several different kinds of materials into an ongoing, cumulative argument that leads to a conclusion (e.g. of what needs to be researched in the present research, how and why). It can be like an extended essay that sets out:

- the argument(s) that the literature review will advance;
- points in favour of the argument(s) or thesis to be advanced/supported;
- points against the argument(s) or thesis to be advanced/supported;
- a conclusion based on the points raised and evidence presented in the literature review.

There are several points to consider in conducting, researching and writing a literature review (cf. University of North Carolina, 2007; Heath, 2009; University of Loughborough, 2009; Creswell, 2012; Wellington, 2015). A literature review:

- defines the field of the research;
- identifies the relevant key concepts, topics, theories, issues, research and ideas in the field under study (including, where relevant, gaps in the field);
- indicates the 'state of the art' in the field chosen;
- sets out the context – temporal, spatial, political etc. – of the research;
- identifies seminal and landmark ideas and research in the field;
- establishes and justifies the need for the research to be conducted, and establishes its significance and originality;
- sets out a rationale for the direction in which the study will go;
- establishes and justifies the methodology to be adopted in the research;
- establishes and justifies the focus of the research;
- sets out and justifies the warrants to be used in the research design.

The literature review is not just a descriptive summary, but an organized and developed argument, usually with subtitles, such that, if the materials were presented in a sequence other than that used, the literature review would lose meaning, coherence, cogency, logic and purpose. It presents, contextualizes, analyses, interprets, critiques and evaluates sources and issues, not just accepting what they say (e.g. it exposes and addresses what the sources overlook, misinterpret, misrepresent, neglect, say something that is contentious, about which they are outdated). It presents arguments and counter-arguments, evidence and counter-evidence about an issue and reveals similarities and differences between authors about the same issue. It sets out and justifies a theoretical framework for the research.

A literature review must state its purposes, methods of working, organization and how it will move to a conclusion, i.e. what it will do, what it will argue, what it will show, what it will conclude and how this links into or informs the subsequent research project. Further, it must state its areas of focus, maybe including a statement of the problem or issue that is being investigated, the hypothesis that the research will test, the themes or topics to be addressed, or the thesis that the research will defend.

A literature review, then, must be conclusive; it must be focused yet comprehensive in its coverage of relevant issues; it must present both sides of an issue or argument; it should address theories, models (where relevant), empirical research, methodological materials, substantive issues, concepts, content and elements of the field in question; and it must include and draw on many sources and types of written material and kinds of data (see, for example, Box 11.2).

In conducting the literature review, Creswell (2012) suggests that the researcher needs to identify key terms, followed by locating the literature, followed by a critical examination of the sources found, for example, for relevance, topicality, accuracy, scope and coverage, followed by the organization of the literature and then subsequent writing of the literature review. For a fuller treatment of conducting and reporting a literature review, we refer readers to Ridley (2010).

A distinction can be drawn between a literature review and a systematic review (cf. Denscombe, 2014). Both collect and synthesize literature, but the former is typically eclectic and even serendipitous, casting its net wide and synthesizing the results, whilst the latter is very focused, typically on empirical research studies (i.e. evidence-based for 'what works'), often those which report research trials (e.g. randomized controlled trials), with stated, often quite narrow or stringent selection and quality criteria, and often requiring measurement and metrics as evidence (though qualitative data are also possible). Systematic reviews are stand-alone documents in their own right, in contrast to literature reviews which tend to be a precursor to an empirical study, clearing the ground for the study to begin. Further, systematic reviews have a narrowly defined scope and focus on a specific question or questions, whereas literature reviews have a wider focus of study.

Systematic reviews typically make explicit the methodologies and criteria they have used in selecting the studies for inclusion (often based on the types and quality of the studies included and their relevance). This is not to argue for literature reviews not being systematic and stringent, or not making clear the criteria used for selecting the literature, or not being rigorous in evaluation of the literature; rather it is to point to the difference in the breadth/narrowness of inclusion criteria and kinds of studies.

Denscombe (2014, pp. 142–3) notes that systematic reviews tend to focus on already-published studies or studies which are publicly available. Whereas in medicine the studies might be of a similar kind (e.g. randomized controlled trials), in the social sciences this may not be the case, rendering comparison and evaluation of studies more problematic (see Chapter 21).

BOX 11.2 TYPES OF INFORMATION IN A LITERATURE REVIEW

Books: hard copy and e-books.

Articles in journals: academic and professional: hard copy and online.

Empirical and non-empirical research.

Reports: from governments, NGOs, organizations, influential associations.

Policy documents: from governments, organizations, 'think tanks'.

Public and private records.

Research papers and reports, for example, from research centres, research organizations.

Theses and dissertations.

Manuscripts.

Databases: searchable collections of records, electronic or otherwise.

Conference papers: local, regional, national, international.

Primary sources: original, first-hand, contemporary source materials such as documents, speeches, diaries and personal journals, letters, autobiographies, memoirs, public records and reports, emails and other correspondence, interview and raw research data, minutes and agendas of meetings, memoranda, proceedings of meetings, communiqués, charters, acts of parliament or government, legal documents, pamphlets, witness statements, oral histories, unpublished works, patents, websites, video or film footage, photographs, pictures and other visual materials, audio-recordings, artefacts, clothing, or other evidence. These are usually produced directly at the time of, close to, or in connection with, the research in question.

Online databases.

Electronic journals or media.

Secondary sources: second-hand, non-original materials, materials written about primary sources, or materials based on sources that were originally elsewhere or which other people have written or gathered, where primary materials have been worked on or with, described, reported, analysed, discussed, interpreted, evaluated, summarized or commented upon, or which are at one remove from the primary sources, or which are written some time after the event, for example, encyclopaedias, dictionaries, newspaper articles, reports, critiques, commentaries, digests, textbooks, research syntheses, meta-analyses, research reviews, histories, summaries, analyses, magazine articles, pamphlets, biographies, monographs, treatises, works of criticism (e.g. literary, political).

Tertiary sources: distillations, collections or compilations of primary and secondary sources, for example, almanacs, bibliographies, catalogues, dictionaries, encyclopaedias, fact books, directories, indexes, abstracts, bibliographies, manuals, guidebooks, handbooks, chronologies.

11.7 Searching for literature on the Internet

The storage and retrieval of research data on the Internet play an important role not only in keeping researchers abreast of developments across the world, but also in providing access to data which can inform literature searches to establish construct and content validity in their own research. Indeed, some kinds of research are essentially large-scale literature searches (e.g. the research papers published in the journals *Review of Educational Research* and *Review of Research in Education*, and materials from the Evidence for Policy and Practice Information and Co-ordinating Centre (EPPI-Centre) at the University of London (http://eppi.ioe.ac.uk/cms) and the What Works Clearinghouse in the United States (http://ies.ed.gov/ncee/wwc)). Online journals, abstracts and titles enable researchers to keep up with the cutting edge of research and to conduct a literature search of relevant material on their chosen topic. Websites and email correspondence enable networks and information to be shared. For example, researchers wishing to gain instantaneous global access to literature and recent developments in research associations can reach all parts of the world in a matter of seconds through websites.

In what follows we indicate the main sources of literature by *kind* only. The companion website to this book gives websites of sources within each kind. Given that websites change and often go out of date quickly, we

strongly recommend that readers go to this companion website, as it is updated and provides many websites, organized by type and source of information. Below we provide websites only for those which have stood the test of time and have not gone out of date for many years.

Researchers wishing to access *educational research associations, organizations and centres* can visit websites such as:

American Educational Research Association: www.aera.net;
Educational Resources Information Center (ERIC): http://eric.ed.gov;
British Educational Research Association: www.bera.ac.uk;
Australian Council for Educational Research: www.acer.edu.au;
European Educational Research Association: www.eera-ecer.de;
National Foundation for Educational Research (UK): www.nfer.ac.uk;
Economic and Social Research Council in the UK: www.esrc.ac.uk.

Researchers wishing to access online journal indices and references for published research results have a variety of websites which they can visit to see *catalogues*, *gateways* and *databases*, and we indicate key sites here on the companion website. These include: the British Education Index; the Organisation for Economic Co-operation and Development (OECD); Social Science Citation Indexes; national statistics services; government departments of education; archives (including statistics databases); the UK's Data Service and Data Archive; UNESCO databases and reports; the Council of European Social Science Data Archive; the gateway to the European Union's sites for data and reports; the United States National Center for Educational Statistics; and the World Bank's gateway to data and statistics.

With regard to searching *libraries*, there are several useful websites for: the British Library and all its online catalogues; the Library site, linking to 18,000 libraries; the United States Library of Congress; the gateway to US libraries; search engines for UK libraries; the Virtual Library; and the Online Computer Library Center. The websites for all these are given in the companion website to this book.

With regard to *items in print*, the website for Books in Print is: www.booksinprint.com, which provides a comprehensive listing of current books in print.

Additional useful *educational research resources* can be found from the National Academies Press (both in total and in its Education Section); centres for the provision of free educational materials and related websites; merged Internet Public Library and the Librarians' Internet Index; and the UK's Research Councils. The websites for all these are given in the companion website to this book.

For *theses*, researchers can go to: the British Library Electronic Theses Online (http://ethos.bl.uk/Home.do); the DART portal for European E-theses; the Aslib Index to Theses; and the Networked Digital Library of Theses and Dissertations (including e-theses). The websites for all of these are given in the companion website to this book.

Most *journals* provide access to abstracts, free online and free alerting services (an email to provide readers with the table of contents of each new issue as it appears), though access to the full article is typically by subscription only. Online journals also provide a comprehensive searching service, in which researchers can search either the specific journal in question or, indeed, the entire range of journals provided by that publisher, using keywords, authors, titles, the digital object identifier (DOI), date and date range, tables of contents, access to articles which appear online before they appear in hard copy etc. Particularly useful here is the facility provided to search the journal in question, or all of that publisher's journals, by keyword. Here the articles can be returned in order by relevance, date, authors, title. It is a first-class facility.

There are many providers of online journals, and we list these, with their websites, in the companion website to the book, including: EBSCO; Emerald Insight; Ingenta; Kluweronline; ProQuest; ProQuest Digital Dissertations and Theses; Science Direct; Web of Knowledge; the Directory of Open Access Journals; the Bath Information and Data Services (BIDS); JSTOR; Journal TOCs (tables of contents). Google Scholar (http://scholar.google.com) is a widely used search engine for articles and books, and it can be interrogated by topic, year, range of years, relevance and the number of citations.

With regard to *statistics*, the companion website to this book provides websites of: the portal to the UK's national statistics; the US National Center for Education Statistics; the UK's Data Service Census Support; and the UK's Office for National Statistics.

When searching the Internet it is useful to keep in mind several points:

- placing words, phrases or sentences inside inverted commas ("…") will keep those words together and in that order in searching for material; this helps to reduce an overload of returned sites;
- placing an asterisk (*) after a word or part of a word will return sites that start with that term but which

have different endings, for example, teach* will return sites on teach, teaching, teacher;
- placing a tilde mark (~) before a word will identify similar words to that which have been entered, for example, ~English teaching will return sites on English language as well as English teaching;
- placing the words *and*, *not*, *or* between phrases or words will return websites where the command indicated in each one of these words is addressed.

Finding research information, where not available from databases and indices on CD-ROMs, is often done through the Internet by trial and error and serendipity, identifying the keywords singly or in combination (between inverted commas). The system of 'bookmarking' websites enables rapid retrieval of these websites for future reference.

Evaluating websites

The use of the Internet for educational research requires an ability to evaluate websites. The Internet is a vast store of disorganized and often unvetted material, and researchers need to be able to ascertain quite quickly how far the web-based material is appropriate. There are several criteria for evaluating websites, including the following (e.g. Tweddle *et al.*, 1998; Rodrigues and Rodrigues, 2000):

- the purpose of the site, as this enables users to establish its relevance and appropriateness;
- the authority and authenticity of the material, which should both be authoritative and declare its sources;
- the content of the material: its up-to-dateness, relevance and coverage;
- the credibility and legitimacy of the material (e.g. is it from a respected source or institution?);
- the correctness, accuracy, completeness and fairness of the material;
- the objectivity and rigour of the material being presented and/or discussed.

In evaluating educational research materials on the web, researchers and teachers can ask themselves several questions:

- Is the author identified?
- Does the author establish her/his expertise in the area, and institutional affiliation?
- Is the organization reputable?
- Is the material referenced; does the author indicate how the material was gathered?
- What is this website designed to do (e.g. to provide information, to persuade)?
- Is the material up-to-date?
- Is the material free from biases, personal opinions and offence?
- How do we know that the author is authoritative on this website?

It is important for the researcher to keep full bibliographic data of the website material used, including the date on which it was retrieved and the website address.

With these preliminary comments, let us turn to the four main areas of the framework for planning research.

11.8 How to operationalize research questions

Chapter 10 indicated that there are many different kinds of research questions that derive from different purposes of the research. For example, research questions may seek:

- to describe what a phenomenon is and what is, or was, happening in a particular situation (e.g. ethnographies, case studies, complexity theory-based studies, surveys);
- to predict what will happen (e.g. experimentation, causation studies, research syntheses);
- to investigate values (e.g. evaluative research, policy research, ideology critique, participatory research);
- to examine the effects of an intervention (e.g. experimentation, ex post facto studies, case studies, action research, causation studies);
- to examine perceptions of what is happening (e.g. ethnography, survey);
- to test a theory;
- to compare the effects of an intervention in different contexts (experimentation, comparative studies);
- to develop, implement, monitor and review an intervention (e.g. participatory research, action research).

Research questions can ask 'what', 'who', 'why', 'when', 'where' and 'how' (cf. Newby, 2010, pp. 65–6). As mentioned in Chapter 10, the researcher has to turn the general purposes of the research into actual practice, i.e. to operationalize the research, turning a general research aim or purpose into specific, particular concrete research questions (or hypotheses) to which exact, specific, concrete answers can be given. It involves specifying a set of operations, elements or behaviours that can be identified, measured or manipulated. The process moves from the general to the particular, from the abstract to the concrete, checking each research question against the research aims until exact, specific, concrete questions have been reached, in all likelihood through an iterative, recursive process (i.e. backwards

and forwards between research aims and emerging research questions) to enable exact, specific, concrete answers to be provided. We provide examples of this in Chapter 10.

11.9 Distinguishing methods from methodologies

In planning research it is important to clarify the distinction between methodology and methods, approaches and instruments, styles of research and ways of collecting data. Simply put, methodology concerns how we find out about the phenomenon, the approach to be used, the principles which underpin it and the justification for using the kind of research approach adopted, the type of study to be conducted, how the research is undertaken (with its associated issues of kinds of research, sampling, instrumentation, canons of validity etc.). Methods concern instrumentation: how data are collected and analysed, whilst methodology justifies the methods used.

The decision on which instrument (method) to use for data collection frequently follows from an earlier decision on which kind (methodology) of research to undertake, for example: a survey; an experiment; an in-depth ethnography; action research; case study research; testing and assessment.

Subsequent chapters of this book set out each of these research styles, their principles, rationales and purposes, and the instrumentation and data types that may be suitable for them. For conceptual clarity it is possible to set out some key features of these (Table 11.3). When decisions have been reached on the stage of research design and methodology, a clear plan of action will have been prepared.

Several of the later chapters of this book are devoted to specific instruments for collecting data, for example: interviews; questionnaires; observation; tests; accounts; biographies; case studies; role-playing; simulations; personal constructs.

11.10 Data analysis

The prepared researcher will need to consider how the data will be analysed. This is important, as it has a specific bearing on the form of the instrumentation. For example, a researcher will need to plan carefully the layout and structure of a questionnaire survey in order to assist data entry for computer reading and analysis; an inappropriate layout may obstruct data entry and subsequent analysis by computer. The planning of data analysis will need to consider:

- What will be done with the data when they have been collected – how will they be processed and analysed?
- How will the results of the analysis be verified, cross-checked and validated?

Decisions will need to be taken with regard to the statistical tests that will be used in data analysis as this will affect the content, type and layout of research items (e.g. in a questionnaire), and the computer packages that are available for processing quantitative and qualitative data, for example, SPSS and NVivo respectively. For statistical processing the researcher will need to ascertain the level of data being processed – nominal, ordinal, interval or ratio (see Chapter 38). Part 5 addresses issues of data analysis and which statistics to use; the choice is not arbitrary (Siegel, 1956; Cohen and Holliday, 1996; Hopkins *et al*., 1996). For qualitative data analysis researchers have at their disposal a range of techniques, for example:

- coding and content analysis of field notes (Miles and Huberman, 1984);
- cognitive mapping (Jones, 1987; Morrison, 1993);
- seeking patterning of responses;
- looking for causal pathways and connections (Miles and Huberman, 1984);
- presenting cross-site analysis (ibid.);
- case studies;
- personal constructs;
- narrative accounts (Flick, 2009; Creswell, 2012);
- action research analysis;
- analytic induction (Denzin, 1989);
- constant comparison and grounded theory (Glaser and Strauss, 1967; Flick 2009; Creswell, 2012);
- discourse analysis (Stillar, 1998);
- biographies and life histories (Atkinson, 1998; Flick, 2009; Creswell, 2012).

The criteria for deciding which forms of data analysis to undertake are governed both by fitness for purpose and legitimacy – the form of data analysis must be appropriate for the kinds of data gathered. For example, it would be inappropriate to use certain statistics with certain kinds of numerical data (e.g. using means with nominal data), or to use causal pathways on unrelated cross-site analysis.

11.11 Presenting and reporting the results

As with the stage of planning data analysis, the prepared researcher will need to consider the form of the

TABLE 11.3 ELEMENTS OF RESEARCH DESIGNS

Model	*Purposes*	*Foci*	*Key terms*	*Characteristics*
Survey	Gathering large-scale data in order to make generalizations Generating statistically manipulable data Gathering context-free data	Opinions Scores Outcomes Conditions Ratings	Measuring Testing Representativeness Generalizability	Describes and explains Represents wide population Gathers numerical data Much use of questionnaires and assessment/test data
Experiment	Comparing under controlled conditions Making generalizations about efficacy Objective measurement of treatment Establishing causality	Initial states, intervention and outcomes Randomized controlled trials	Pre-test and post-test Identification, isolation and control of key variables Generalizations Comparing Causality	Control and experimental groups Treats situations like a laboratory Causes due to experimental intervention Does not judge worth Simplistic
Ethnography	Portrayal of events in subjects' terms Subjective and reporting of multiple perspectives Description, understanding and explanation of a specific situation	Perceptions and views of participants Issues as they emerge over time	Subjectivity Honesty, authenticity Non-generalizable Multiple perspectives Exploration and rich reporting of a specific context Emergent issues	Context-specific Formative and emergent Responsive to emerging features Allows room for judgements and multiple perspectives Wide database gathered over a long period of time Time consuming to process data
Action research	To plan, implement, review and evaluate an intervention designed to improve practice/solve local problem To empower participants through research involvement and ideology critique To develop reflective practice To promote equality democracy To link practice and research To promote collaborative research	Everyday practices Outcomes of interventions Participant empowerment Reflective practice Social democracy and equality Decision making	Action Improvement Reflection Monitoring Evaluation Intervention Problem solving Empowering Planning Reviewing	Context-specific Participants as researchers Reflection on practice Interventionist – leading to solution of 'real' problems and meeting 'real' needs Empowering for participants Collaborative Promoting praxis and equality Stakeholder research

continued

TABLE 11.3 CONTINUED

Case study	To portray, analyse and interpret the uniqueness of real individuals and situations through accessible accounts To catch the complexity and situatedness of behaviour To contribute to action and intervention To present and represent reality – to give a sense of 'being there'	Individuals and local situations Unique instances A single case Bounded phenomena and systems: ■ individual ■ group ■ roles ■ organizations ■ community	Individuality, uniqueness In-depth analysis and portrayal Interpretive and inferential analysis Subjective Descriptive Analytical Understanding specific situations Sincerity Complexity Particularity	In-depth, detailed data from wide data source Participant and non-participant observation Non-interventionist Empathic Holistic treatment of phenomena What can be learned from the particular case
Testing and assessment	To measure achievement and potential To diagnose strengths and weaknesses To assess performance and abilities	Academic and non-academic, cognitive, affective and psychomotor domains – low order to high order Performance, achievement, potential, abilities Personality characteristics	Reliability Validity Criterion-referencing Norm-referencing Domain-referencing Item-response Formative Summative Diagnostic Standardization Moderation	Materials designed to provide scores that can be aggregated Enables individuals and groups to be compared In-depth diagnosis Measures performance

reporting of the research and its results, giving due attention to the needs of different audiences (e.g. an academic audience may require different contents from a wider professional audience and, a fortiori, from a lay audience). Decisions here address:

- How to write up and report the research;
- When to write up and report the research (e.g. ongoing or summative);
- How to present the results in tabular and/or written-out form;
- How to present the results in non-verbal forms;
- To whom to report (the necessary and possible audiences of the research);
- How frequently to report.

For an example of setting out a research report, see the accompanying website.

11.12 A planning matrix for research

In planning a piece of research, the range of questions to be addressed can be set into a matrix. Table 11.4 provides such a matrix, in the left-hand column of which are the questions which figure in the four main areas set out so far:

1 orienting decisions;
2 research design and methodology;
3 data analysis;
4 presenting and reporting the results.

Questions 1–10 are the orienting decisions, questions 11–22 concern the research design and methodology, questions 23–4 cover data analysis, and questions 25–30 deal with presenting and reporting the results. Within each of the thirty questions there are several sub-questions which research planners may need to address. For example, within question 5 ('What are the

TABLE 11.4 A MATRIX FOR PLANNING RESEARCH

Orienting decisions

Question	*Sub-issues and problems*	*Decisions*
1 Who wants the research?	Is the research going to be useful? Who might wish to use the research? Are the data going to be public? What if different people want different things from the research? Can people refuse to participate?	Find out the controls over the research which can be exercised by respondents. Set out the scope and audiences of the research. Determine the reporting mechanisms.
2. Who will receive the research?	Will participants be able to veto the release of parts of the research to specified audiences? Will participants be able to give the research to whomsoever they wish? Will participants be told to whom the research will go?	Determine the proposed internal and external audiences of the research. Determine the controls over the research which can be exercised by the participants. Determine the rights of the participants and the researcher to control the release of the research.
3. What powers do the recipients of the research have?	What use will be made of the research? How might the research be used for or against the participants? What might happen if the data fall into the 'wrong' hands? Will participants know in advance what use will and will not be made of the research?	Determine the rights of recipients to do what they wish with the research. Determine the respondents' rights to protection as a result of the research.
4 What are the timescales of the research?	Is there enough time to do all the research? How to decide what to be done within the timescale?	Determine the timescales and timing of the research.
5 What are the purposes of the research?	What are the formal and hidden agendas here? Whose purposes are being served by the research? Who decides the purposes of the research? How will different purposes be served in the research?	Determine all the possible uses of the research. Determine the powers of the respondents to control the uses made of the research. Decide on the form of reporting and the intended and possible audiences of the research.
6 What are the research questions?	Who decides what the questions will be? Do participants have rights to refuse to answer or take part? Can participants add their own questions?	Determine the participants' rights and powers to participate in the planning, form and conduct of the research. Decide the balance of all interests in the research.
7 What must be the focus in order to answer the research questions?	Is sufficient time available to focus on all the necessary aspects of the research? How will the priority foci be decided? Who decides the foci?	Determine all the aspects of the research, prioritize them, and agree on the minimum necessary areas of the research. Determine decision-making powers on the research.

continued

TABLE 11.4 CONTINUED

8 What costs are there – human, material, physical, administrative, temporal?	What support is available for the researcher? What materials are necessary?	Cost out the research.
9 Who owns the research?	Who controls the release of the report? What protections can be given to participants? Will participants be identified and identifiable/traceable? Who has the ultimate decision on what data are included?	Determine who controls the release of the report. Decide the rights and powers of the researcher. Decide the rights of veto. Decide how to protect those who may be identified/identifiable in the research.
10 At what point does the ownership pass from the respondent to the researcher and from the researcher to the recipients?	Who decides the ownership of the research? Can participants refuse to answer certain parts if they wish, or, if they have the option not to take part, must they opt out of everything? Can the researcher edit out certain responses?	Determine the ownership of the research at all stages of its progress. Decide the options available to the participants. Decide the rights of different parties in the research, e.g. respondents, researcher, recipients.

Research design and methodology

Question	*Sub-issues and problems*	*Decisions*
11 What are the specific purposes of the research?	How do these purposes derive from the overall aims of the research? Will some areas of the broad aims be covered, or will the specific research purposes have to be selective? What priorities are there?	Decide the specific research purposes and write them as concrete questions.
12 How are the general research purposes and aims operationalized into specific research questions?	Do the specific research questions together cover all the research purposes? Are the research questions sufficiently concrete as to suggest the kinds of answers and data required and the appropriate instrumentation and sampling? How to balance adequate coverage of research purposes with the risk of producing an unwieldy list of sub-questions?	Ensure that each main research purpose is translated into specific, concrete questions that, together, address the scope of the original research questions. Ensure that the questions are sufficiently specific as to suggest the most appropriate data types, kinds of answers required, sampling and instrumentation. Decide how to ensure that any selectivity still represents the main fields of the research questions.
13 What are the specific research questions?	Do the specific research questions demonstrate construct and content validity?	Ensure that the coverage and operationalization of the specific questions addresses content and construct validity respectively.
14 What needs to be the focus of the research in order to answer the research questions?	How may foci are necessary? Are the foci clearly identifiable and operationalizable?	Decide the number of foci of the research questions. Ensure that the foci are clear and can be operationalized.

15 What is the main methodology of the research?	How many methodologies are necessary? Are several methodologies compatible with each other? Will a single focus/research question require more than one methodology (e.g. for triangulation and concurrent validity)?	Decide the number, type and purposes of the methodologies to be used. Decide whether one or more methodologies is/are necessary to gain answers to specific research questions. Ensure that the most appropriate form of methodology is employed.
16 How will validity and reliability be addressed?	Will there be the opportunity for cross-checking? Will the depth and breadth required for content validity be feasible within the constraints of the research (e.g. time constraints, instrumentation)? In what senses are the research questions valid (e.g. construct validity)? Are the questions fair? How does the researcher know if people are telling the truth? What kinds of validity and reliability are to be addressed? How will the researcher take back the research to respondents for them to check that the interpretations are fair and acceptable? How will data be gathered consistently over time? How to ensure that each respondent is given the same opportunity to respond?	Determine the process of respondent validation of the data. Decide a necessary minimum of topics to be covered. Subject the plans to scrutiny by critical friends ('jury' validity). Pilot the research. Build in cross-checks on data. Address the appropriate forms of reliability and validity. Decide the questions to be asked and the methods used to ask them. Determine the balance of open and closed questions.
17 How will reflexivity be addressed?	How will reflexivity be recognized? Is reflexivity a problem? How can reflexivity be included in the research?	Determine the need to address reflexivity and to make this public. Determine how to address reflexivity in the research.
18 What kinds of data are required?	Does the research need words, numbers or both? Does the research need opinions, facts or both? Does the research seek to compare responses and results or simply to illuminate an issue?	Determine the most appropriate types of data for the foci and research questions. Balance objective and subjective data. Determine the purposes of collecting different types of data and the ways in which they can be processed.
19 From whom will data be acquired (i.e. sampling)?	Will there be adequate time to go to all the relevant parties? What kind of sample is required (e.g. probability/non-probability/random/ stratified etc.)? How to achieve a representative sample (if required)?	Determine the minimum and maximum sample. Decide on the criteria for sampling. Decide the kind of sample required. Decide the degree of representativeness of the sample. Decide how to follow up and not to follow up on the data gathered.

continued

TABLE 11.4 CONTINUED

20 Where else will data be available?	What documents and other written sources of data can be used? How to access and use confidential material? What will be the positive or negative effects on individuals of using certain documents?	Determine the necessary/desirable/possible documentary sources. Decide access and publication rights and protection of sensitive data.
21 How will the data be gathered (i.e. instrumentation)?	What methods of data gathering are available and appropriate to yield data to answer the research questions? What methods of data gathering will be used? How to construct interview schedules/questionnaires/tests/ observation schedules? What will be the effects of observing participants? How many methods should be used (e.g. to ensure reliability and validity)? Is it necessary or desirable to use more than one method of data collection on the same issue? Will many methods yield more reliable data? Will some methods be unsuitable for some people or for some issues?	Determine the most appropriate data-collection instruments to gather data to answer the research questions. Pilot the instruments and refine them subsequently. Decide the strengths and weaknesses of different data-collection instruments in the short and long term. Decide which methods are most suitable for which issues. Decide which issues will require more than one data-collection instrument. Decide whether the same data-collection methods will be used with all the participants.
22 Who will undertake the research?	Can different people plan and carry out different parts of the research?	Decide who will carry out the data collection, processing and reporting.
Data Analysis		
Question	*Sub-issues and problems*	*Decisions*
23 How will the data be analysed?	Are the data to be processed numerically or verbally? What computer packages are available to assist data processing and analysis? What statistical tests will be needed? How to perform a content analysis of word data? How to summarize and present word data? How to process all the different responses to open-ended questions? Will the data be presented person by person, issue by issue, aggregated to groups, or a combination of these? Does the research seek to make generalizations? Who will process the data?	Clarify the legitimate and illegitimate methods of data processing and analysis of quantitative and qualitative data. Decide which methods of data processing and analysis are most appropriate for which types of data and for which research questions. Check that the data processing and analysis will serve the research purposes. Determine the data protection issues if data are to be processed by 'outsiders' or particular 'insiders'.

24 How to verify and validate the data and their interpretation?	What opportunities will there be for respondents to check the researcher's interpretation? At what stages of the research is validation necessary? What will happen if respondents disagree with the researcher's interpretation?	Determine the process of respondent validation during the research. Decide the reporting of multiple perspectives and interpretations. Decide respondents' rights to have their views expressed or to veto reporting.
Presenting and reporting the results		
Question	*Sub-issues and problems*	*Decisions*
25 How to write up and report the research?	Who will write the report and for whom? How detailed must the report be? What must the report contain? What channels of dissemination of the research are to be used?	Ensure that the most appropriate form of reporting is used for the audiences. Keep the report as short, clear and complete as possible. Provide summaries if possible/fair. Ensure that the report enables fair critique and evaluation to be undertaken.
26 When to write up and report the research (e.g. ongoing or summative)?	How many times are appropriate for reporting? For whom are interim reports compiled? Which reports are public?	Decide the most appropriate timing, purposes and audiences of the reporting. Decide the status of the reporting (e.g. formal, informal, public, private).
27 How to present the results in tabular and/or written-out form?	How to ensure that everyone will understand the language or the statistics? How to respect the confidentiality of the participants? How to report multiple perspectives?	Decide the most appropriate form of reporting. Decide whether to provide a glossary of terms. Decide the format(s) of the reports. Decide the number and timing of the reports. Decide the protection of the individual's rights, balancing this with the public's rights to know.
28 How to present the results in non-verbal forms?	Will different parties require different reports? How to respect the confidentiality of the participants? How to report multiple perspectives?	Decide the most appropriate form of reporting. Decide the number and timing of the reports. Ensure that a written record is kept of oral reports. Decide the protection of the individual's rights, balancing this with the public's rights to know.
29 To whom to report (the necessary and possible audiences of the research)?	Do all participants receive a report? What will be the effects of not reporting to stakeholders?	Identify the stakeholders. Determine the least and most material to be made available to the stakeholders.
30 How frequently to report?	Is it necessary to provide interim reports? If interim reports are provided, how might this affect the future reports or the course of the research?	Decide on the timing and frequency of the reporting. Determine the formative and summative nature of the reports.

purposes of the research?') the researcher would have to differentiate major and minor purposes, explicit and maybe implicit purposes, whose purposes are being served by the research and whose interests are being served by the research. An example of these sub-issues and problems is contained in the second column.

At this point the planner is still at the divergent phase of the research planning, dealing with *planned possibilities*, opening up the research to all facets and interpretations. In the column headed 'decisions' the research planner is moving towards a convergent phase, where planned possibilities become visible within the terms of constraints available to the researcher. Here the researcher moves down the column marked 'decisions' to see how well the decision which is taken in regard to one issue/question fits in with the decisions in regard to other issues/questions. For one decision to fit with another, four factors must be present:

1. All of the cells in the 'decisions' column must be coherent – they must not contradict each other;
2. All of the cells in the 'decisions' column must be mutually supporting;
3. All of the cells in the 'decisions' column must be practicable when taken separately;
4. All of the cells in the 'decisions' column must be practicable when taken together.

Not all of the planned possibilities might be practicable when these four criteria are applied. It would be of very little use if the methods of data collection listed in the 'decisions' column of question 21 ('How will the data be gathered?') offered little opportunity to fulfil the needs of acquiring information to answer question 7 ('What must be the focus in order to answer the research questions?'), or if the methods of data collection are impracticable within the timescales available in question 4.

In the matrix of Table 11.4 the cells have been completed in a deliberately content-free way, i.e. the matrix as presented here does not deal with the specific, actual points which might emerge in a particular research proposal. If the matrix were to be used for planning an actual piece of research, then, instead of couching the wording of each cell in generalized terms, it would be more useful if *specific, concrete* responses were given which address particular issues and concerns in the research proposal.

Many of these questions concern rights, responsibilities and the political uses (and abuses) of the research. This underlines the view that research is an inherently political and moral activity; it is not politically or morally neutral. The researcher has to be concerned with the uses as well as the conduct of the research.

11.13 Managing the planning of research

It should not be assumed that research will always go according to plan. For example, the attrition of the sample might happen (participants leaving during the research), or a poor response rate to questionnaires might be encountered, rendering subsequent analysis, reporting and generalization problematical; administrative support might not be forthcoming, or there might be serious slippage in the timing. This is not to say that a plan for the research should not be made; rather it is to suggest that it is dangerous to put absolute faith in it. For an example of what to include in a research proposal, see the accompanying website.

To manage the complexity in planning outlined above, a simple four-stage model can be proposed:

Stage 1: Identify the purposes of the research.
Stage 2: Identify and give priority to the constraints under which the research will take place;
Stage 3: Plan the possibilities for the research within these constraints.
Stage 4: Decide the research design.

Each stage contains several operations. Figure 11.1 clarifies this four-stage model, drawing out the various operations contained in each stage.

Research planners can consider which instruments will be used at which stage of the research and with which sectors of the sample population. Table 11.5 sets out a matrix of these for planning, for example, a small-scale piece of research.

A matrix approach such as this enables research planners to see at a glance their coverage of the sample and of the instruments used at particular points in time, making omissions clear and promoting such questions as:

- Why are certain instruments used at certain times and not at others?
- Why are certain instruments used with certain people and not with others?
- Why do certain times in the research use more instruments than other times?
- Why is there such a concentration of instruments at the end of the study?
- Why are certain groups involved in more instruments than other groups?
- Why are some groups apparently neglected (e.g. parents), for example, is there a political dimension to the research?
- Why are questionnaires the main kinds of instrument to be used?

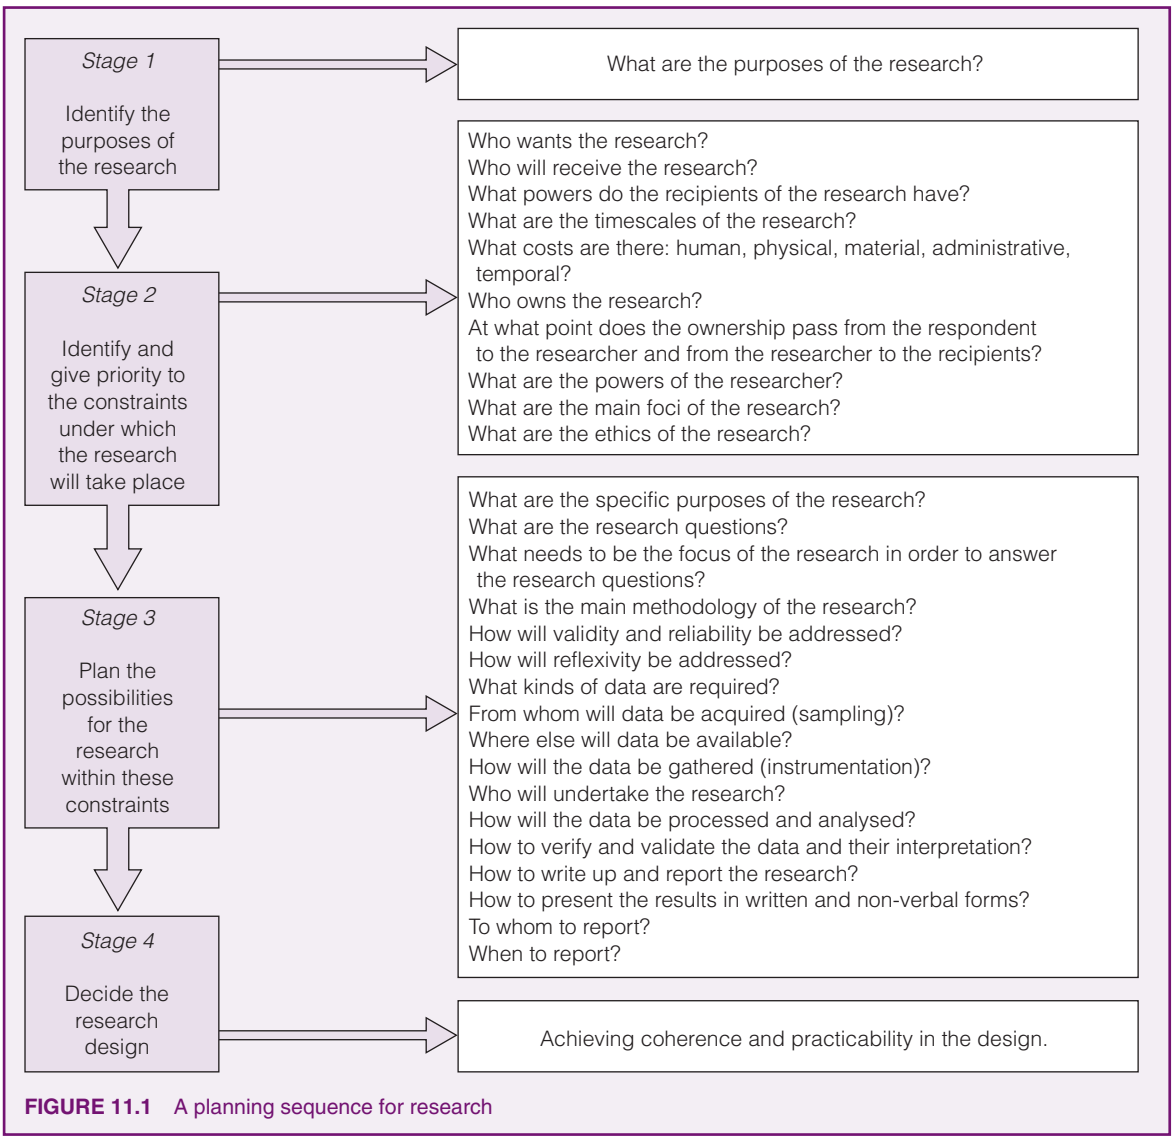

FIGURE 11.1 A planning sequence for research

- Why are some instruments (e.g. observation, testing) not used at all?
- What makes the five stages separate?
- Are documents only held by certain parties (and, if so, might one suspect an 'institutional line' to be revealed in them)?
- Are some parties more difficult to contact than others (e.g. university teacher educators)?
- Are some parties more important to the research than others (e.g. school principals)?
- Why are some parties excluded from the sample (e.g. school governors, policy makers, teachers' associations and unions)?
- What is the difference between the three groups of teachers?

Matrix planning is useful for exposing key features of the planning of research. Further matrices might be constructed to indicate other features of the research, for example:

- the timing of the identification of the sample;
- the timing of the release of interim reports;
- the timing of the release of the final report;
- the timing of pre-tests and post-tests (in an experimental style of research);

TABLE 11.5 A PLANNING MATRIX FOR RESEARCH

Time sample	*Stage 1 (start)*	*Stage 2 (3 months)*	*Stage 3 (6 months)*	*Stage 4 (9 months)*	*Stage 5 (12 months)*
Principal/ Headteacher	Documents Interview Questionnaire 1	Interview	Documents Questionnaire 2	Interview	Documents Interview Questionnaire 3
Teacher group 1	Questionnaire 1		Questionnaire 2		Questionnaire 3
Teacher group 2	Questionnaire 1		Questionnaire 2		Questionnaire 3
Teacher group 3	Questionnaire 1		Questionnaire 2		Questionnaire 3

Parents	Questionnaire 1		Questionnaire 2		Questionnaire 3
University teacher educators	Interview Documents				Interview Documents

- the timing of intensive necessary resource support (e.g. reprographics);
- the timing of meetings of interested parties.

These examples cover timings only; other matrices might be developed to cover other combinations, for example: reporting by audiences; research team meetings by reporting; instrumentation by participants etc. They are useful summary devices.

11.14 A worked example

Let us say that a school is experiencing low morale and the researcher has been brought in to investigate the school's organizational culture as it impacts on morale. The researcher has been given open access to the school and has five months from the start of the project to producing the report. (For a fuller version of this, see the accompanying website.) She plans the research thus:

1 Purposes

i To present an overall and in-depth picture of the organizational culture(s) and subcultures, including the prevailing cultures and subcultures, within the school;
ii To provide an indication of the strength of the organizational culture(s);
iii To make suggestions and recommendations about the organizational culture of, and its development at, the school.

2 Research questions

i What are the major and minor elements of organizational culture in the school?
ii What are the organizational cultures and subcultures in the school?
iii Which (sub)cultures are the most and least prevalent in the school, and in which parts of the school are these most and least prevalent?
iv How strong and intense are the (sub)cultures in the school?
v What are the causes and effects of the (sub)cultures in the school?
vi How can the (sub)cultures be improved in the school?

3 Focus

Three levels of organizational cultures will be examined:

i underlying values and assumptions;
ii espoused values and enacted behaviours;
iii artefacts.

Organizational culture concerns values, assumptions, beliefs, espoused theories, observed practices, areas of conflict and consensus, the formal and hidden messages contained in artefacts, messages, documents and language, the 'way we do things', the physical environment, relationships, power, control, communication, customs and rituals, stories, the reward system and motivation, the micro-politics of the school, involvement in decision making, empowerment and exploitation/manipulation, leadership, commitment, and so on.

In terms of the 'possible sequence of considerations' set out earlier in the chapter, the 'preparatory issues' here include: (i) a literature review on organizational culture, organizational health, leadership of organizations, motivation, communication and empowerment; (ii) the theoretical framework underpinning the research

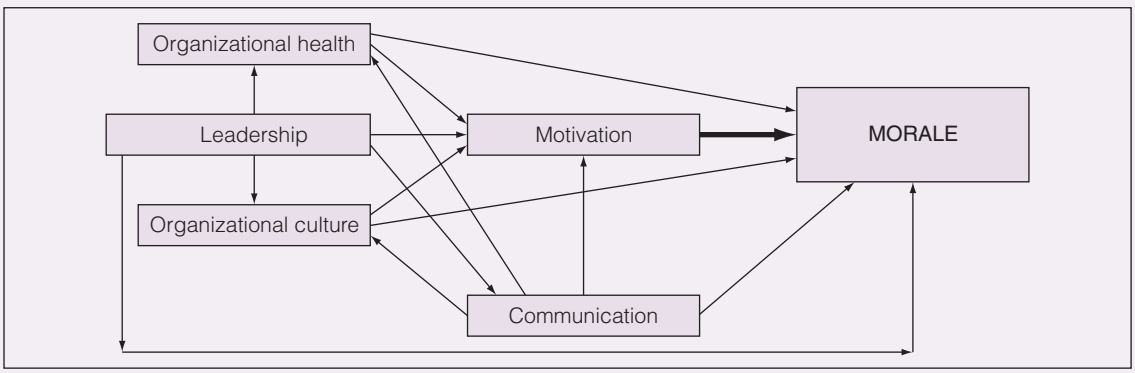
(see Figure 11.2); and (iii) the devising of the conceptual framework to include: levels of organizational culture (artefacts, enacted values and underlying assumptions; see Figure 11.3); key features of organizational health; key issues in, and styles of, leadership; key features of communication (e.g. direction, content, medium); and motivation (intrinsic and extrinsic). Together these constitute the ontological dimension of the 'preparatory issues' of the 'possible sequence of considerations'.

4 Methodology

The methodologies here address the epistemological dimension of the 'preparatory issues' of the 'possible sequence of considerations' set out earlier in the chapter: how we can know about, and research, the phenomenon. Here organizational culture is intangible, yet its impact on a school's operations and morale is very tangible. This suggests that, whilst quantitative measures may be used, they are likely only to yield comparatively superficial information about the school's culture. In order to probe beneath the surface of the school's culture, to examine the less overt aspects of the school's culture(s) and subcultures, it is important to combine quantitative and qualitative methodologies for data collection. A mixed methodology will be used for the data collection, using numerical and verbal data, in order to gather rounded, reliable data. A survey approach will be used to gain an overall picture, and a more fine-grained analysis will be achieved through qualitative approaches (Figure 11.3).

5 Instrumentation

The data gathered will be largely perception-based, and will involve gathering employees' views of the (sub)cultures. As the concept of organizational culture is derived,



Though at first sight the graphic looks complex, because there are many arrows, in fact it is not complicated. The theory underpinning this, which derives from a literature review of empirical studies of organizational behaviour, leadership, individual and social psychology, is that these five identified key factors influence morale: organizational health, organizational culture, leadership, communication and motivation. Of course, there are many, many more factors, but the research has assumed that these are key factors in the present study. This highlights an important feature of theory: it is selective in what it includes and it operates at a high level of generality (a conceptual model would provide much closer detail here, breaking down the main areas into more specific elements).

The arrows indicate the assumed directions of influence of key factors in morale which derive from literature. Here *organizational health* and *organizational culture* have a direct effect on morale and motivation; *leadership* has a direct effect on organizational health, organizational culture, motivation, communication and morale – in other words it is a key factor; *communication* has a direct effect on motivation, organizational culture, organizational health and morale – in other words, it is an important factor; and *motivation* has a direct effect on morale. Note that the direction of inferred causality is one-way, even though, in reality, the causality is multi-directional and reciprocal. This indicates another key feature of the theory: it is selective in its inferred or assumed direction of causality (and, indeed, in causal modelling).

The theory here is also that leadership is a key driver: note that the causal arrows lead *from*, rather than *to*, leadership. Further, motivation is a key recipient of factors, and, in turn, it is assumed to influence morale. One can infer from this that motivation exerts an important influence on morale, and this is reflected in the thickness of the causal arrow from motivation to morale.

The graphic here, then, is a portrayal of the theoretical assumptions that underpin the research on morale.

FIGURE 11.2 Theoretical framework for investigating low morale in an organization

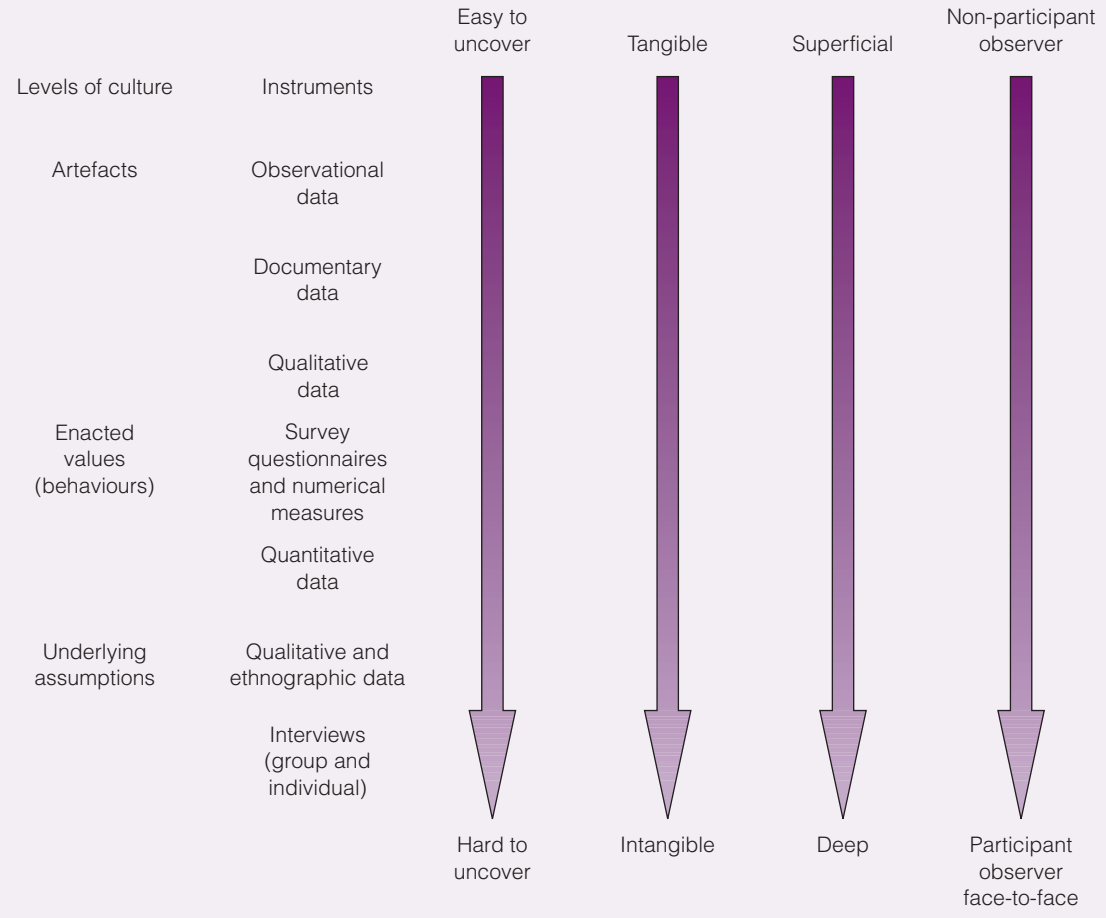


FIGURE 11.3 Understanding the levels of organizational culture

in part, from ethnography and anthropology, the research will use qualitative and ethnographic methods.

One of the difficulties anticipated is that the less tangible aspects of the school might be the most difficult on which to collect data. Not only will people find it harder to articulate responses and constructs, but they may also be reluctant to reveal these in public. The more the project addresses intangible and unmeasurable elements, and the richer the data that are to be collected, the more there is a need for increased and sensitive interpersonal behaviour, face-to-face data-collection methods, and qualitative data.

There are several instruments for data collection: questionnaires, semi-structured interviews (individual and group), observational data, documentary data and reports will constitute a necessary minimum, as follows (see also Figure 11.3):

i *Questionnaire surveys*, using commercially available instruments, each of which measures different aspects of school's culture, in particular:

- the organizational culture questionnaire by Harrison and Stokes (1992), which looks at overall cultures and provides a general picture in terms of *role*, *power*, *achievement* and *support* cultures, and examines the differences between existing and preferred cultures;
- the Organizational Culture Inventory by Cooke and Lafferty (1989), which provides a comprehensive and reliable analysis of the presenting organizational cultures.

Questionnaires, using rating scales, will catch articulated, espoused, enacted, visible aspects of organizational

culture, and will measure, for example, the extent of sharedness of culture, congruence between existing and ideal, and strength and intensity of culture.

ii *Semi-structured qualitative interviews for individuals and groups*, gathering data on the more intangible aspects of the school's culture, for example, values, assumptions, beliefs, wishes, problems. Interviews will be semi-structured, i.e. with a given agenda and open-ended questions. As face-to-face individual interviews might be intimidating for some groups, group interviews will be used. In all of the interviews the important part will be the supplementary question, 'why?'.

iii *Observational data* will comment on the physical environment, and will then be followed up with interview material to discover participants' responses to, perceptions of, messages contained in, and attitudes to, the physical environment. Artefacts, clothing, shared and private spaces, furniture, notices, regulations etc. all give messages to participants.

iv *Documentary analysis and additional stored data*, reporting the formal matters in the school, examined for what they include and what they exclude.

6 Sampling

i The questionnaire will be given to all employees who are willing to participate;

ii The semi-structured interviews will be conducted on a 'critical case' basis, i.e. with participants who are in key positions and who are 'knowledgeable people' about the activities and operations of the school.

There will be stratified sampling for the survey instruments, in order to examine how perceptions of the school's organizational culture vary according to the characteristics of the sub-samples. This will enable the levels of congruence or disjunction between the responses of the various sub-groups to be charted. Nominal characteristics of the sampling will be included, for example, age, level in the school, departments, gender, ethnicity, nationality and years of working in the school.

7 Parameters

i The data will be collected on a 'one-shot' basis rather than longitudinally;

ii A multi-method approach will be used for data collection.

8 Stages in the research

There are five stages in the research:

Stage one: Development and operationalization, including

i A review of literature and commercially produced instruments;

ii Clarification of the research questions;

iii Clarification of methodology and sampling;

Stage two: Instrumentation and the piloting of the instruments

i Questionnaire development and piloting;

ii Semi-structured interview schedules and piloting;

iii Gathering of observational data;

iv Analysis of documentary data;

Because of the limited number of senior staff, it will not be possible to conduct pilot interviews with them, as this will preclude them from the final data collection.

Stage three: Data collection, which will proceed in the following sequence

Administration of the questionnaire → Analysis of questionnaire data to provide material for the interviews → Interviews to be conducted concurrently.

Stage four: Data analysis and interpretation

Numerical data will be processed with SPSS, which will also enable the responses from sub-groups of the school to be separated for analysis. Qualitative data will be analysed using protocols of content analysis.

Stage five: Reporting

A full report on the findings will include conclusions, implications and recommendations.

9 Ethics and ownership

Participation in the project will be on the basis of informed consent, and on a voluntary basis, with rights of withdrawal at any time. Given the size and scope of the cultural survey, it is likely that key people in the school will be identifiable, even though the report is confidential. This will be made clear to the potential participants. Copies of the report will be available for all the employees. Data, once given to the researcher, are his/hers, and she/he may not use them in any way which will publicly identify the school; the report is the property of the school.

10 Time frames

The project will be completed in five months:

BOX 11.3 A CHECKLIST FOR PLANNING RESEARCH

1. How have you taken account of the ontological and epistemological characteristics of the phenomenon to be investigated?
2. Have you clarified the purposes of the research?
3. What do you want the research to do, to 'deliver', to find out?
4. What are the purposes and objectives of the research?
5. Have you identified the constraints on your research? What are they?
6. Is your research feasible within the required time frames?
7. What approaches to the research (methodologies) are most suitable for the research, in terms of the ontology and epistemology of the phenomenon under investigation, and the purposes of the research?
8. What warrants have you provided to link evidence to conclusions?
9. What are the methodology(ies) and paradigm(s) on which the research is built? How comfortably do they fit the research purposes and the nature of the phenomena under investigation?
10. Does your research seek to test a theory or hypothesis, to develop a theory, to investigate and explore, to understand, to describe, to develop specific practices, to evaluate, to investigate?
11. Will your research best be accomplished by research that is naturalistic, interpretive, positivist, post-positivist, mixed methods-based, participatory, evaluatory, ideology critical, feminist, complexity theory-based, either alone or in combination?
12. Will your research use survey, documentary research, quantitative methods, ethnographic or qualitative methods, experiments, historical sources, action research, case studies, *ex post facto* designs, either alone or in combination?
13. Do you need to identify independent and dependent variables?
14. Is your research seeking to establish causation?
15. Are you seeking to generalize from your research?
16. In planning your research, have you indicated how you will address validity and reliability in the conceptualization, planning, methodology, instrumentation, data analysis, discussion, the drawing of conclusions and reporting?
17. Who will gather, enter, process, analyse, interpret and verify your data?
18. Have you identified how you will address reflexivity?
19. Have you identified what you need to focus on in order to answer the research questions and conduct the research?
20. Have you identified whom you need to contact in connection with conducting the research?
21. Have you checked that all the ethical issues in the research have been addressed with all the necessary parties? Have you gained ethical clearance to conduct the research?
22. Is your research overt or covert? If it is covert, or involves intentional deceit, how is this justified?
23. Have you conducted a literature review, and how does the literature review inform your research?
24. Does your research need research questions? If not, why not? If so, what are they and have they been operationalized comprehensively, concretely and fairly?
25. Have you operationalized your research purposes into research questions?
26. What are the timescales for the different stages of your research?
27. Have you identified what kinds of data you need at different stages of the research, and why?
28. Have you identified the instruments that you will need for data collection at the different stages of the research, for example: interviews, questionnaires, observations, role-plays, accounts, personal constructs, tests, case studies, field notes, diaries, documents, etc.?
29. Is your research 'front-loaded' or 'end-loaded' in terms of planning, conduct and analysis?
30. Who are the participants?
31. Do you need a sample or a population? What is the population and what are the sample and the sampling strategy?
32. Have you planned how you will analyse the data, and at what stages of the research?
33. Have you planned how you will validate your data and interpretation of the data?
34. Have you planned when and how you will report and present the research findings, and to whom?
35. Have you planned how you will disseminate your research findings?
36. Have you identified what controls you will place on the release of your findings, and to whom, why and for how long, and who owns the research and the data?

- the first month for a review of the relevant literature;
- the second month to develop the instrumentation and research design;
- the third month to gather the data;
- the fourth month to analyse the data;
- the fifth month to complete the report.

The example indicates a systematic approach to the planning and conduct of the research that springs from a perceived need in the school. It works within given constraints and makes clear what it will 'deliver'. Though the research does not specify hypotheses to be tested, nevertheless it would not be difficult to convert the research questions into hypotheses if this style of research were preferred.

11.15 Ensuring quality in the planning of research

'Fitness for purpose' reigns in planning research; the research plan must suit the purposes of the research. If the reader is left feeling, at the end of this chapter, that the task of research is complex, then that is an important message, for rigour and thoughtful, thorough planning are necessary if the research is to be worthwhile and effective. For a checklist for evaluating research, see Box 11.3 and the accompanying website.

The intention of the research planning and design is to ensure that rigour, fitness for purpose and high quality are addressed. Furlong and Oancea (2005, pp. 11–15) identify several clear dimensions of quality in educational research. For theoretical and methodological robustness they identify quality in terms of: (a) the 'trustworthiness' of the research; (b) its 'contribution to knowledge'; (c) its 'explicitness in designing and reporting'; (d) its 'propriety' (conformance to legal and ethical requirements); and (e) the 'paradigm-dependence' (fidelity to the paradigm, ontology and epistemological premises of the research).

For 'value for use' (the 'technological dimension'), Furlong and Oancea (2005, pp. 12–13) identify key indicators of quality as: (a) the 'salience/timeliness' of the research; (b) its 'purposivity' (fitness for purpose); (c) its 'specificity and accessibility' (scope, responsiveness to user needs, and predicted usage); (d) its 'concern for enabling impact' (dissemination for impact); and (e) its 'flexibility and operationalisability' (development into practical terms and utility for audiences).

For 'capacity building and value for people' (Furlong and Oancea, 2005, pp. 13–14), they identify key indicators of quality as residing in: (a) 'partnership, collaboration and engagement'; (b) 'plausibility' ('from the practitioner's perspective'); (c) 'reflection and criticism' (research that develops reflexivity and self-reflection); (d) 'receptiveness' (research that enhances the receptiveness of practitioners and a wider audience); and (e) 'stimulating personal growth'.

For their 'economic dimension', Furlong and Oancea (2005, pp. 14–15) indicate six elements of quality in research: (a) 'cost-effectiveness'; (b) 'marketability' and 'competitiveness' (e.g. in the research market); (c) 'auditability'; (d) 'feasibility'; (e) 'originality'; and (f) 'value-efficiency'.

The sections of this chapter and the preceding chapter, separately and together, have indicated how these can be addressed in the planning of research.

Companion Website

The companion website to the book provides PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Sampling

CHAPTER 12

Sampling is a crucial element of research, and this chapter introduces key issues in sampling, including:

- sample size
- statistical power
- sampling error
- sample representativeness
- access to the sample
- sampling strategy
- probability samples
- non-probability samples
- sampling in qualitative research
- sampling in mixed methods research
- planning the sampling

12.1 Introduction

The quality of a piece of research stands or falls by the appropriateness of its methodology and instrumentation and by the suitability of the sampling strategy that has been adopted. Questions of sampling arise directly out of the issue of defining the population on which the research will focus.

Researchers must take sampling decisions early in the overall planning of research, not least of which is whether to have a sample or an entire population. However, as this chapter concerns sampling we keep to this topic, and here factors such as expense, time and accessibility frequently prevent researchers from gaining information from the whole population. Therefore they often need to be able to obtain data from a smaller group or subset of the total population in such a way that the knowledge gained is representative of the total population (however defined) under study. This smaller group or subset is the *sample*. Experienced researchers start with the total population and work down to the sample. By contrast, less experienced researchers often work from the bottom up, that is, they determine the minimum number of respondents needed to conduct the research (Bailey, 1994). However, unless they identify the total population in advance, it is virtually impossible for them to assess how representative the sample is that they have drawn.

Suppose that a class teacher has been released from her teaching commitments for one month in order to conduct some research into the abilities of thirteen-year-old students to undertake a set of science experiments. The research is to draw on three secondary schools which contain 300 such students each, a total of 900 students, and the method that the teacher has been asked to use for data collection is a semi-structured interview. Because of the time available to the teacher it would be impossible for her to interview all 900 students (the total population being all the cases). Therefore she has to be selective and to interview fewer than all 900 students. How will she decide that selection; how will she select which students to interview?

If she were to interview 200 of the students, would that be too many? If she were to interview just twenty of the students, would that be too few? If she were to interview just the males or just the females, would that give her a fair picture? If she were to interview just those students whom the science teachers had decided were 'good at science', would that yield a true picture of the total population of 900 students? Perhaps it would be better for her to interview those students who were experiencing difficulty in science and who did not enjoy science, as well as those who were 'good at science'. Suppose that she turns up on the days of the interviews only to find that those students who do not enjoy science have decided to absent themselves from the science lesson. How can she reach those students?

Decisions and problems such as these face researchers in deciding the sampling strategy to be used. Judgements have to be made about several key factors in sampling, for example:

- the sample size;
- statistical power;
- the representativeness and parameters of the sample;
- access to the sample;
- the sampling strategy to be used;
- the kind of research that is being undertaken (e.g. quantitative/qualitative/mixed methods).

The decisions here will influence the sampling strategy to be used. This assumes that a sample is actually required; there may be occasions on which the researcher can access the whole population rather than a sample.

Uprichard (2013) adds to these a range of ontological, epistemological and logistical matters. Ontological matters concern the unit of analysis – why choose the unit of analysis (the 'case') that has been chosen? For example, a key problem in addressing populations and samples is whether the population size and characteristics are actually known (which are needed to identify a sampling frame) and how much we know about the sample, and this may be a major difficulty in some kinds of social and educational research (Uprichard, 2013, p. 3). This is also an ontological and epistemological problem, for example, how we have any knowledge of the population and the sample (the 'cases') and what that knowledge is, from which we can proceed with some security (p. 4). How much, for example, does our own construction of the social world influence what we regard as the population and the sample?

The point here is to inject a cautionary note: much of the material that follows can be regarded as 'technical' knowledge, but this would be mistaken, as our point here is that behind that technical knowledge reside ontological and epistemological issues – one cannot simply read off a sampling strategy or design mechanistically. There are no 'hard and fast' rules to be followed unthinkingly; rather, decisions on sampling are deliberative, requiring the exercise of judgement and a reflexive attitude to the assumptions that we might all too easily make. Uprichard (2013) makes the point that issues of sample size and sample error, both of which we meet below, are meaningless unless we know how and why they matter at all (p. 7). Researchers, she avers, have to decide when a sample is good enough, or large enough, or small enough, and this is not simply a question of reading off figures from a table, but a deliberative, reflexive, ontological and epistemological matter (p. 7), a matter of praxis in which action and reflection combine. It is problematic. It is in this spirit that we proceed here.

12.2 The sample size

A question that novice researchers often ask is just how large their samples for the research should be. This is a deceptively simple question but there is no clear-cut or simple answer, for the sample size depends on a large array of factors:

- the research purposes, questions and design;
- the size and nature of the population from which the sample is drawn;
- the heterogeneity of the population from which the sample is drawn;
- the confidence level and confidence interval required;
- the level of accuracy required (the smallest sampling error to be tolerated);
- the statistical power required;
- the representativeness of the population sought in the sample;
- the allowances to be made for attrition and non-response;
- the number of strata in the sample;
- the variability of the factor under study;
- the number of variables included in the research;
- the statistics to be used;
- the scales being used;
- the kind(s) of sample to be used;
- the nature of the research (e.g. quantitative, qualitative, mixed methods).

However, it is possible to give some advice on this matter. Generally speaking, for quantitative research, the larger the sample the better, as this not only gives greater reliability but also enables more sophisticated statistics to be used.

Thus, a sample size of thirty is held by many to be the minimum number of cases if researchers plan to use some form of statistical analysis on their data, though this is a very small number and we would advise very considerably more. Researchers need to think, in advance of any data collection, of the sorts of relationships that they wish to explore within sub-groups of their eventual sample. The number of variables researchers set out to control in their analysis, and the types of statistical tests that they wish to make, must inform their decisions about sample size prior to the actual research undertaking. Typically an anticipated minimum of thirty cases per variable should be used as a 'rule of thumb', i.e. one must be assured of having a minimum of thirty cases for each variable (of course, the thirty cases for variable one could also be the same thirty for variable two), though this is a very low estimate indeed. This number rises rapidly if different sub-groups of the population are included in the sample (discussed below), which is frequently the case.

Further, depending on the kind of analysis to be performed, some statistical tests will require larger samples. For example, let us imagine that one wished to calculate the chi-square statistic, a commonly used test (see Part 5) with crosstabulated data, for example, looking at two sub-groups of stakeholders in a primary school containing sixty ten-year-olds and twenty teachers and their responses to a question on a five-point scale:

Variable: Ten-year-olds should do one hour's homework each weekday evening					
	Strongly disagree	*Disagree*	*Neither agree nor disagree*	*Agree*	*Strongly agree*
10-year-old pupils in the school	25	20	3	8	4
Teachers in the school	6	4	2	4	4

Here the sample size is eighty cases, an apparently reasonably sized sample. However, six of the ten cells of responses (60 per cent) contain fewer than five cases. The chi-square statistic requires there to be five cases or more in 80 per cent of the cells (i.e. eight out of the ten cells). In this example only 40 per cent of the cells contained more than five cases, so even with a comparatively large sample, the statistical requirements for reliable data with a straightforward statistic such as chi-square have not been met. The message is clear, one needs to anticipate, as far as one is able, some possible distributions of the data and see if these will prevent appropriate statistical analysis; if the distributions look unlikely to enable reliable statistics to be calculated then one should increase the sample size, or exercise great caution in interpreting the data because of problems of reliability, or not use particular statistics, or, indeed, consider abandoning the exercise if the increase in sample size cannot be achieved.

The point here is that each variable may need to be ensured of a reasonably large sample size. Indeed Gorard (2003, p. 63) suggests that one can start from the minimum number of cases required in each cell, multiply this by the number of cells, and then double the total. In the example above, with six cases in each cell, the minimum sample would be 120 ($6 \times 10 \times 2$), though to be on the safe side, to try to ensure ten cases in each cell a minimum sample of 200 might be better ($10 \times 10 \times 2$), though even this is no guarantee that the distributions will be safe.

The issue arising out of the example here is also that one can observe considerable variation in the responses from the participants in the research. Gorard (2003, p. 62) suggests that if a phenomenon contains a lot of potential variability then this will increase the sample size. Surveying a variable such as IQ, for example, with a potential range from 70 to around 150, may require a larger sample rather than a smaller sample.

As well as the requirement of a minimum number of cases in order to examine relationships between subgroups, researchers must obtain the minimum sample size that will accurately represent the population being targeted. With respect to size, will a large sample guarantee representativeness? Not necessarily! In our first example, the researcher could have interviewed a total sample of 450 females and still not have represented the male population. Will a small size guarantee representativeness? Again, not necessarily! The latter falls into the trap of saying that 50 per cent of those who expressed an opinion said that they enjoyed science, when the 50 per cent was only one student, as the researcher interviewed only two students in all. Too large a sample might become unwieldy and too small a sample might be unrepresentative (e.g. in the first example, the researcher might have wished to interview 450 students but this would have been unworkable in practice or the researcher might have interviewed only ten students, which, in all likelihood, would have been unrepresentative of the total population of 900 students).

Where simple random sampling is used, the sample size needed to reflect the population value of a particular variable depends both on the size of the population and the amount of heterogeneity in the population (Bailey, 1994). Generally, for populations of equal heterogeneity or variance, the larger the population, the larger the sample that must be drawn. For populations of equal size and the greater the heterogeneity on a particular variable, the larger the sample that is needed. If the population is heterogeneous then a large sample is preferable; if the population is homogeneous then a smaller sample is possible. To the extent that a sample fails to represent accurately the population involved, there is sampling error, discussed below.

Sample size is also determined to some extent by the style of the research. For example, a survey style usually requires a large sample, particularly if inferential statistics are to be calculated. In ethnographic or qualitative research it is more likely that the sample size will be small. Sample size might also be constrained by cost – in terms of time, money, stress, administrative support, the number of researchers, and resources.

Borg and Gall (1979, pp. 194–5) suggest that correlational research requires a sample size of no fewer than thirty cases, that causal-comparative and experimental methodologies require a sample size of no fewer than fifteen cases and that survey research should have

no fewer than 100 cases in each major sub-group and twenty to fifty in each minor sub-group. They advise that sample size has to begin with an estimation of the smallest number of cases in the smallest sub-group of the sample, and 'work up' from that, rather than vice versa (p. 186). So, for example, if 5 per cent of the sample must be teenage boys, and this sub-sample must be thirty cases (e.g. for correlational research), then the total sample will be $30 \div 0.05 = 600$; if 15 per cent of the sample must be teenage girls and the sub-sample must be forty-five cases, then the total sample must be $45 \div 0.15 = 300$ cases.

The size of a probability (e.g. random) sample can be determined in two ways, either by the researcher exercising prudence and ensuring that the sample represents the wider features of the population with the minimum number of cases or by using a table which, from a mathematical formula, indicates the appropriate size of a random sample for a given number of the wider population (see Table 12.1). One such example is provided by Krejcie and Morgan (1970), whose work suggests that if the researcher were devising a sample from a wider population of thirty or fewer (e.g. a class of students or a group of young children in a class) then she/he would be well advised to include the whole population as the sample.

Krejcie and Morgan indicate that the smaller the number of cases there are in the population, the larger the proportion of that population must be which appears in the sample. The converse of this is true: the larger the number of cases there are in the population, the smaller the proportion of that population can appear in the sample. They note that as the population increases, the proportion of the population required in the sample diminishes and, indeed, remains constant at around 384 cases (p. 610). Hence, for example, a piece of research involving all the children in a small rural primary or elementary school (up to 100 students in all) might require between 80 per cent and 100 per cent of the school to be included in the sample, whilst a secondary school of 1,200 students might require a sample of 25 per cent of the school in order to achieve randomness. As a rough guide in a random sample, the larger the sample, the greater is its chance of being representative.

In determining sample size for a probability sample, one has to consider not only the population size but also the error margins that one wishes to tolerate. These are expressed in terms of the confidence level and confidence interval. The confidence *level*, usually expressed as a percentage (usually 95 or 99 per cent), is an index of how sure we can be (e.g. 95 per cent of the time or 99 per cent of the time) that the responses lie within a given variation range. The confidence *interval* is that degree of variation or variation range (e.g. ±1 per cent, or ±2 per cent, or ±3 per cent) that one wishes to ensure.

For example, the confidence *interval* in many opinion polls is ±3 per cent; this means that, if a voting survey indicates that a political party has 52 per cent of the votes then it could be as low as 49 per cent (52 − 3) or as high as 55 per cent (52 + 3). The confidence interval is affected by sample size, population size and the percentage of the sample giving the 'true' answer. A confidence *level* of 95 per cent here would indicate that we could be 95 per cent sure that this result will be within this range of 46 to 55, i.e. ±3 per cent. The confidence level is calculated statistically, based on sample size, confidence level and the percentages of an area under the normal curve of distribution, for example, a 95 per cent confidence level covers 95 per cent of the curve of distribution.

If we want to have a very high confidence level (say 99 per cent of the time) then the sample size will be high. On the other hand, if we want a less stringent confidence level (say 90 per cent of the time), then the sample size will be smaller. Usually a compromise is reached, and researchers opt for a 95 per cent confidence level. Similarly, if we want a very small confidence interval (i.e. a limited range of variation, e.g. 3 per cent) then the sample size will be high, and if we are comfortable with a larger degree of variation (e.g. 5 per cent) then the sample size will be lower.

Some research may require a very stringent confidence level and confidence interval (e.g. 99 per cent and 1 per cent respectively) to ensure certainty. For example, medical research, say for a new drug, cannot tolerate errors as the incorrect result could be fatal. Other kinds of research may be content with a less stringent requirement (e.g. 95 per cent confidence level and 3 per cent confidence interval).

A full table of sample sizes for a random probability sample is given in Table 12.1, with three confidence levels (90 per cent, 95 per cent and 99 per cent) and three confidence intervals (5 per cent, 4 per cent and 3 per cent).

Here the size of the sample reduces at an increasing rate as the population size increases; generally (but not always) the larger the population, the smaller the proportion of the probability sample can be. Also, the higher the confidence level, the greater the sample, and the lower the confidence interval, the higher the sample. A conventional sampling strategy will be to use a 95 per cent confidence level and a 3 per cent confidence interval.

There are several websites that offer sample size calculation services for random samples. Some free sites at the time of writing are:

TABLE 12.1 SAMPLE SIZE, CONFIDENCE LEVELS AND CONFIDENCE INTERVALS FOR RANDOM SAMPLES

Here the researcher inputs the desired confidence level, confidence interval and the population size, and the sample size is automatically calculated.

A further consideration in the determination of sample size is the kind of variables included. Bartlett *et al*. (2001) indicate that sample sizes for categorical variables (e.g. sex, education level) will differ from those of continuous data (e.g. marks in a test, money in the bank); typically categorical data require larger samples than continuous data. They provide a summary table (Table 12.2) to indicate the different sample sizes required for categorical and continuous data:

Within the discussion of categorical and continuous variables, Bartlett *et al*. (2001, p. 45) suggest that, for categorical data, a 5 per cent margin of error is commonplace, whilst for continuous data, a 3 per cent margin of error is usual, and these are the intervals that they use in their table (Table 12.2). Here, for both categorical and continuous data, the proportion of the population decreases as the sample increases, and, for continuous data, there is no difference in the sample sizes for populations of 2,000 or more. The researcher should normally opt for the larger sample size (i.e. the sample size required for categorical data) if both categorical and continuous data are being used.

Bartlett *et al*. (2001, pp. 48–9) also suggest that the sample size will vary according to the statistics to be used. They suggest that if multiple regressions are to be calculated then 'the ratio of observations [cases] to independent variables should not fall below five', though some statisticians suggest a ratio of 10 : 1, particularly for continuous data, as, in continuous data, the sample sizes tend to be smaller than for categorical data. They also suggest that, in multiple regression: (a) for *continuous* data, if the number of independent variables is in the ratio of 5 : 1 then the sample size should be no fewer than 111 and the number of regressors (independent variables) should be no more than 22; (b) for *continuous* data, if the number of independent variables is in the ratio of 10 : 1 then the sample size should be no fewer than 111 and the number of regressors (independent variables) should be no more than 11; (c) for *categorical* data, if the number of independent variables is in the ratio of 5 : 1 then the sample size should be no fewer than 313 and the number of regressors (independent variables) should be no more than 62; (d) for *categorical* data, if the number of independent variables is

TABLE 12.2 SAMPLE SIZES FOR CATEGORICAL AND CONTINUOUS DATA

Population size	*Sample size*					
	Continuous data (margin of error = 0.3)			*Categorical data (margin of error = 0.05)*		
	alpha = 0.10	*alpha = 0.05*	*alpha = 0.01*	*alpha = 0.10*	*alpha = 0.05*	*alpha = 0.01*
100	46	55	68	74	80	87

Source: Bartlett *et al*. (2001, p. 48), reproduced with permission from R. G. Brookshire and J. E. Bartlett

in the ratio of 10 : 1 then the sample size should be no fewer than 313 and the number of regressors (independent variables) should be no more than 31. Bartlett *et al*. (2001, p. 49) also suggest that, for factor analysis, a sample size of no fewer than 100 observations (cases) should be the general rule. However, size can go as low as thirty cases, and the ratio of sample size to number of variables varies from 5 : 1 to 30 : 1 (Tabachnick and Fidell, 2013).

If different sub-groups or strata are to be used then the requirements placed on the total sample also apply to each sub-group, i.e. each stratum (sub-group) becomes a population. Much educational research and sampling concerns itself with strata rather than whole samples, so the issue is significant, and using strata (sub-groups) can rapidly generate the need for a very large sample. If sub-groups are required then the same rules for calculating overall sample size apply to each of the sub-groups. We consider stratified sampling later in this chapter.

Further, determining the size of the sample will also have to take account of non-response, as it may be that non-respondents are not randomly distributed. As Gorard (2013, p. 88) remarks, there may be 'systematic differences' between those who do and do not respond, between those who do and do not take part in a piece of research. Gorard advocates the use of 'sensitivity analysis' (p. 88) to judge the impact of non-respondents, which involves judging (e.g. by calculation) how much difference the non-respondents would need to make to the overall findings for the findings to be false, for example, to reverse the findings.

Next we consider attrition and respondent mortality. Some participants will fail to return questionnaires, leave the research, return incomplete or spoiled questionnaires (e.g. missing out items, putting two ticks in a row of choices instead of only one). Hence it is advisable to overestimate (oversample) rather than to underestimate the size of the sample required, to build in redundancy (Gorard, 2003, p. 60). Unless one has guarantees of access, response and, perhaps, the researcher's own presence at the time of conducting the research (e.g. presence when questionnaires are being completed), then it might be advisable to estimate up to double the size of required sample in order to allow for such loss of clean and complete copies of questionnaires/responses.

Further, with very small sub-groups of populations, it may be necessary to operate a weighted sample – an oversampling – in order to gain any responses at all as, if a regular sample were to be gathered, there would be so few people included as to risk being unrepresentative of the sub-group in question. A weighted sample, in this instance, is where a higher proportion of the sub-group is sampled, and then the results are subsequently scaled down to be fairer in relation to the whole sample.

In some circumstances, meeting the requirements of sample size can be done on an evolutionary basis. For example, let us imagine that you wish to sample 300 teachers, randomly selected. You succeed in gaining positive responses from 250 teachers to, for example, a telephone survey or a questionnaire survey, but you are fifty short of the required number. The matter can be resolved simply by adding another fifty to the random sample, and, if not all of these are successful, then adding some more until the required number is reached.

Borg and Gall (1979, p. 195) suggest that, as a general rule, sample sizes should be large where:

- there are many variables;
- only small differences or small relationships are expected or predicted;
- the sample will be broken down into sub-groups;
- the sample is heterogeneous in terms of the variables under study;
- reliable measures of the dependent variable are unavailable.

Oppenheim (1992, p. 44) adds to this the point that the nature of the scales to be used also exerts an influence on the sample size: the larger the scale, the larger the sample must be. For nominal data the sample sizes may well have to be larger than for interval and ratio data, i.e. a variant of the issue of the number of sub-groups to be addressed, where the greater the number of sub-groups or possible categories, the larger the sample will have to be.

Borg and Gall (1979) set out a formula-driven approach to determining sample size (see also Moser and Kalton, 1977; Ross and Rust, 1997, pp. 427–38), and they also suggest using correlational tables for correlational studies – available in most texts on statistics – as it were 'in reverse' to determine sample size (p. 201), i.e. looking at the significance levels of correlation coefficients and then reading off the sample sizes usually required to demonstrate that level of significance. For example, a correlational significance level of 0.01 would need a sample size of ten if the required coefficient of correlation is 0.65, or a sample size of twenty if the required correlation coefficient is 0.45, and a sample size of 100 if the required correlation coefficient is 0.20. Again, an inverse proportion can be seen – the larger the sample population, the smaller the

required correlation coefficient can be to be deemed significant.

With both qualitative and quantitative data, the essential requirement is that the sample is representative of the population from which it is drawn. In a dissertation concerned with a life history (i.e. n=1), the sample is the population! In a qualitative study of thirty highly able girls of similar socio-economic background following an A-level Biology course, a sample of five or six may suffice the researcher who is prepared to obtain additional corroborative data by way of validation.

Where there is heterogeneity in the population, then a larger sample must be selected on some basis that respects that heterogeneity. Thus, from a staff of sixty secondary school teachers differentiated by gender, age, subject specialism, management or classroom responsibility etc., it would be insufficient to construct a sample consisting of ten female classroom teachers of arts and humanities subjects.

For quantitative data, a precise sample number can be calculated according to the *level of accuracy* and the *level of probability* that the researcher requires in her work. She can then report in her study the rationale and the basis of her research decision (Blalock, 1979). By way of example, suppose a teacher/researcher wishes to sample opinions of an activity (an extra-curricular event) among 1,000 secondary school students. She intends to use a ten-point scale ranging from 0=totally unsatisfactory to 10=absolutely fabulous. She already has data from her own class of thirty students and suspects that the responses of other students will be broadly similar. Her own students rated the activity as follows: mean score=8.27; standard deviation=1.98. In other words, her students were pretty much 'bunched' about a positive appraisal on the ten-point scale. How many of the 1,000 students does she need to sample in order to gain an accurate (i.e. reliable) assessment of what the whole school (n=1,000) thinks of the extra-curricular event?

It all depends on what degree of accuracy and what level of probability she is willing to accept.

A simple calculation from a formula by Blalock (1979, pp. 215–18) shows that:

- if she is happy to be within ±0.5 of a scale point and accurate 19 times out of 20, then she requires a sample of 60 out of the 1,000;
- if she is happy to be within ±0.5 of a scale point and accurate 99 times out of 100, then she requires a sample of 104 out of the 1,000;
- if she is happy to be within ±0.5 of a scale point and accurate 999 times out of 1,000, then she requires a sample of 170 out of the 1,000;
- if she is a perfectionist and wishes to be within ±0.25 of a scale point and accurate 999 times out of 1,000, then she requires a sample of 679 out of the 1,000.

It is clear that sample size is a matter of judgement as well as mathematical precision; even formula-driven approaches make it clear that there are elements of prediction, standard error and human judgement involved in determining sample size.

12.3 Sampling error

If many samples are taken from the same population, it is unlikely that they will all have characteristics identical with each other or with the population; their means will be different. In brief, there will be sampling error (see Cohen and Holliday, 1979, 1996). Sampling error is often taken to be the difference between the sample mean and the population mean. Sampling error is not necessarily the result of mistakes made in sampling procedures. Rather, variations may occur due to the chance selection of different individuals. For example, if we take a large number of samples from the population and measure the mean value of each sample, then the sample means will not be identical. Some will be relatively high, some relatively low, and many will cluster around an average or mean value of the samples. We show this diagrammatically in Figure 12.1.

Why should this occur? We can explain the phenomenon by reference to the Central Limit Theorem which is derived from the laws of probability. This

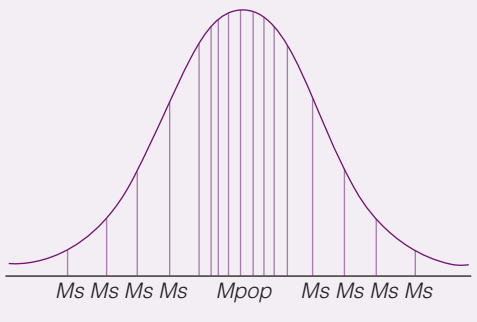

FIGURE 12.1 Distribution of sample means showing the spread of a selection of sample means around the population mean

Source: Cohen and Holliday (1979)

states that if random large samples of equal size are repeatedly drawn from any population, then the mean of those samples will be approximately normally distributed. The distribution of sample means approaches the normal distribution as the size of the sample increases, regardless of the shape – normal or otherwise – of the parent population (Hopkins *et al*., 1996, pp. 159, 388). Moreover, the average or mean of the sample means will be approximately the same as the population mean. The authors demonstrate this (pp. 159–62) by reporting the use of a computer simulation to examine the sampling distribution of means when computed 10,000 times. Rose and Sullivan (1993, p. 144) remind us that 95 per cent of all sample means fall between plus or minus 1.96 standard errors of the sample and population means, i.e. that we have a 95 per cent chance of having a single sample mean within these limits, that the sample mean will fall within the limits of the population mean.

By drawing a large number of samples of equal size from a population, we create a sampling distribution. We can calculate the error involved in such sampling. The standard deviation of the theoretical distribution of sample means is a measure of sampling error (SE) and is called the standard error of the mean (SE_M). Thus,

$$SE = \frac{SD_S}{\sqrt{N}}$$

where SD_S = the standard deviation of the sample and N = the number in the sample.

Strictly speaking, the formula for the standard error of the mean is:

$$SE = \frac{SD_{pop}}{\sqrt{N}}$$

where SD_{pop} = the standard deviation of the population.

However, as we are usually unable to ascertain the *SD* of the total population, the standard deviation of the sample is used instead. The standard error of the mean provides the best estimate of the sampling error. Clearly, the sampling error depends on the variability (i.e. the heterogeneity) in the population as measured by SD_{pop} as well as the sample size (N) (Rose and Sullivan, 1993, p. 143). The smaller the SD_{pop}, the smaller the sampling error; the larger the N, the smaller the sampling error. Where the SD_{pop} is very large, then N needs to be very large to counteract it. Where SD_{pop} is very small, then N, too, can be small and still give a reasonably small sampling error. As the sample size increases, the sampling error decreases. Hopkins *et al*. (1996, p. 159) suggest that, unless there are some very unusual distributions, samples of twenty-five or greater usually yield a normal sampling distribution of the mean; this is comforting!

The standard error of proportions

We said earlier that one consideration in answering 'how big a sample must I obtain?' is 'how accurate do I want my results to be?' This is illustrated in the following example.

A school principal finds that the twenty-five students she talks to at random are reasonably in favour of a proposed change in the lunch break hours, 66 per cent being in favour and 34 per cent being against. How can she be sure that these proportions are truly representative of the whole school of 1,000 students?

A simple calculation of the standard error (SE) of proportions provides the principal with her answer.

$$SE = \frac{P \times Q}{N}$$

where:
P = the percentage in favour
Q = 100 per cent – P
N = the sample size.

The formula assumes that each sample is drawn on a simple random basis. A small correction factor called the finite population correction (*fpc*) is generally applied as follows:

$$\text{SE of proportions} = \sqrt{\frac{(1-f)P \times Q}{N}}$$ where f is the proportion included in the sample.

Where, for example, a sample is 100 out of 1,000, f is 0.1.

$$\text{SE of proportions} = \sqrt{\frac{(1-0.1)(66 \times 34)}{100}} = 4.49$$

With a sample of twenty-five, the SE = 9.4. In other words, the favourable vote can vary between 56.6 per cent and 75.4 per cent; likewise, the unfavourable vote can vary between 43.4 per cent and 24.6 per cent. Clearly, a voting possibility ranging from 56.6 per cent in favour to 43.4 per cent against is less decisive than 66 per cent as opposed to 34 per cent. Should the school principal enlarge her sample to include 100 students, then the SE becomes 4.5 and the variation in the range is reduced to 61.5–70.5 per cent in favour and 29.5–38.5 per cent against. Sampling the whole school's opinion (n = 1,000) reduces the SE to 1.5 and the ranges to 64.5–67.5 per cent in favour and 32.5–35.5 per cent against. It is easy to see why political opinion surveys are often based upon sample sizes of 1,000 to 1,500 (Gardner, 1978).

What is being suggested here generally is that, in order to overcome problems of sampling error, in order to ensure that one can separate random effects and variation from non-random effects, and in order for the power of a statistic to be felt, one should have as large a sample as possible. Samples of fewer than thirty are dangerously small, as they allow the possibility of considerable standard error, and, for over around eighty cases, any increases to the sample size have little effect on the standard error.

12.4 Statistical power and sample size

In calculating sample size, a further consideration is the statistical power required (for quantitative studies), and statistical power influences effect size. We discuss statistical power in Chapter 39; here we refer only to those aspects of statistical power that relate to sample size. Similarly, we mention here the concepts of effect size, statistical significance and one-tailed and two-tailed tests as they relate to sample size, but readers looking for full discussions of these terms should go to Chapter 39.

Statistical power is the probability that a study will detect an effect when there really is an effect there to be detected, separating this from random chance. Power is the probability that a test will correctly reject a false null hypothesis (H_0) and correctly accept the alternative hypothesis (H_1) when it is true, i.e. finding a true effect (see Chapter 39).

Statistical power analysis has four main parameters:

1. The effect size;
2. The sample size (number of observations);
3. The alpha (α) significance level (usually 0.05 or lower);
4. The power of the statistical test (setting the acceptable β level – the probability of committing a Type II error (a false negative) – and the desired power ($1-\beta$), e.g. β of 0.20 and power of 0.80).

Statistical power influences sample size. To calculate the sample size, taking account of statistical power, one needs to set the levels of the alpha (α), the beta (β) and the intended effect size sought (see Chapter 39). Here one can use published tables to determine the sample sizes. Key texts here also include useful guidance and tables, for example, Cohen (1988) and Ellis (2010), setting out sample sizes for different statistical tests (see also Cohen, 1992). Campbell *et al*. (1995) offer useful advice on calculating sample size from power analysis in two-group studies with binary and ordered categorical data (i.e. ordinal data), and they provide tables from which one can read off the sample size required.

Lehr (1992) sets out a straightforward method for calculating sample size needed per group if the power level is 0.80 and the alpha is 0.05, i.e. the two commonly used settings, which is to take the number 16 and divide it by the square of the effect size. Then, for two groups (e.g. a control group and an experimental group) the researcher doubles the result. For example, if the effect size sought is 0.8 (a large effect), then the sample size should be $16/0.8^2 = 16/0.64 = 25$ in each group, 50 in total; if the effect size sought is 0.5 (a moderate effect), then the sample size should be $16/0.5^2 = 16/0.25 = 64$ in each group, 128 in total; if the effect size sought is 0.3 (a small effect), then the sample size should be $16/0.3^2 = 16/0.09 = 177.8$, rounded to 178 in each group, 356 in total. This is an easy-to-use method.

There are many online calculators of sample size which work with effect size, statistical power and the different statistics that the researcher wishes to use, for example:

For a range of statistics: http://powerandsamplesize.com/Calculators
For a range of statistics (go to 'sample size'): www.danielsoper.com/statcalc3
For multiple regression: www.danielsoper.com/statcalc3/calc.aspx?id=1
For hierarchical multiple regression: www.danielsoper.com/statcalc3/calc.aspx?id=16
For t-tests: www.danielsoper.com/statcalc3/calc.aspx?id=47
For post hoc t-tests: www.danielsoper.com/statcalc3/calc.aspx?id=49
For structural equation models: www.danielsoper.com/statcalc3/calc.aspx?id=89
For t-tests and correlations: www.ai-therapy.com/psychology-statistics/sample-size-calculator

In using these sources, both online and in hard copy, the researcher decides the alpha level, the intended effect size (ES) and the statistics to be used (Cohen's *d*, the Pearson correlation, the chi-square, one-way ANOVA, multiple regression, and whether a one-tailed or two-tailed test is being used – see Chapters 40 to 42). From here the researcher can read off the sample size required. For example, setting the power level at 0.80, if one is using Cohen's *d* (a measure of the size of a difference), with an alpha of 0.05 and an effect size of 0.50, and a two-tailed test, then a sample size of 128 people is needed (e.g. 64 in each of two groups between

whom the size of the difference is calculated); with the same alpha and power level, if the effect size is large (0.80) then a sample size of 52 people is needed (e.g. 26 in each of two groups between whom the size of the difference is calculated). For correlations, setting the power level at 0.80, if one is using Pearson's *r* (a measure of association), with an alpha of 0.05 and an effect size (correlation coefficient) of 0.30 then a sample size of 53 people is needed; with the same alpha, if the effect size is large (0.50) then a sample size of 31 people is needed. Examples from these are given in Table 12.3.

Important points to note here are that statistical power and their related sample size calculations vary according to the statistical test used, so researchers must have in mind at the research design stage the statistics that they will use for processing and analysing the numerical data, and they need to decide in advance (Ellis, 2010):

- the type of test to be used, for example, independent t-test, paired t-test, ANOVA, regression etc.;
- the alpha value or significance level to be used (usually 0.01 or 0.05);
- the expected or hoped-for effect size.

Ellis (2010) notes that it is important to know these *before* rather than *after* the data have been collected as it affects decisions on sample size, particularly in the case of small samples (Pituch and Stevens, 2016), though authors note that large samples can often ensure high statistical power. On the other hand, Tabachnick and Fidell (2013) note that there is also a danger of using large samples, as it is almost certain to lead to rejection of the null hypothesis (see Chapter 39).

To improve the statistical power of the test, researchers should strive to use a bigger sample. Torgerson and Torgerson (2008) note that small samples may not be able to detect effect sizes, and that the size of the sample is inversely related to the effect size sought, i.e. if the effect size is expected to be small then a large sample will be needed in order to detect it (p. 128).

Similarly, in using statistical power as part of the calculation of sample size, researchers will need to decide in advance what to set as their alpha (α), beta (β), power levels and their desired effect size. Power analysis is a useful guide to sample size, but caution must be exercised in relying too heavily on it alone, as it is affected by the interaction of several key factors such as effect size, alpha levels and beta levels. Change one of these and the sample size changes. Overall, having as large a sample as possible is desirable for considerations of power analysis and sample size. The work of Ellis (2010) is useful in understanding statistical power and sample size.

12.5 The representativeness of the sample

The researcher will need to consider the extent to which it is important that the sample in fact represents the whole population in question if it is to be a valid sample, to be clear what is being represented, i.e. to set the parameter characteristics of the wider population – the sampling frame – clearly and correctly. There is a popular example of how poor sampling may be unrepresentative and unhelpful for a researcher. A national newspaper reports that one person in every two suffers from backache; this headline stirs alarm in every doctor's surgery throughout the land. However, the newspaper fails to make clear the parameters of the study which gave rise to the headline. It turns out that the research took place (a) in a damp part of the country where the incidence of backache might be expected to be

TABLE 12.3 MINIMUM SAMPLE SIZES AT POWER LEVEL 0.80 WITH TWO-TAILED TEST

	$\alpha = 0.05$			$\alpha = 0.01$		
	Small	*Medium*	*Large*	*Small*	*Medium*	*Large*
	ES = 0.20	ES = 0.50	ES = 0.80	ES = 0.20	ES = 0.50	ES = 0.80
Cohen's *d* (difference test)	788	128	52	1,172	192	78
	ES = 0.10	ES = 0.30	ES = 0.50	ES = 0.10	ES = 0.30	ES = 0.50
Pearson's *r* (measure of association	159	53	31	235	78	45

higher than elsewhere, (b) in a part of the country which contained a disproportionate number of elderly people, again who might be expected to have more backaches than a younger population, (c) in an area of heavy industry where the working population might be expected to have more backache than in an area of lighter industry or service industries, (d) by using two doctors' records only, overlooking the fact that many backache sufferers went to those doctors' surgeries because the two doctors concerned were known to be sympathetic to, rather than responsibly suspicious of, backache sufferers.

These four variables – climate, age group, occupation and reported incidence – exerted a disproportionate effect on the study, i.e. if the study had been carried out in an area where the climate, age group, occupation and reporting were different, then the results might have been different. The newspaper report sensationally generalized beyond the parameters of the data, thereby overlooking the limited representativeness of the study.

It is important to consider adjusting the weightings of sub-groups in the sample once the data have been collected. For example, in a secondary school where half of the students are male and half are female, consider the following table of pupils' responses to the question 'how far does your liking of the form teacher affect your attitude to work?':

Variable: How far does your liking of the form teacher affect your attitude to school work?					
	Very little	*A little*	*Somewhat*	*Quite a lot*	*A very great deal*
Male	10	20	30	25	15
Female	50	80	30	25	15
Total	60	100	60	50	30

Let us say that we are interested in the attitudes according to the gender of the respondents, as well as overall. In this example one could surmise that generally the results indicate that the liking of the form teacher has only a small to moderate effect on the students' attitude to work. However, we have to observe that twice as many girls as boys are included in the sample, and this is an unfair representation of the population of the school, which comprises 50 per cent girls and 50 per cent boys, i.e. girls are over-represented and boys are under-represented. If one equalizes the two sets of scores by gender to be closer to the school population (either by doubling the number of boys or halving the number of girls) then the results look very different, for example:

Variable: How far does your liking of the form teacher affect your attitude to school work?					
	Very little	*A little*	*Somewhat*	*Quite a lot*	*A very great deal*
Male	20	40	60	50	30
Female	50	80	30	25	15
Total	70	120	90	75	45

In this latter case a much more positive picture is painted, indicating that the students regard their liking of the form teacher as a quite important feature in their attitude to school work. Here equalizing the sample to represent more fairly the population by weighting yields a different picture. Weighting the results is important.

12.6 The access to the sample

Access is a key issue and is an early factor that must be decided in research. Researchers will need to ensure not only that access is permitted but is, in fact, practicable. For example, if a researcher were to conduct research into truancy and unauthorized absence from school, and she decided to interview a sample of truants, the research might never commence as the truants, by definition, would not be present! Similarly, access to sensitive areas might be not only difficult but also problematical both legally and administratively, for example, access to child abuse victims, child abusers, disaffected students, drug addicts, school refusers, bullies and victims of bullying. In some sensitive areas access to a sample might be denied by the potential participants themselves, for example, an AIDS counsellor with young people might be so seriously distressed by her work that she simply cannot face discussing with a researcher the subject matter of her traumatic work; it is distressing enough to do the job without living through it again with a researcher.

Access might also be denied by the potential sample participants themselves for very practical reasons, for example, a doctor or a teacher simply might not have the time to spend with the researcher. Further, access might be denied by people who have something to protect, for example, a school which has recently received a very poor inspection result or poor results on external examinations, or a person who has made an important discovery or a new invention and who does not wish to disclose the secret of her success (the trade in intellectual property has rendered this a live issue for many researchers). There are many reasons which

might prevent access to the sample, and researchers cannot afford to neglect this potential source of difficulty in planning research; it is a key issue.

In many cases access is guarded by 'gatekeepers': people who can control the researcher's access to those whom she/he really wants to target. For school staff this might be, for example, headteachers/principals, school governors, school secretaries, form teachers; for students this might be friends, gang members, parents, social workers and so on. It is critical for researchers not only to consider whether access is possible but how access will be sought – to whom does one have to go, both formally and informally, to gain access to the target group.

Not only might access be difficult but its corollary – release of information – might be problematic. For example, a researcher might gain access to a wealth of sensitive information and appropriate people, but there might be a restriction on the release of the data collected; reports may be suppressed, delayed or 'doctored'. It is not always enough to be able to 'get to' the sample, the problem might be to 'get the information out' to the wider public, particularly if it could be critical of powerful people.

12.7 The sampling strategy to be used

There are two main methods of sampling (Cohen and Holliday, 1979, 1982, 1996). The researcher must decide whether to opt for a probability (also known as a random sample) or a non-probability sample (also known as a purposive sample). The difference between them is this: in a probability sample the chances of members of the wider population being selected for the sample are known, whereas in a non-probability sample the chances of members of the wider population being selected for the sample are unknown. In the former (probability sample) every member of the wider population has an equal chance of being included in the sample; inclusion or exclusion from the sample is a matter of chance and nothing else. In the latter (non-probability sample) some members of the wider population definitely will be excluded and others definitely included, i.e. every member of the wider population does not have an equal chance of being included in the sample. In this latter type the researcher has deliberately – purposely – selected a particular section of the wider population to include in or exclude from the sample.

12.8 Probability samples

A probability sample, because it draws randomly from the wider population, is useful if the researcher wishes to be able to make generalizations, because it seeks representativeness of the wider population. (It also permits many statistical tests to be conducted with quantitative data.) This is a form of sampling used in randomized controlled trials. Randomization has two stages – random selection from a population and random allocation to groups (e.g. a control and an experimental group) – and these are key requirements for many experiments and statistics. Randomization, as one of its founding figures, Ronald Fisher (1966), remarked, is designed to overcome myriad within-group and between-group differences. It ensures that the average result, taking into account range and spread, within one group is similar to the average within another group (Torgerson and Torgerson, 2008, p. 29); as the authors remark, '[t]he presence of *all* variables that could affect outcome … in *all* groups will cancel out their effect in the analysis' (p. 29), and if, by chance, other variables are not the same in both groups, then this is unlikely to affect the outcome. Indeed Fisher commented that randomization, intended to overcome individual differences, is sufficient 'to guarantee the validity of the test of significance' in an experiment (1966, p. 21). Randomization has the potential to address external validity, i.e. generalizability, and internal validity, i.e. to avoid selection bias (p. 29).

On the other hand, a non-probability sample deliberately avoids representing the wider population; it seeks only to represent a particular group, a particular named section of the wider population, for example, a class of students, a group of students who are taking a particular examination, a group of teachers.

A probability sample will have less risk of bias than a non-probability sample, whereas, by contrast, a non-probability sample, being unrepresentative of the whole population, may demonstrate skewness or bias. This is not to say that the former is bias-free; there is still likely to be sampling error in a probability sample (discussed below), a feature that has to be acknowledged, for example, opinion polls usually declare their error factors (e.g. ±3%).

There are several types of probability samples: simple random samples; systematic samples; stratified samples; cluster samples; stage samples; and multiphase samples. They all have a measure of randomness built into them and therefore have a degree of generalizability.

Simple random sampling

In simple random sampling, each member of the population under study has an equal chance of being selected and the probability of a member of the population being selected is unaffected by the selection of other members of the population, i.e. each selection is entirely independent of the next. The method involves selecting at random from a list of the population (a sampling frame) the required number of subjects for the sample. This can be done by drawing names out of a hat until the required number is reached, or by using a table of random numbers set out in matrix form (these are reproduced in many books and websites on quantitative research methods and statistics). Researchers can also use software (e.g. SPSS, Excel) to generate random samples and randomly allocate individuals to groups, though some of these might have technical bias in their programming.

Using computer-generated samples for random allocation to different groups may, inadvertently, lead to an imbalance between those groups on key variables of interest (Torgerson, and Torgerson, 2008, p. 31). For example, Garcia *et al*. (2014) encountered this problem in their initial random allocation into two groups (control and experimental) in a school project, which led to imbalance in terms of assessed student performance levels in key subjects, and the random allocation had to be iterated more than once in order to arrive at random allocation which overcame such imbalance. In such cases 'matched randomization' might be considered. Here, for example, a pair of children might be matched on the variables of interest and then one from each pair is randomly allocated to either the control or experimental group (cf. Torgerson and Torgerson, 2008, p. 35).

Addressing probability and chance, the sample should contain subjects with characteristics similar to the population as a whole; some old, some young, some tall, some short, some fit, some unfit, some rich, some poor etc. One potential problem associated with this particular sampling method is that a complete list of the population is needed and this is not always readily available. On the other hand, Table 12.1 indicates the number of people needed in a random sample with regard to the population size, regardless of detailed characteristics of the sample. This requires the researcher to define carefully the population from which the sample is drawn: for example, it is little help in trying to generalize to all the males and females in a school if only males are taken as the population from which the sample is drawn.

Systematic sampling

This method is a modified form of simple random sampling. It involves selecting subjects from a population list in a systematic rather than a random fashion. For example, if from a population of, say, 2,000 a sample of 100 is required, then every twentieth person can be selected. The starting point for the selection is chosen at random.

One can decide how frequently to make systematic sampling by a simple statistic – the total number of the wider population being represented divided by the sample size required:

$$f = \frac{N}{sn}$$

f = frequency interval
N = the total number of the wider population
sn = the required number in the sample.

Let us say that the researcher is working with a school of 1,400 students; by looking at the table of sample size (Table 12.1) required for a random sample of these 1,400 students, she sees that 301 students are required to be in the sample. Hence the frequency interval (*f)* is:

$$\frac{1400}{302} = 4.635 \text{ (which rounds up to 5.0)}$$

Hence the researcher would pick out every fifth name on the list of cases.

Such a process, of course, assumes that the names on the list themselves have been listed in a random order. A list of females and males might list all the females first, before listing all the males; if there were 200 females on the list, the researcher might have reached the desired sample size before reaching that stage of the list which contained males, thereby distorting (skewing) the sample. Another example is where the researcher decides to select every thirtieth person from a list of school students, but it happens that: (a) the school has just over thirty students in each class; (b) each class is listed from high-ability to low-ability students; (c) the school listing identifies the students by class. Here, although the sample is drawn from each class, it is not fairly representing the whole school population since it is drawing almost exclusively on the lower-ability students. This is the issue of *periodicity* (Calder, 1979).

Not only is there the question of the order in which names are listed in systematic sampling, but there is also the issue that this process may violate one of the fundamental premises of probability

sampling, namely that every person has an equal chance of being included in the sample. In the example above where every fifth name is selected, this guarantees that names 1–4, 6–9, etc. will be excluded, i.e. everybody does not have an equal chance to be chosen. The ways to reduce this problem are to ensure that the initial listing is selected randomly and that the starting point for systematic sampling is similarly selected randomly.

Random stratified sampling

Random stratified sampling involves dividing the population into homogeneous groups, each group containing subjects with similar characteristics, and then randomly sampling within those groups. For example, group A might contain males and group B, females. In order to obtain a sample representative of the whole population in terms of sex, a random selection of subjects from group A and group B must be taken. If needed, the exact proportion of males to females in the whole population can be reflected in the sample. For example, if a school has a population with 75 per cent of students whose first language is English and 25 per cent with a different first language then the researcher can randomly sample to contain 75 per cent of first-language English speakers and 25 per cent with different first languages, in order to keep the proportions in the sample the same as those in the population. The researcher will need to identify those characteristics of the wider population which must be included in the sample, i.e. to identify the parameters of the wider population. This is the essence of establishing the sampling frame.

To organize a stratified random sample is a simple two-stage process. First, identify those characteristics that appear in the wider population which must also appear in the sample, i.e. divide the wider population into homogeneous and, if possible, discrete groups (strata), for example, males and females. Second, randomly sample within these groups, the size of each group being determined either by the judgement of the researcher or by reference to Tables 12.1 or 12.2.

The decision on which characteristics to include should strive for simplicity as far as possible, as the more factors there are, not only the more complicated the sampling becomes, but often the larger the sample will have to be in order to include representatives of all strata of the wider population. For example, imagine that we are surveying a whole school of 1,000 students in a multi-ethnic school. Table 12.1 suggests that we need 278 students in our random sample, to ensure representativeness. However, let us imagine that we wished to stratify our groups into, for example, Chinese (50 students), Spanish (100 students), English (800 students) and Arabic (50 students). From tables of random sample sizes we work out a random sample *with* stratification, i.e. for each stratum, which yields the following:

Students	*Population*	*Sample*
English-speakers	800	260
Spanish-speakers	100	80
Arabic-speakers	50	44
Mandarin-speakers	50	44
Total	1,000	428

Our original sample size of 278 has now increased, very quickly, to 428. The message is very clear: the more strata (sub-groups) we have, the larger the sample will be. Hence the advice here is to have as few strata as is necessary, but no fewer.

A random stratified sample is a useful blend of randomization and categorization, thereby enabling both a quantitative and qualitative piece of research to be undertaken. Quantitative research can use statistical analysis, whilst qualitative research can target those groups in institutions or clusters of participants who might be approached to participate in the research.

Cluster sampling

When the population is large and widely dispersed, gathering a simple random sample poses administrative problems. Suppose we want to survey students' fitness levels in a particularly large community or across a country. It would be completely impractical to select students randomly and spend an inordinate amount of time travelling about in order to test them. By cluster sampling, the researcher can select a specific number of schools and test all the students in those selected schools, i.e. a geographically close cluster is sampled.

One has to be careful to ensure that cluster sampling does not build in bias. For example, let us imagine that we take a cluster sample of a city in an area of heavy industry or great poverty; this may not represent all kinds of cities or socio-economic groups, i.e. there may be similarities within the sample that do not catch the variability of the wider population. The issue here is one of representativeness; hence it might be safer to take several clusters and to sample lightly within each cluster, rather than to take fewer clusters and sample heavily within each.

Cluster samples are widely used in small-scale research. In a cluster sample the parameters of the wider population are often drawn very sharply; a researcher, therefore, would have to comment on the generalizability of the findings. The researcher may also need to stratify within this cluster sample if useful data, i.e. those which are focused and which demonstrate discriminability, are to be acquired.

Stage sampling

Stage sampling is an extension of cluster sampling. It involves selecting the sample in stages, that is, taking samples from samples. For example, one type of stage sampling might be to select a number of schools at random, and from within each of these schools, select a number of classes at random, and from within those classes select a number of students.

Morrison (1993, pp. 121–2) provides an example of stage sampling. Let us say that a researcher wants to administer a questionnaire to all sixteen-year-olds in secondary schools in one region, and chooses eleven such schools from a population of, say, fifteen schools. By contacting the eleven schools she finds that there are 2,000 sixteen-year-olds on roll. Because of questions of confidentiality she is unable to find out the names of all the students so it is impossible to draw their names out of a hat to achieve randomness (and even if she had the names, it would be a mind-numbing activity to write out 2,000 names to draw out of a hat!). From looking at Table 8.1 she finds that, for a random sample of the 2,000 students, the sample size is 322 students. How can she proceed?

The first stage is to list the eleven schools on a piece of paper and then to put the names of the eleven schools onto a small card and place each card in a hat. She draws out the first name of the school, puts a tally mark by the appropriate school on her list and returns the card to the hat. The process is repeated 321 times, bringing the total to 322. The final totals might appear thus:

School	1	2	3	4	5	6	7	8	9	10	11	Total
Required number of students	22	31	32	24	29	20	35	28	32	38	31	322

For the second stage she then approaches the eleven schools and asks each of them to select randomly the required number of students for each school. Randomness has been maintained in two stages and a large number (2,000) has been rendered manageable. The process at work here is to go from the general to the specific, the wide to the focused, the large to the small. Caution has to be exercised here, as the assumption is that the schools are of the same size and are large; that may not be the case in practice, in which case this strategy may be inadvisable.

The issue can become more complex, as the eleven schools are a sample of the population of the schools in the region, raising the question of what the sample is: the eleven schools or the 322 students (cf. Gorard, 2013, pp. 82–3). Whilst the eleven schools are the random sample from the population of fifteen schools, the 322 students are a clustered sample from the eleven schools. Gorard provides some useful advice here: if the intention is to *compare* institutions then the sample size here would be eleven, and if the intention is to look at overall results then the sample size is 322.

Multi-phase sampling

In stage sampling there is a single unifying purpose throughout the sampling. In the previous example the purpose was to reach a particular group of students from a particular region. However, in a multi-phase sample the purposes change at each phase, for example, at phase one the selection of the sample might be based on the criterion of geography (e.g. students living in a particular region); phase two might be based on an economic criterion (e.g. schools whose budgets are administered in markedly different ways); phase three might be based on a political criterion (e.g. schools whose students are drawn from areas with a tradition of support for a particular political party), and so on. Here the sample population changes at each phase of the research.

12.9 Non-probability samples

The selectivity which is built into a non-probability sample derives from the researcher targeting a particular group, in the full knowledge that it does not represent the wider population; it simply represents itself. This is frequently the case in small samples or small-scale research, for example, one or two schools, two or three groups of students, a particular group of teachers, where no attempt to generalize is desired. It is also frequently the case for ethnographic research, action research or case study research. Small-scale research often uses non-probability samples because, despite their non-representativeness, they are far less complicated to set up, are considerably less expensive and can prove perfectly adequate where researchers do not seek to generalize their findings beyond the sample in question, or where they are simply piloting a questionnaire as a prelude to the main study.

Just as there are several types of probability sample, so there are several types of non-probability sample: convenience sampling, quota sampling, dimensional sampling, purposive sampling and snowball sampling. Each type of sample seeks only to represent itself or instances of itself in a similar population, rather than attempting to represent the whole, undifferentiated population.

Convenience sampling

Convenience sampling, or, as it is sometimes called, accidental or opportunity sampling, involves choosing the nearest individuals to serve as respondents and continuing that process until the required sample size has been obtained of those who happen to be available and accessible at the time. Captive audiences such as students or student teachers often serve as respondents based on convenience sampling. The researcher simply chooses the sample from those to whom she has easy access. As it does not represent any group apart from itself, it does not seek to generalize to the wider population; for a convenience sample that is an irrelevance. The researcher, of course, must take pains to report this point – that generalizability in this type of sampling is negligible. A convenience sample may be selected for a case study or a series of case studies.

Quota sampling

Quota sampling has been described as the non-probability equivalent of stratified sampling (Bailey, 1994). Like a stratified sample, a quota sample strives to represent significant characteristics (strata) of the wider population and sets out to represent these in the proportions in which they can be found in the wider population. For example, suppose that the wider population comprised 55 per cent females and 45 per cent males, then the sample would have to contain 55 per cent females and 45 per cent males; if the population of a school contained 80 per cent of students up to and including the age of sixteen, and 20 per cent of students aged seventeen and over, then the sample would have to contain 80 per cent of students up to the age of sixteen and 20 per cent of students aged seventeen and above. A quota sample, then, seeks to give proportional weighting to selected factors (strata) which reflects their weighting/proportions in the wider population. The researcher wishing to devise a quota sample can proceed in three stages:

Stage 1: Identify those characteristics (factors) that appear in the wider population which must also appear in the sample, i.e. divide the wider population into homogeneous and, if possible, discrete groups (strata), for example, males and females, Asian, Chinese and African-Caribbean.

Stage 2: Identify the proportions in which the selected characteristics appear in the wider population, expressed as a percentage.

Stage 3: Ensure that the percentaged proportions of the characteristics selected from the wider population appear in the sample.

Ensuring correct proportions in the sample may be difficult to achieve if the proportions in the wider community are unknown or if access to the sample is difficult; sometimes a pilot survey might be necessary in order to establish those proportions (and even then sampling error or a poor response rate might render the pilot data problematical).

It is straightforward to determine the minimum number required in a quota sample. Let us say that the total number of students in a school is 1,700, comprising:

Performing arts	300 students
Natural sciences	300 students
Humanities	600 students
Business and social sciences	500 students

The proportions being 3 : 3 : 6 : 5, a minimum of seventeen students might be required (3 + 3 + 6 + 5) for the sample. Of course, this would be a minimum only, and it might be desirable to go higher than this. The price of having too many characteristics (strata) in quota sampling is that the minimum number in the sample very rapidly can become very large, hence in quota sampling it is advisable to keep the numbers of strata to a minimum. The larger the number of strata, the larger the number in the sample will become, often very quickly.

Purposive sampling

In purposive sampling, often (but by no means exclusively) a feature of qualitative research, researchers handpick the cases to be included in the sample on the basis of their judgement of their typicality or possession of the particular characteristic(s) being sought. They assemble the sample to meet their specific needs.

Purposive sampling is undertaken for several kinds of research (Teddlie and Yu, 2007), including: to achieve representativeness, to enable comparisons to be made, to focus on specific, unique issues or cases, to generate theory through the gradual accumulation of data from different sources. Purposive sampling, Teddlie and Yu aver, involves a trade-off: on the one hand it provides greater depth to the study than probability sampling; on the other hand it provides less breadth to the study than probability sampling.

As its name suggests, a purposive sample has been chosen for a specific purpose, for example: (a) a group of principals and senior managers of secondary schools is chosen as the research is studying the incidence of stress among senior managers; (b) a group of disaffected students has been chosen because they might indicate most distinctly the factors which contribute to students' disaffection (they are *critical cases*, akin to 'critical events' discussed in Chapter 33, or *deviant cases* – those cases which go against the norm) (Anderson and Arsenault, 1998, p. 124); (c) one class of students has been selected to be tracked throughout a week in order to report on the curricular and pedagogic diet offered to them so that other teachers in the school can compare their own teaching to that reported. Whilst this type of sample may satisfy the researcher's needs, it does not pretend to represent the wider population; it is deliberately and unashamedly selective and biased.

In many cases purposive sampling is used in order to access 'knowledgeable people', i.e. those who have in-depth knowledge about particular issues, maybe by virtue of their professional role, power, access to networks, expertise or experience (Ball, 1990). There is little benefit in seeking a random sample when most of the random sample may be largely ignorant of particular issues and unable to comment on matters of interest to the researcher, in which case a purposive sample is vital. Though they may not be representative and their comments may not be generalizable, this is not the primary concern in such sampling; rather the concern is to acquire in-depth information from those who are in a position to give it.

Another variant of purposive sampling is the *boosted* sample. Gorard (2003, p. 71) comments on the need to use a boosted sample in order to include those who may otherwise be excluded from, or under-represented in, a sample because there are so few of them. For example, one might have a very small number of special needs teachers or students in a primary school or nursery, or one might have a very small number of children from certain ethnic minorities in a school, such that they may not feature in a sample. In this case the researcher will deliberately seek to include a sufficient number of them to ensure appropriate statistical analysis or representation in the sample, adjusting any results from them, through weighting, to ensure that they are not over-represented in the final results. This is an endeavour, perhaps, to meet the demands of social inclusion.

A further variant of purposive sample is *negative case sampling*. Here the researcher deliberately seeks those people who might disconfirm the theories being advanced (the Popperian equivalent of falsifiability), thereby strengthening the theory if it survives such potentially disconfirming cases. A softer version of negative case sampling is *maximum variation sampling*, selecting cases which are as varied as possible on the issue in question (Anderson and Arsenault, 1998, p. 124) in order to ensure strength and richness to the data, their applicability and their interpretation. In this latter case, it is almost inevitable that the sample size will increase or be large.

Teddlie and Yu (2007), Teddlie and Tashakkori (2009, p. 174) and Flick (2009, pp. 122–3) provide a typology of several kinds of purposive sample; they group these under several main areas. In terms of sampling, in order to achieve representativeness or comparability they include several types of purposive sample:

- typical case sampling, in which the sample includes the most typical cases of the group or population under study, i.e. representativeness;
- extreme or deviant case sampling, in which the most extreme cases (at either end of a continuum, e.g. success and failure, tolerance and intolerance, most and least stressed) are studied in order to provide the most outstanding examples of a particular issue, to compare with the typical cases (i.e. comparability) or to expose issues that might not otherwise present themselves (e.g. what can happen when a young child is exposed to drug pushers, family violence or repeated failure at school);
- intensity sampling of a particular group (e.g. highly effective teachers, highly talented children) in which the sample provides clear examples of the issue in question;
- maximum variation sampling, in which samples are chosen that possess or exhibit a very wide range of characteristics or behaviours respectively in connection with a particular issue;
- homogeneous sampling, in which the samples are chosen for their similarity (which can then be used for contrastive analysis or comparison with maximum variation groups or intensity sampling of other groups);
- reputational case sampling, in which samples are selected by key informants, on the recommendation of others or because the researchers are aware of their characteristics (e.g. a Minister of Education, a politician) – see below, snowball sampling and respondent-driven sampling;
- criterion sampling, in which all the cases are sampled which fit a particular criterion being studied.

In terms of sampling of special or unique cases, purposive sampling includes four types:

- revelatory case sampling, in which individuals are approached because they are members of a particular group and can reveal heretofore unknown insights, for example, fundamentalist religious schools, schools for refugees or single-ethnic minorities;
- critical case sampling: a widely used sampling technique, akin to extreme case sampling, in which a particular individual, group of individuals or cases is studied in order to yield insights that might have wider application, for example, Tripp's (1993) study of critical incidents in teaching, or Morrison's (2006) study of sensitive educational research, focusing on small states and territories, which treats one small territory as a critical case study of issues in the fields in question, which are felt to be their strongest, and which can illuminate issues in the topic which are of wider concern for other similar small states and territories;
- politically important case sampling, for example, Ball's (1990) interviews with senior politicians and Bowe's *et al.*'s (1992) interviews with a UK cabinet minister and politicians;
- complete collection sampling, in which all the members of a particular group are included, for example, all the high-achieving, musically gifted students in a sixth form.

Teddlie and Tashakkori (2009, p. 174) also indicate four examples of 'sequential sampling' in their typologies of purposive sampling:

- theoretical sampling (discussed below, cf. Glaser and Strauss, 1967), in which those cases are selected that will yield greater insight into the theoretical issue(s) under investigation. As Glaser and Strauss (1967, p. 45) suggest, the data collection is for theory generation, and, as the theory emerges, so will the next step in the data collection suggest itself, i.e. the theory drives the investigation. An example of this might be in examining childhood poverty, in which the researchers might look at those who have always been poor, those who have moved out of – or into – poverty, rural poverty, urban poverty, poverty in small families, poverty in large families, poverty in single parent families, and so on;
- conforming and disconforming case sampling, in which samples are selected from those that do and do not conform to typical trends or patterns, in order to study the causes or reasons for their conformity or disconformity;
- opportunistic sampling (see also above, convenience sampling), in which further individuals or groups are sampled as the research develops or changes and which, as validity and reliability dictate, should be included;
- snowball sampling (discussed below), in which researchers use social networks, informants and contacts to put them in touch with further individuals or groups.

Purposive sampling is a key feature of qualitative research.

Dimensional sampling

One way of reducing the problem of sample size in quota sampling is to opt for dimensional sampling. Dimensional sampling, a refinement of quota sampling, involves identifying various factors of interest in a population and obtaining at least one respondent of every combination of those factors. Thus, in a study of racism, for example, researchers may wish to distinguish first-, second- and third-generation immigrants. Their sampling plan might take the form of a multi-dimensional table with 'ethnic group' across the top and 'generation' down the side. A second example might be of a researcher who may be interested in studying disaffected students, girls and secondary-aged students and who may find a single disaffected secondary female student, i.e. a respondent who is the bearer of all of the characteristics sought.

Snowball sampling

In snowball sampling researchers identify a small number of individuals who have the characteristics in which they are interested. These people are then used as informants to identify, or put the researchers in touch with, others who qualify for inclusion; these, in turn, identify yet others – hence the term snowball sampling (also known as 'chain-referral methods'). This method is useful for sampling a population where access is difficult, maybe because the topic for research (and hence the sample) is sensitive (e.g. teenage solvent abusers; issues of sexuality; criminal gangs), or where participants might be suspicious of researchers, or where contact is difficult, for example, those without telephones, the homeless (Heckathorn, 2002). As Faugier and Sargeant (1997), Browne (2005) and Morrison (2006) argue, the more sensitive the research, the more difficulty there is in sampling and gaining access to a sample.

Hard-to-reach groups include minorities, marginalized or stigmatized groups, 'hidden groups' (those who

do not wish to be contacted or reached, e.g. drug pushers, gang members, sex workers, problem drinkers or gamblers, residents of 'safe houses' or women's refuges), old or young people with disabilities, the very powerful or social elite (Noy, 2008), dispersed communities (e.g. rural farm workers) (Brackertz, 2007).

Snowball sampling is also useful where communication networks are undeveloped (e.g. where a researcher wishes to interview stand-in teachers – teachers who are brought in on an ad hoc basis to cover for absent regular members of a school's teaching staff – but finds it difficult to acquire a list of these stand-in teachers), or where an outside researcher has difficulty in gaining access to schools (going through informal networks of friends/acquaintance and their friends and acquaintances and so on rather than through formal channels). The task for the researcher is to establish who are the critical or key informants with whom initial contact must be made.

Snowball sampling is particularly valuable in qualitative research, indeed is often pre-eminent in qualitative research; it is a means in itself, rather than a default, fall-back position (Noy, 2008, p. 330). It uses participants' social networks and personal contacts for gaining access to people. In snowball sampling, interpersonal relations feature very highly (Browne, 2005), as the researcher is reliant on: (a) friends, friends of friends, friends of friends of friends; (b) acquaintances, acquaintances of acquaintances, acquaintances of acquaintances of acquaintances; (c) contacts (personally known or not personally known), contacts of contacts, contacts of contacts of contacts. 'Snowball sampling is essentially social' (Noy, 2008, p. 332), as it often relies on strong interpersonal relations, known contacts and friends; it requires social knowledge and an equalization of power relations (Noy, 2008, p. 329). In this respect it reduces or even dissolves asymmetrical power relations between researcher and participants, as the contacts might be built on friendships, peer group membership and personal contacts and because participants can act as gatekeepers to other participants and informants exercise control over whom else to involve and refer. Indeed in respondent-driven sampling (discussed below), a variant of snowball sampling, the respondents not only identify further contacts for the researcher but actively recruit them to be involved in the research (Heckathorn, 1997, p. 178), i.e. participants who might be initially uncooperative with researchers might be cooperative for their peer group members who approach them (p. 197). Snowball sampling here, then, is 'respondent driven' (Heckathorn, 1997, 2002), where respondents identify others for the researcher to contact.

In researching 'hidden populations' typically there are no sampling frames, so researchers do not know the population from which the sample can be drawn, and there is often a problem of access as such groups may guard their privacy (e.g. if their behaviour is illegal, or stigmatized) and, even if access is gained, truthful responses may not be forthcoming as participants may deliberately conceal the truth in order to protect themselves (Heckathorn, 1997, p. 174).

Snowball sampling may rely on personal, social contacts, but it can also rely on 'reputational contacts' (e.g. Farquharson, 2005), where people may be able to identify to the researcher other known persons in the field. The 'reputational snowball' (p. 347) can be a powerful means of identifying significant others in a 'micro-network' (p. 349), particularly if one is researching powerful individuals and policy makers who are not always known to the public. As Farquharson (2005, p. 346) remarks, 'policy networks' are groups of interconnected institutions and/or people who are influential in the field, perhaps to advance, promote, block, develop or initiate policy. A reputational snowball can be generated by asking individuals – either at interview or by open-ended questions on a questionnaire – to identify others in the field who are particularly influential, important or worth contacting.

On the one hand, snowball sampling can reach the hard-to-reach, not least if the researcher is a member of the groups being researched (e.g. Browne's (2005) study of non-heterosexual women, of which she was one and therefore had her own circle of friends and contacts, and in which rapport and trust were easier to establish).

On the other hand, snowball sampling can be prone to biases stemming from the influence of the initial contact and the problem of volunteer-only samples (Heckathorn, 2002, p. 12). Browne (2005) indicates that, because she was a member of a white, middle-class group of non-heterosexual women, her contacts tended to be from similar backgrounds, and other non-heterosexual women were not included because they were not in the same 'loop' of social contacts. In other words, snowball sampling is influenced by the researcher's initial points of contact, as these drive the subsequent contacts, and, indeed, can lead to sampling or over-sampling of cooperative groups or individuals (Heckathorn, 1997, p. 175). Two methods can be employed to overcome this: (a) key informant sampling asks participants about others' behaviours (but this raises the problem of informed consent and confidentiality of others) (Heckathorn, 2002, p. 13), whilst (b) targeted sampling tries to ensure a non-biased sample, to include all those who should be included (i.e. to

prevent under-sampling) and who represent different facets of the issue or group under study (see Heckathorn (1997, 2002) for a fuller discussion of this matter and for how to address and overcome bias in respondent-driven samples).

Further, if a researcher is to move beyond his or her personal contacts, to try to be more inclusive of otherwise excluded sub-groups or individuals, then there is a risk in having such small numbers of others that tokenism is at work. Browne (2005, p. 53) writes that the women who participated in her research were also gatekeepers of contact to other non-heterosexual women who, for a variety of reasons (not least of which was the wish to avoid revealing too much to a friend), may not have wished to be involved. Bias can both include and exclude members of a population and a sample; it 'can create other "hidden populations"' (Browne, 2005, p. 53), and the gatekeepers can protect friends by not referring them to the researcher (Heckathorn, 1997, p. 175).

Figure 12.2 indicates a linear, sequential method of sampling (with unidirectional arrows). Noy (2008, p. 333) comments that, as the ordinal succession proceeds, the later members of the sample might have different characteristics or attributes from the earlier members of the sample, i.e. the sample is not necessarily homogeneous. This is important, as it overcomes the problem indicated earlier, where the influence of initial contacts on later contacts is high; having many waves of contacts reduces this influence (Heckathorn, 1997, p. 197).

Snowball sampling can be used as the main method of gaining access to people or as an auxiliary method of gaining access to people for further, in-depth data collection and exploration of issues.

Volunteer sampling

In cases where access is difficult, the researcher may have to rely on volunteers, for example, personal friends, or friends of friends, or participants who reply to a newspaper advertisement, or those who happen to be interested from a particular school, or those attending courses. Sometimes this is inevitable (Morrison, 2006) as it is the only kind of sampling that is possible, and it may be better to have this kind of sampling than no research at all.

In these cases one has to be very cautious in making any claims for generalizability or representativeness, as volunteers may have a range of different motives for volunteering, for example, wanting to help a friend, interest in the research, wanting to benefit society, an opportunity for revenge on a particular school or headteacher/principal. Volunteers may be well intentioned, but they do not necessarily represent the wider population, and this has to be made clear.

Theoretical sampling

Theoretical sampling is a feature of grounded theory (see Chapter 37). In grounded theory the sample size is relatively immaterial, as one works with the data that one has. Indeed grounded theory would argue that the sample size could be infinitely large, or, as a fall-back

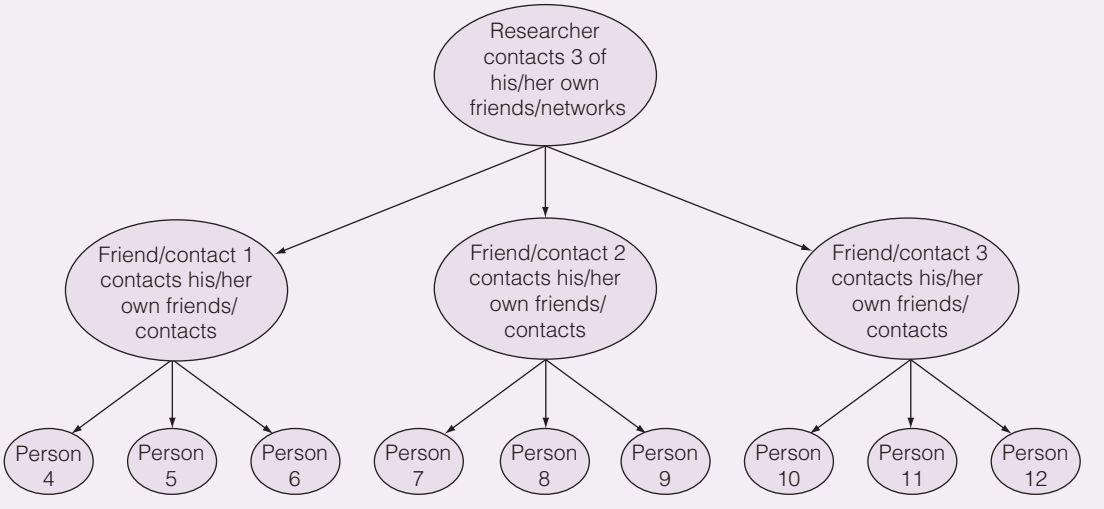

FIGURE 12.2 Snowball sampling

position, large enough to 'saturate' the categories and issues, such that new data do not cause any modification to the theory which has been generated.

Theoretical sampling requires the researcher to have sufficient data to be able to generate and 'ground' the theory in the research context, however defined, i.e. to create a theoretical explanation of what is happening in the situation, without finding any more data that do not fit the theory. Since the researcher will not know in advance how much or what range of data will be required, it is difficult, to the point of impossibility, exhaustion or time limitations, to know in advance the sample size required. Having conducted analysis of collected data, the researcher decides what further data to collect and from whom, in order to develop the emergent theory (Glaser and Strauss, 1967, p. 4). Theoretical sampling places the development of theory as the prime concern (cf. Creswell, 2012, p. 433), and so the researcher gathers more and more data until the theory remains unchanged or until the boundaries of the context of the study have been reached, until no modifications to the grounded theory are made in light of constant comparisons, and this may mean several rounds of data collection from different samples (Flick, 2009, p. 118). 'Theoretical saturation' (Glaser and Strauss, 1967, p. 61) occurs when no additional data are found which advance, modify, qualify, challenge, extend or add to the theory developed (see also Krueger and Casey, 2000).

Two key questions for the grounded theorist using theoretical sampling (Glaser and Strauss, 1967) are: (a) to which groups does one turn next for data? (b) for what theoretical purposes does one seek further data? In response to (a), Glaser and Strauss (p. 49) suggest that the decision is based on theoretical relevance, i.e. those groups that will assist in the generation of as many properties and categories as possible. The size of the data set may be fixed by the number of participants in the organization, or the number of people to whom one has access, but the researcher has to consider that the door may have to be left open for him/her to seek further data in order to ensure theoretical adequacy and to check what has been found so far with further data (Flick *et al*., 2004a, p. 170). In this case it is not always possible to predict at the start of the research just how many, and who, the researcher will need for the sampling; it becomes an iterative process. Flick (2009, p. 118) makes the point that individuals and groups are selected on the basis of their potential to yield new insights into, and enrich, the developing/emergent theory, i.e. the researcher asks whom to turn to next in contributing to the development of the theory.

Theoretical sampling differs from statistical sampling in that: (a) the former does not know in advance what will be the relevant population, whereas the latter does; (b) the former may involve ongoing, new, multiple samples whereas the latter typically does not; (c) the former does not define in advance the sample size, whereas the latter does; (d) in the former the sampling ends when theoretical saturation has been reached whereas in the latter the sampling ends when the whole, predefined sample has been studied; (e) sampling is based on the relevance to the case whereas the latter is based on representativeness (Flick, 2009, pp. 119–21).

Non-probability sampling can be of *people* and of *issues*. Samples of people might be selected because the researcher is concerned to address specific issues, for example, students who misbehave, those who are reluctant to go to school, those with a history of drug dealing, those who prefer extra-curricular to curricular activities. Here it is the issue that drives the sampling, and so the questions become not only 'whom should I sample?' but 'what should I sample?' (Mason, 2002, pp. 127–32). It is not only people who may be sampled, but texts, documents, records, settings, environments, events, objects, organizations, occurrences, activities, and so on.

12.10 Sampling in qualitative research

In qualitative research, often non-probability, purposive samples are employed. However, whilst much of the discussion of probability samples is more relevant to quantitative research (though not exclusively so), and whilst much of the discussion of non-probability samples is more relevant to qualitative research (though not exclusively so), some qualitative research also raises a fundamental question about sampling. The question is this: if sampling presupposes an identifiable population from which a sample is drawn, then is it actually realistic or relevant to identify a population or its sample?

In much qualitative research the emphasis is placed on the uniqueness, the idiographic and exclusive distinctiveness of the phenomenon, group or individuals in question, i.e. they only represent themselves, and nothing or nobody else. In such cases it is perhaps unwise to talk about a 'sample', and more fitting to talk about a group, or individuals. How far they are representative of a wider population or group is irrelevant, as much qualitative research seeks to explore the particular group under study, not to generalize. If, in the process, other groups find that issues raised apply to

them then this is a bonus rather than a necessity, for example, as in case study research.

Further, a corollary of the sympathy between qualitative research and non-probability sampling is that there are no clear rules on the size of the sample in qualitative research; size is informed by 'fitness for purpose', and sample size, therefore, might vary from one to many (Marshall and Rossman, 2016, p. 108). For example, a case study might involve only one child (e.g. Axline, 1964); a grounded theory might continue to add samples until theoretical saturation is reached (i.e. where new data no longer add to the theory construction or themes, or their elements); an ethnography takes in the whole of the group under study, sometimes without any intention of representing a wider population (e.g. Patrick, 1973) and at other times seeking to represent some key features of a wider population (e.g. Willis, 1977). Indeed Flick (2009, p. 123) notes that the basis of choosing sample strategies in qualitative research (including all the non-probability sampling strategies introduced above) is to provide 'rich and relevant information'.

This is not to say that there are no occasions on which, in qualitative research, a sample cannot fairly represent a population. Indeed Onwuegbuzie and Leech (2007, p. 240) argue that external generalizability and inferences to a whole population can feature in qualitative research, and that, as in quantitative research, this typically requires a large sample to be drawn (p. 242). The authors contrast this with internal generalizability, in which data from a sub-group of a sample seeks to be generalizable to the whole sample. That said, they note (p. 249) that, many times, the purpose of the sampling is not to make generalizations, not to make comparisons, but to present unique cases that have their own, intrinsic value.

Onwuegbuzie and Leech (2007, p. 242) suggest that, in qualitative research, the sample size should be large enough to generate 'thick descriptions' (Geertz, 1973) and rich data, though not so large as to prevent this from happening due to data overload or moves towards generalizability, and not so small as to prevent theoretical saturation (discussed earlier) from being achieved. They also counsel (p. 245) that sub-groups in a sample should not be so small as to prevent data redundancy or data saturation, and, in this respect, they recommend that each sub-group should contain no fewer than three cases. As with quantitative data, they note that, as the number of strata increases, so will the size of the sample.

12.11 Sampling in mixed methods research

We introduced sampling in mixed methods research in Chapter 2. We take the discussion further here. Teddlie and Tashakkori (2009, pp. 180–1), drawing on the work of Teddlie and Yu (2007), indicate that it is commonplace for mixed methods research to use more than one kind of sample (probability, non-probability) and to use samples of different sizes, scope and types (cases: people; materials: written, oral observational; other elements in social situations: locations, times, events etc.) within the same piece of research. This harks back to the work of Spradley (1980) on participant observation, Patton (1990) on qualitative research and Miles and Huberman (1994) in discussing actors (participants), settings, events and processes. Even though mixed methods may be used, this does not rule out the fact that, in some mixed methods research, a numerical approach may predominate – with the sampling implications indicated earlier in this chapter (e.g. probability sampling and sample size calculation) – whilst in other mixed methods approaches qualitative data may predominate, with an emphasis on purposive and non-probability sampling (cf. Teddlie and Yu, 2007, p. 85).

Teddlie and Tashakkori (2009, pp. 185–91) provide a useful overview of different mixed methods sampling designs (see also Chapter 2 this volume). In *parallel mixed methods sampling* both probability and non-probability samples are selected, running side by side simultaneously, but separate from each other, i.e. data from one sample do not influence the collection of data from the other and vice versa. Onwuegbuzie and Leech (2007, p. 239) add that parallel sampling designs enable comparisons to be made across two or more sub-groups of a sample that are within the same level of the sample (e.g. girls and boys).

In *sequential mixed methods sampling* (Teddlie and Tashakkori, 2009, pp. 185–91) one kind of sample (both probability and non-probability) precedes another and influences the proceeding sample; in other words, what one gathers from an early sample influences what one does in the next stage with a different sample. For example, numerical data might set the scene for in-depth interviewing, perhaps identifying extreme or deviant cases, critical cases, variables on which the results are either homogeneous or highly varied; alternatively, qualitative data (e.g. case studies or focus groups) might identify issues for exploration in a numerical survey.

In *multilevel mixed methods sampling*, different kinds of sample (both probability and non-probability and either separately or together) are used at different levels of units of analysis, for example: individual

students, classes, schools, local authorities, regions. Onwuegbuzie and Leech (2007, p. 240) suggest that multilevel sampling designs enable comparisons to be made between two or more sub-groups that are drawn from different levels of the study (e.g. individual students and teachers, or individual students and schools, as there is a perceptible hierarchy operating here). They add that this is facilitated by software (e.g. NVivo) that enables such comparative data to be collected and presented by sub-group. They also caution researchers to note that, often, a sub-sample from one level is not the same size as the sub-sample from another (p. 249). For instance, there may be thirty individual students but only one or two teachers for that group of students (they note, in this context, that it is frequently the case that the levels are related, e.g. students and teachers from the same school, rather than being separate, e.g. students from one school and teachers from another).

Teddlie and Tashakkori (2009, p. 191) provide a worked example of a multilevel, mixed methods sampling design in a school effectiveness study, in which:

- at level one, students were selected by probability (random) and purposive sampling (typical cases and complete collection sampling);
- at level two, teachers and classrooms were selected by probability (random and random stratified) and purposive sampling (intensity and typical case sampling);
- at level three, schools were sampled using purposive samples (extreme and deviant case sampling, intensity sampling and typical case sampling);
- at level four, school districts were sampled using probability sampling (cluster samples) and stratified purposive samples;
- at level five, state school systems were sampled using purposive or convenience sampling.

Teddlie and Tashakkori (2009, p. 186) suggest that, in *stratified purposive sampling* the researcher identifies the different strata (e.g. sub-groups) within the population under study, and then selects a limited number of cases from within each of those sub-groups, ensuring that the selection of these cases is based on purposive sampling strategies (i.e. fitness for purpose), drawing on the range of purposive sampling strategies outlined earlier in this chapter. This, they aver, enables the researcher to make comparisons across groups (strata) as required. In this case the purposive sample is a subset of the probability sample (Teddlie and Yu, 2007, p. 93).

Teddlie and Tashakkori (2009, pp. 186–7) also commend *purposeful random sampling*, in which the researcher takes a random sample from a small number of cases from the population (a probability sample) that has already been drawn from a purposive sample (where the population has been chosen for a specific purpose).

Onwuegbuzie and Leech (2007, p. 239) introduce *nested sampling designs*, which enable comparisons to be made between two or more members of the same sub-group and the whole sample. The members of a sub-group represent a sub-sample of the whole sample (p. 246). They give the example (p. 240) of a comparison between key informants and the whole sample.

Teddlie and Tashakkori (2009) also provide useful guidance for sampling in mixed methods research (pp. 192–3), suggesting that the sampling strategy should:

- derive logically from the research questions or hypotheses being investigated/tested;
- be faithful to the assumptions on which the sampling strategies are based (e.g. random allocation, even distributions of characteristics in the population etc.);
- generate qualitative and quantitative data for answering the research questions;
- enable clear inferences to be drawn from both the numerical and qualitative data;
- abide by ethical principles;
- be practicable (able to be done) and efficient;
- enable generalizability of the results (and should indicate to whom the results are generalizable);
- be reported in a level of detail that will enable other researchers to understand it and perhaps use it in the future.

12.12 Planning a sampling strategy

There are several stages in planning the sampling strategy:

Stage 1: Decide whether you need a sample, or whether it is possible to have the whole population.
Stage 2: Identify the population, its important features (the sampling frame) and its size.
Stage 3: Identify the kind of sampling strategy you require (e.g. which variant of probability, non-probability or mixed methods sample you require).
Stage 4: Ensure that access to the sample is guaranteed. If not, be prepared to modify the sampling strategy (stage 3).
Stage 5: For probability sampling, identify the confidence level and confidence intervals that you require. For non-probability sampling, identify the people whom you require in the sample.

Stage 6: Calculate the numbers required in the sample, allowing for non-response, incomplete or spoiled responses, attrition and sample mortality, i.e. build in redundancy by oversampling.
Stage 7: Decide how to gain and manage access and contact (e.g. advertisement, letter, telephone, email, personal visit, personal contacts/friends).
Stage 8: Be prepared to weight (adjust) the data, once collected.

12.13 Conclusion

The message from this chapter is the same as for many of the others, namely, every element of the research should not be arbitrary but planned and deliberate, and the criterion of planning must be 'fitness for purpose'. The selection of a sampling strategy must be governed by the criterion of suitability. The choice of which strategy to follow must be mindful of the purposes of the research, the timescales and constraints on the research, the research design, the methods of data collection and the methodology of the research. The sampling chosen must be appropriate for all of these factors if validity is to be served.

To the question 'how large should my sample be?', the answer is complicated. This chapter has suggested that it all depends on:

- the research purposes, questions and design;
- the size and nature of the population from which the sample is drawn;
- the heterogeneity of the population from which the sample is drawn;
- the confidence level and confidence interval required;
- the likely response rate;
- the accuracy required (the smallest sampling error sought);
- the kinds of variables to be used (categorical, continuous);
- the statistical power required;
- the statistics to be used;
- the scales being used;
- the number of strata required;
- the number of variables included in the study;
- the variability of the factor under study;
- the kind(s) of sample (different kinds of sample within probability, non-probability and mixed methods sampling);
- the representativeness of the population in the sample;
- the allowances to be made for attrition and non-response;
- the need to keep proportionality in a proportionate sample;
- the kind of research that is being undertaken (qualitative/quantitative/mixed methods).

That said, this chapter has urged researchers to use large rather than small samples in quantitative research and sufficiently large and small samples to enable thick descriptions to be achieved in qualitative research. Table 12.4 presents a summary of the types of samples introduced in this chapter.

Decisions on sampling must be made with reference to the criterion of fitness for purpose of the research (internally on the purposes of the study and externally on the intention to generalize or not to generalize), fitness with the research question(s) and match with the focus of the research. Which and how many individuals, groups, communities, institutions, events, places, sites, actions, processes, behaviours etc. to include, and whether to use random sampling (which may or may not provide depth of description and explanation), are complex issues (Marshall and Rossman, 2016, p. 110). How systematic and predetermined or open are the samples depends on the nature of the study. Sampling strategies, as Flick (2009) remarks, describe ways of disclosing and understanding the field (p. 125), and this may require a large, small, wide or narrow sample. Sampling decisions may determine the nature, reliability, validity, credibility, trustworthiness, utility and generalizability of the data collected and, indeed, how to collect such data.

TABLE 12.4 TYPES OF SAMPLE

Probability samples	*Non-probability samples*	*Mixed methods sampling designs*
Simple random sampling	Convenience sampling	Parallel mixed methods sampling
Systematic sampling	Quota sampling	Sequential mixed methods sampling
Random stratified sampling	Purposive sampling:	Multilevel mixed methods sampling
Cluster sampling	Boosted sample	Stratified purposive sampling
Stage sampling	Negative case sampling	Purposeful random sampling
Multi-phase sampling	Typical case sampling	Nested sampling designs
	Extreme/deviant case sampling	
	Intensity sampling	
	Maximum variation sampling	
	Homogeneous sampling	
	Reputational case sampling	
	Revelatory case sampling	
	Critical case sampling	
	Politically important case sampling	
	Complete collection sampling	
	Theoretical sampling	
	Confirming and disconfirming case sampling	
	Opportunistic sampling	
	Snowball sampling	
	Dimensional sampling	
	Volunteer sampling	

Companion Website

The companion website to the book provides PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Sensitive educational research

CHAPTER 13

This chapter addresses several aspects of sensitive research:

- defining sensitive research
- issues of sampling and access
- ethical issues
- effects on the researcher
- researching powerful people
- researching powerless and vulnerable people
- asking questions

It argues that researchers have to be acutely aware of the sensitivities at work in any piece of research that they are undertaking.

13.1 Introduction

All educational research is sensitive or has the potential to become sensitive (cf. Fahie, 2014); the question is one of degree. The researcher has to be sensitive to the context, the cultures, the participants, the consequences of the research on a range of parties (including not only those being researched but also, e.g., researchers, transcribers and readers), the powerless, the powerful, people's agendas and suchlike. Being sensitive is as much about ethics and behaving ethically as it is about the research itself. Researchers have to be very careful on a variety of delicate issues.

The chapter sets out different ways in which educational research might be sensitive. It then takes two significant issues in the planning and conduct of sensitive research – sampling and access – and indicates why these might be challenging for researchers and how they might be addressed. This includes a discussion of gatekeepers and their roles. Sensitive research raises a range of difficult, sometimes intractable, ethical issues; it can also affect researchers and other participants in the research, and we address these here. Investigations involving powerful and powerless people are taken as an instance of sensitive educational research, and this is used to examine several key problematic matters in such research. The chapter moves to a practical note, proffering advice on how to ask questions in sensitive research. Finally, the chapter sets out a range of key issues to be addressed in the planning, conduct and reporting of sensitive research.

13.2 What is sensitive research?

Sensitive research is that 'which potentially poses a substantial threat to those who are involved or have been involved in it' (Lee, 1993, p. 4), when those studied view the research as somehow undesirable (Van Meter, 2000), or when the research generates risk or potential harm for the participants (widely defined) (Corbin and Morse, 2003; Dickson-Swift *et al*., 2007, 2008, 2009; Fahie, 2014; Emerald and Carpenter, 2015). However, sensitivity can derive from many sources, including:

- consequences for the participants (Sieber and Stanley, 1988, p. 49; McCosker *et al*., 2001; Kavanagh *et al*., 2006, p. 245);
- consequences for others, for example, family members, associates, social groups and the wider community, research groups and institutions (Lee, 1993, p. 5), researchers, transcribers and readers (Dickson-Swift *et al*., 2007, 2008, 2009; Fahie, 2014);
- contents, for example, taboo or emotionally charged areas of study (Farberow, 1963), such as criminality, deviance, sex and sexual abuse, race, bereavement, violence, politics, policing, human rights, drugs, poverty, illness, mental health, religion and the sacred, lifestyle, family, finance, physical appearance, power and vested interests (Lee, 1993; Arditti, 2002; Chambers, 2003; Dickson-Swift *et al*., 2007, 2008, 2009; Fahie, 2014);
- situational and contextual circumstances (Lee, 1993);
- intrusion into private, intimate spheres and deep personal experience (Lee and Renzetti, 1993, p. 5), for example, sexual behaviour, religious practices, death and bereavement, even income and age;
- potential sanction, risk or threat of stigmatization, incrimination, costs or career loss to the researcher,

participants or others, for example, groups and communities (Lee and Renzetti, 1993; Renzetti and Lee, 1993; De Laine, 2000), a particular issue for the researcher who studies human sexuality and who, consequently, suffers from 'stigma contagion', i.e. sharing the same stigma as those being studied (Lee, 1993, p. 9);

- impingement on political alignments (Lee, 1993);
- penetration of personal defences, be they of the researched or the researcher (Dickson-Swift *et al*., 2006, 2007, 2008, 2009; Fahie, 2014);
- cultural and cross-cultural factors and inhibitions (Sieber, 1992, p. 129; Tillman, 2002);
- fear of scrutiny and exposure (Payne *et al*., 1980);
- threat to the researcher and to the family members and associates of those studied (Lee, 1993); Lee suggests that 'chilling' may take place, i.e. where researchers are 'deterred from producing or disseminating research' because they anticipate hostile reactions from colleagues, for example, on race or ethnicity (p. 34). 'Guilty knowledge' may bring personal and professional risk from colleagues (De Laine, 2000, p. 67; see also Dickson-Swift *et al*., 2008); it is threatening both to researchers and participants (ibid., p. 84);
- methodologies and conduct, for example, when junior researchers conduct research on powerful people, when men interview women, when senior politicians are involved, and where access and disclosure are difficult (Simons, 1989; Ball, 1990, 1994a; Liebling and Shah, 2001; Walford, 2012).

Sometimes all, or nearly all, of the issues listed above are present simultaneously. Indeed what starts as seemingly innocuous research can turn out to be sensitive (McCosker *et al*., 2001).

In some situations the very activity of actually undertaking educational research per se may be sensitive. This has long been the situation in totalitarian regimes, where permission has typically had to be granted by senior government officers and departments in order to undertake educational research. Closed societies may only permit educational research on approved, typically non-sensitive and comparatively apolitical topics. As Lee (1993, p. 6) suggests: 'research for some groups … is quite literally an anathema'. The very *act* of doing the educational research, regardless of its purpose, focus, methodology or outcome, is itself a sensitive matter (Morrison, 2006). In this situation the conduct of educational research may hinge on interpersonal relations, local politics and micro-politics. What start as being simply methodological issues can turn out to be ethical and political/micro-political minefields.

Lee (1993, p. 4) suggests that sensitive research falls into three main areas: (a) intrusive threat (probing into areas which are 'private, stressful or sacred'); (b) studies of deviance and social control, i.e. which could reveal information that could stigmatize or incriminate (threat of sanction); and (c) political alignments, revealing the vested interests of 'powerful persons or institutions, or the exercise of coercion or domination', or extremes of wealth and status (Lee, 1993). As Beynon (1988, p. 23) says, 'the rich and powerful have encouraged hagiography, not critical investigation'.

Lee (1993, p. 8) argues that there has been a tendency to 'study down' rather than 'study up', i.e. to direct attention to powerless rather than powerful groups, not least because these are sometimes easier and less sensitive to investigate. Sensitive educational research can act as a voice for the weak, the oppressed, those without a voice or who are not listened to; equally it can focus on the powerful and those in high-profile positions.

The three kinds of sensitivities indicated above, (a), (b) and (c), may appear separately or in combination. The sensitivity concerns not only the topic itself, but, often more importantly, 'the relationship between that topic and the social context' within which the research is conducted (Lee, 1993, p. 5). What appears innocent to the researcher may be highly sensitive to the researched or to other parties. Threat is a major source of sensitivity; indeed Lee (p. 5) suggests that, rather than generating a list of sensitive topics, it is more fruitful to look at the conditions under which 'sensitivity' arises within the research process. Given this issue, the researcher will need to consider how sensitive the educational research will be, not only in terms of the subject matter itself, but also in terms of the several parties that have a stake in it, for example: headteachers/principals and senior staff; parents; students; schools; governors; local politicians and policy makers; the researcher(s) and research community; government officers; the community; social workers and school counsellors; sponsors and members of the public; members of the community being studied; and so on.

Sensitivity inheres both in the educational topic under study, but also, much more significantly, in the social context in which the educational research takes place and on the likely consequences of that research on all parties. Doing research is not only a matter of designing a project and collecting, analysing and reporting data – that is the optimism of idealism or ignorance; it is also a matter of interpersonal relations, potentially continual negotiation, delicate forging and sustaining of relationships, setbacks, modification and

compromise. In an ideal world educational researchers would be able to plan and conduct their studies untrammelled; however, this typically does not happen in the real world, and sensitive educational research exposes this very clearly. Whilst most educational research will incur sensitivities, the benefit of discussing sensitive research per se is that it highlights what these delicate issues might be and how they might be felt at their sharpest. We advise readers to consider most educational research as sensitive, to anticipate what those sensitivities might be and what trade-offs might be necessary.

13.3 Sampling and access

Lee (1993, p. 60) suggests that there are potentially serious difficulties in sampling and access in sensitive research, not least because of the problem of estimating the size of the population from which the sample is to be drawn, as members of particular groups, for example, deviant or clandestine groups, will not want to disclose their associations. Similarly, like-minded groups may not wish to open themselves to public scrutiny. They may have much to lose by revealing their membership and, indeed, their activities may be illicit, critical of others, unpopular, threatening to their own professional security, deviant and less frequent than activities in other groups, making access a major obstacle. What if a researcher is researching truancy, or teenage pregnancy, or bullying, or solvent abuse among school students, or alcohol and medication use among teachers, or family relationship problems brought about by stress in teaching?

Lee (1993) suggests several strategies to be used (p. 61), either separately or in combination, for sampling 'special' populations (e.g. rare or deviant populations):

- *List sampling*: looking through public domain lists of, for example, the recently divorced (though such lists may be more helpful to social researchers than, specifically, educational researchers).
- *Multi-purposing*: using an existing survey to reach populations of interest (though problems of confidentiality may prevent this from being employed).
- *Screening*: targeting a particular location and canvassing within it (which may require much effort for little return).
- *Outcropping*: going to a particular location where known members of the target group congregate or can be found (e.g. Humphreys' celebrated study of homosexual 'tearoom trade' in 1970); in education this may be a particular staffroom (for teachers), or meeting place for students. Outcropping risks bias, as there is no simple check for representativeness of the sample.
- *Servicing*: Lee (1993, p. 72) suggests that it may be possible to reach research participants by offering them some sort of benefit or service in return for their participation. Researchers must be certain that they really are able to provide the services promised.
- *Professional informants*: Lee (1993, p. 73) suggests these could be, for example, police, doctors, priests or other professionals. In education these may include social workers and counsellors. This may be unrealistic optimism, as these very people may be bound by terms of legal or ethical confidentiality or voluntary self-censorship (e.g. an AIDS counsellor, after a harrowing day at work, may not wish to continue talking to a stranger about AIDS counselling, or a social worker or counsellor may be constrained by professional confidentiality, or an exhausted teacher may not wish to talk about her teaching difficulties). Further, even if such people agree to participate, they may not know the full story (cf. Walford, 2012). Lee gives the example of drug users (p. 73), whose contacts with the police may be very different from their contacts with doctors or social workers, or, the corollary of this, the police, doctors and social workers may not see the same group of drug users.
- *Advertising*: though this can potentially reach a wide population, it may be difficult to control the nature of those who respond, in terms of representativeness or suitability (a particular issue in online research, e.g. surveys).
- *Networking*: this is akin to snowball sampling (see Chapter 12), where one set of contacts puts the researcher in touch with more contacts, who, in turn, put the researcher in touch with yet more contacts and so on. This is a widely used technique, though Lee (1993, p. 66) reports that it is not always easy for contacts to be passed on, as initial informants may be unwilling to divulge members of a close-knit community. On the other hand, Morrison (2006) reports that networking is a popular technique where it is difficult to penetrate a formal organization such as a school, if the gatekeepers (those who can grant or prevent access to others, e.g. the headteacher or senior staff) refuse access. He reports the extensive use of informal networks by researchers, in order to contact friends and professional associates, and, in turn, their friends and professional associates, thereby sidestepping the formal lines of contact through schools.

Hammersley and Atkinson (1983, p. 54) suggest that gaining access is a practical matter and it provides insights into the 'social organisation of the setting'. Walford (2001, p. 33, 2012) argues that gaining access and becoming accepted is a slow process. He sets out a four-stage process of gaining access (2001, pp. 36–47):

Stage 1: *Approach* (gaining entry, perhaps through a mutual friend or colleague – a link person). Walford cautions that an initial letter should only be used to gain an initial interview or an appointment, or even to arrange to telephone the headteacher in order to arrange an interview, not to conduct the research or to gain access.
Stage 2: *Interest* (using a telephone call to arrange an initial interview). Here Walford notes (p. 43) that headteachers may like to talk, and so it is important to let them talk, even on the telephone when arranging an interview to discuss the research.
Stage 3: *Desire* (overcoming objections and stressing the benefits of the research). As Walford wisely comments (p. 44): 'after all, schools have purposes other than to act as research sites'. He makes the telling point that the research may actually benefit the school, but that the school may not realize this until it is pointed out. For example, a headteacher may wish to confide in a researcher; teachers may benefit from discussions with a researcher; students may benefit from being asked about their learning.
Stage 4: *Sale* (where the participants agree to the research).

Whitty and Edwards (1994, p. 22) argue that in order to overcome problems of access, ingenuity and even subterfuge could be considered: 'denied co-operation initially by an independent school, we occasionally contacted some parents through their child's primary school and then told the independent schools we already were getting some information about their pupils'. They also add that it is sometimes necessary for researchers to indicate that they are 'on the same side' as those being researched.[1] Indeed they report that 'we were questioned often about our own views, and there were times when to be viewed suspiciously from one side proved helpful in gaining access to the other' (p. 22). This harks back to Becker's (1967) advice to researchers to decide whose side they are on (cf. Hammersley, 2000).

The use of snowball sampling builds in 'security' (Lee, 1993), as the contacts are those who are known and trusted by the members of the 'snowball'. That said, this itself can lead to bias, as relationships between participants in the sample may consist of 'reciprocity and transitivity' (p. 67), i.e. participants may have close relationships with one another and may not wish to break these. Thus homogeneity of the sample's attributes may result.

Snowball sampling may alter the research, for example changing random, stratified or proportionate sampling into convenience sampling, thereby compromising generalizability or generating the need to gain generalizability by synthesizing many case studies. Nevertheless, it often comes to a choice between accepting non-probability strategies or doing nothing.

Issues of access to people in order to conduct sensitive research may require researchers to demonstrate a great deal of ingenuity and forethought in their planning. Investigators have to be adroit in anticipating problems of access, and set up their studies in ways that circumvent such problems and prevent them from arising in the first place, for example, by exploring their own institutions or personal situations, even if this compromises generalizability. Such anticipatory behaviour can lead to a glut of case studies, action research and accounts of their own institutions, as these are the only kinds of research possible, given the problem of access.

Gatekeepers

Access might be gained through gatekeepers, that is, those who control access. Lee (1993, p. 123) suggests that 'social access crucially depends on establishing *interpersonal trust*'. Gatekeepers play a significant role in research, particularly in ethnographic research (Miller and Bell, 2002, p. 53), as they control access and re-access (p. 55). They may provide or block access; they may steer the course of a piece of research, 'shepherding the fieldworker in one direction or another' (Hammersley and Atkinson, 1983, p. 65), or exercise surveillance over the research.

Gatekeepers may wish to avoid, contain, spread or control risk and therefore may bar access or make access conditional. Making research conditional may require researchers to change the nature of their original plans in terms of methodology, sampling, focus, dissemination, reliability and validity, reporting and control of data (Morrison, 2006). Morrison (2006) found that in conducting sensitive educational research, there were problems of:

- gaining access to schools and teachers;
- gaining permission to conduct the research (e.g. from school principals): resentment by principals;
- people vetting which data could be used;
- finding enough willing participants for the sample;

- schools/institutions/people not wishing to divulge information about themselves;
- schools/institutions not wishing to be identifiable, even with protections guaranteed;
- local political factors that impinged on the school/educational institution;
- teachers'/participants' fear of being identified/traceable, even with protections guaranteed (e.g. if they raised critical matters about the school or others they could lose their contracts);
- unwillingness of teachers to be involved because of their workload;
- the principal deciding on whether to involve the staff, without consulting the staff;
- schools' fear of criticism/loss of face or reputation;
- the sensitivity of the research – the issues being investigated;
- the power/position of the researcher (e.g. if the researcher is a junior or senior member of staff or an influential person in education).

Risk reduction may result in participants imposing conditions on research (e.g. on what information investigators may or may not use; to whom the data can be shown; what is 'public'; what is 'off the record' (and what should be done with off-the-record remarks)). It may also lead to surveillance/'chaperoning' of the researcher whilst the study is being conducted on site (Lee, 1993, p. 125).

Gatekeepers may want to 'inspect, modify or suppress the published products of the research' (Lee, 1993, p. 128). They may also wish to use the research for their own ends, i.e. their involvement may not be selfless or disinterested, or they may want something in return, for example, for the researcher to include in the study an area of interest to the gatekeeper, or to report directly – and maybe exclusively – to the gatekeeper. The researcher has to negotiate a potential minefield here, for example, not to be seen as an informer for the headteacher. As Walford (2001, p. 45) writes: 'headteachers [may] suggest that researchers observe certain teachers whom they want information about'. Researchers may need to reassure participants that their data will not be given to the headteacher.

On the other hand, Lee (1993, p. 127) suggests that the researcher may have to make a few concessions in order to be able to undertake the investigation, i.e. that it is better to do a little of the gatekeeper's bidding rather than not to be able to do the research at all (cf. Morrison, 2006).

In addition to gatekeepers, the researcher may find a 'sponsor' in the group being studied. A sponsor may provide access, information and support. A celebrated example of this is in the figure of 'Doc' in Whyte's classic study of *Street Corner Society* (1993; original study published 1943). Here Doc, a leading gang figure in the Chicago street corner society, is quoted as saying:

> You tell me what you want me to see, and we'll arrange it. When you want some information, I'll ask for it, and you listen. When you want to find out their philosophy of life, I'll start an argument and get it for you.… You won't have any trouble. You come in as a friend.
>
> (Whyte, 1993, p. 292)

As Whyte writes:

> My relationship with Doc changed rapidly.… At first he was simply a key informant – and also my sponsor. As we spent more time together, I ceased to treat him as a passive informant. I discussed with him quite frankly what I was trying to do, what problems were puzzling me, and so on … so that Doc became, in a real sense, a collaborator in the research.
>
> (Whyte, 1993, p. 301)

Whyte comments on how Doc was able to give him advice on how best to behave when meeting people as part of the research:

> Go easy on that 'who', 'what', 'why', 'when', 'where' stuff, Bill. You ask those questions and people will clam up on you. If people accept you, you can just hang around, and you'll learn the answers in the long run without even having to ask the questions.
>
> (Whyte, 1993, p. 303)

Indeed Doc played a role in the writing of the research: 'As I wrote, I showed the various parts to Doc and went over them in detail. His criticisms were invaluable in my revision' (p. 341). In his 1993 edition, Whyte reflects on the study with the question as to whether he exploited Doc (p. 362); it is a salutary reminder of the essential reciprocity that might be involved in conducting sensitive research.

In addressing issues of sampling and access, there are several points that arise from the discussion (Box 13.1).

Much research stands or falls on the sampling. Rather than barring the research altogether, compromises may have to be reached in sampling and access. It may be better to compromise rather than to abandon the research altogether.

BOX 13.1 ISSUES OF SAMPLING AND ACCESS IN SENSITIVE RESEARCH

- How to calculate the population and sample.
- How representative of the population the sample may or may not be.
- What kind of sample is desirable (e.g. random), but what kind may be the only sort that is practicable (e.g. snowball).
- How to use networks for reaching the sample, and what kinds of networks to utilize.
- How to research in a situation of threat to the participants (including the researcher).
- How to protect identities and threatened groups.
- How to contact the hard-to-reach.
- How to secure and sustain access.
- How to find and involve gatekeepers and sponsors.
- What to offer gatekeepers and sponsors.
- On what matters compromise may need to be negotiated.
- On what matters can there be no compromise.
- How to negotiate entry and sustained field relations.
- What services the researcher may provide.
- How to manage initial contacts with potential groups for study.

13.4 Ethical issues in sensitive research

A difficulty arises in sensitive research in that the researcher can be party to 'guilty knowledge' (De Laine, 2000) and have 'dirty hands' (Klockars, 1979) about deviant groups or members of a school who may be harbouring counter-attitudes to those prevailing in the school's declared mission. Pushed further, this means that the researcher will need to decide the limits of tolerance, beyond which he/she will not venture. For example, in Patrick's (1973) study of a Glasgow gang, the researcher is witness to a murder. Should he report the matter to the police and, thereby, 'blow his cover', or remain silent in order to keep contact with the gang, thereby breaking the law which requires a murder to be reported?

In interviewing students, they may reveal sensitive matters about themselves, their family or their teachers, and the researcher will need to decide whether and how to act on this kind of information. What should the researcher do, for example, if, during the course of an interview with a teacher about the leadership of the headteacher, the interviewee indicates that the headteacher has had sexual relations with a parent, or has an alcohol problem? Does the researcher, in such cases, do nothing in order to gain research knowledge, or does he act? What is in the public interest – the protection of an individual participant's private life, or the interests of the researcher? Indeed Lee (1993, p. 139) suggests that some participants may even deliberately engineer situations whereby the researcher gains 'guilty knowledge' in order to test the researcher's affinities: 'trust tests'.

Ethical issues are thrown into sharp relief in sensitive educational research. The question of covert research rises to the fore, as the study of deviant or sensitive situations may require the researcher to go under cover in order to obtain data. Access is often a serious problem in educational and social research (Munro *et al*., 2004, p. 295), particularly if such access is controlled by powerful people (Morrison, 2006). Powerful gatekeepers may control several aspects of participants' lives (Munro *et al*., 2004, p. 302) such as promotion, in-service training and work allocations, and it may be necessary to consider covert research or deception. Covert research may overcome 'problems of reactivity' (Lee, 1993, p. 143), wherein the research influences the behaviour of the participants (Hammersley and Atkinson, 1983, p. 71). Deception, though questioned in codes of practice for educational research (see Chapter 7), is not ruled out in these same codes, and there may be cases where the violation of informed consent, or telling lies, or not disclosing that one is conducting research, may be considered to be justified in order to obtain data on honest, natural behaviours, views or practices. If a researcher seeks the informed consent of violent teachers to study their violent behaviour, is there any real likelihood that the research will actually take place, whereas if one asks permission to study the behaviour of the students in their class, and keeps quiet about the real purpose which is to study violent teachers, is it more likely that access will be granted? And yet, surely, it is important in the interests of the

students, the school, even the violent teacher themselves, that the problem be exposed and be evidence-based?

Covert research or deliberate deception may also enable the researcher to obtain insiders' true views, for, without the cover of those being researched not knowing that they are being studied, entry could easily be denied, and access to important areas of understanding could be lost. This is particularly so in the case of researching powerful people who may not wish to disclose information and who, therefore, may prevent or deny access. The ethical issue of informed consent, in this case, is violated in the interests of exposing matters that are in the public interest.

To the charge that this is akin to spying, Mitchell (1993, p. 46) makes it clear that there is a vast difference between covert research and spying:

- Spies, he argues, seek to further a particular value system or ideology; research seeks to understand rather than to persuade.
- Spies have a sense of mission and try to achieve certain instrumental ends, whereas research has no such specific mission.
- Spies believe that they are morally superior to their subjects, whereas researchers have no such feelings; indeed, with reflexivity being so important, they are sensitive to how their own role in the investigation may distort the research.
- Spies are supported by institutions which train them to behave in certain ways of subterfuge, whereas researchers have no such training.
- Spies are paid to do the work, whereas researchers often operate on a not-for-profit or individualistic basis.

On the other hand, not to gain informed consent could lead to participants feeling duped, very angry, used and exploited when the results of the research are eventually published and they realize that they have been studied without their approval or informed consent.[2] The researcher is seen as a predator (Lee, 1993, p. 157), using the research 'as a vehicle for status, income or professional advancement which is denied to those studied'. As Lee remarks (p. 157), 'it is not unknown for residents in some ghetto areas of the United States to complain wryly that they have put dozens of students through graduate school'. Further, the researched may: have no easy right of reply; feel misrepresented by the research; feel that they have been denied a voice; have wished not to be identified and their situation put into the public arena; feel that they have been exploited.

The cloak of anonymity is often vital in sensitive research, such that respondents are entirely untraceable. This raises the issue of 'deductive disclosure' (Boruch and Cecil, 1979), wherein it is possible to identify the individuals (people, schools, departments, etc.) in question by reconstructing and combining data. Researchers should guard against this possibility. Where the details that are presented could enable identification of a person (e.g. in a study of a school there may be only one male teacher aged fifty who teaches biology, such that putting a name is unnecessary, as he will be identifiable), it may be incumbent on the researcher not to disclose such details, so that readers, even if they wished to reassemble the details in order to identify the respondent, are unable to do so.

The researcher may wish to preserve confidentiality and non-traceability, but may also wish to be able to gather data from individuals on more than one occasion. In this case a 'linked file' system (Lee, 1993, p. 173) can be employed. Here three files are kept; in the first file the data are held and arbitrary numbers are assigned to each participant; the second file contains the list of respondents; the third file contains the list information necessary to be able to link the arbitrarily assigned numbers from the first file to the names of the respondents in the second, and this third file is kept by a neutral 'broker', not the researcher. This procedure is akin to double-blind clinical experiments, in which the researcher does not know the names of those who are or are not receiving experimental medication or a placebo. That this may be easier in respect of quantitative rather than qualitative data is acknowledged by Lee (1993, p. 179).

Clearly, in some cases, it is impossible for individual people, schools and departments not to be identified, for example, schools may be highly distinctive and, therefore, identifiable (Whitty and Edwards, 1994, p. 22). In such cases clearance may need to be obtained for the disclosure of information. This is not as straightforward as it may seem. For example, a general principle of educational research is that no individuals should be harmed (non-maleficence), but what if a matter that is in the legitimate public interest is brought to light (e.g. a school's failure to keep to proper accounting procedures)? Should the researcher follow up the matter privately, publicly or not at all? If it is followed up then certainly harm may come to the school's officers.

Ethical issues in the conduct of research are thrown into sharp relief against a backdrop of personal, institutional and societal politics, and the boundaries between public and private spheres are not only relative but ambiguous. The ethical debate is heightened, for example in the potential tension between the individual's right to privacy versus the public's right to know,

and the concern not to damage or harm individuals versus the need to serve the public good. Because public and private spheres may merge, it is difficult, if not impossible, to resolve such tensions straightforwardly (cf. Day, 1985; Lee, 1993). As Walford (2001, p. 30) writes: 'the potential gain to public interest … was great. There would be some intrusion into the private lives of those involved, but this could be justified in research on … an important policy issue'. The end justified the means.

These issues are felt most sharply if the research risks revealing negative findings. To expose practices to research scrutiny may be like taking the plaster off an open wound (Wood, 1980). What responsibility to the research community does the researcher have? If a negative research report is released, will schools retrench, preventing future research in schools from being undertaken (a particular problem if the researcher wishes to return or wishes not to prevent further researchers from gaining access)? Whom is the researcher serving – the public, the schools, the research community? The sympathies of the researcher may be called into question here; politics and ethics may be uncomfortable bedfellows in such circumstances. Research data, such as the negative hidden curriculum of training for conformity in schools (Morrison, 2009) may not endear researchers to schools.

This can risk stifling educational research – it is simply not worth the personal or public cost. As Simons (2000, p. 45) says: 'the price is too high'.

Further, Mitchell (1993) writes that adhering to privacy may lead to 'timorous social scientists' excusing themselves from risks associated with confronting powerful people, the privileged and self-protecting groups who may not wish to disclose their actions to the scrutiny of the public (p. 54) (see also Lee, 1993, p. 8). Researchers may not wish to risk offending the powerful or placing themselves in uncomfortable situations. As Simons and Usher (2000, p. 5) remark: 'politics and ethics are inextricably entwined'.

In private, students and teachers may criticize their own schools, for example, in terms of management, leadership, work overload and stress, but they may be reluctant to do so in public, and indeed teachers who are on renewable contracts will not bite the hand that feeds them; they may say nothing rather than criticize (Burgess, 1993a; Morrison, 2002b).

The field of ethics in sensitive research may be different from ethics in everyday research, in significance rather than range of focus. The same issues faced in all educational research are addressed here, and we advise readers to review Chapter 7 on ethics. However, sensitive research highlights particular ethical issues very sharply, as presented in Box 13.2.

These are only introductory issues. We refer the reader to Chapter 7 for further discussion of these and other ethical issues. The difficulty with ethical issues is that they are 'situated' (Simons and Usher, 2000), i.e. contingent on specific local circumstances and situations. They have to be negotiated and worked out in

BOX 13.2 ETHICAL ISSUES IN SENSITIVE RESEARCH

- How does the researcher handle 'guilty knowledge' and 'dirty hands'?
- Whose side is the researcher on? Does this need to be disclosed? What if the researcher is not on the side of the researched?
- When are covert research or deception justified?
- When is the lack of informed consent justified?
- Is covert research spying?
- How should the researcher overcome the charge of exploiting the participants (i.e. treating them as objects instead of as subjects of research)?
- How should the researcher address confidentiality and anonymity?
- How should the balance be struck between the individual's right to privacy and the public's right to know?
- What is really in the public interest?
- How to handle the situation where it is unavoidable to identify participants?
- What responsibility does the researcher have to the research community, some of whom may wish to conduct further research in the field?
- How does the researcher handle frightened or threatened groups who may reveal little?
- What protections are in the research, for whom, and from what?
- What obligations does the researcher have?

relation to the specifics of the situation; universal guidelines may help but they don't usually solve the practical problems; they have to be interpreted locally.

13.5 Effects of sensitive research on the researcher

Sensitive research can take its toll on several parties: those who are being researched, researchers, transcribers, supervisors, examiners and, indeed, readers (Dickson-Swift *et al*., 2007, 2008, 2009; McCosker *et al*., 2001; Fahie, 2014). Here the earlier definition from Lee (1993) as that 'which potentially poses a substantial threat to those who are involved or have been involved in it' (p. 4) applies not only to those being researched but to other parties who might be affected by the research. Fahie (2014), for example, reporting a study of workplace bullying in primary schools, notes the potential risk to the researcher here, commenting that one research participant managed to obtain the personal contact details of the researcher and telephoned him some 40–50 times over the course of one year, intruding into his personal life.

Let us say that the researcher is faced by a teenager who sobs uncontrollably when recounting her genuinely dreadful account of childhood abuse, which really touches the researcher, the transcriber of the research interview (Dickson-Swift *et al*., 2007) and indeed the reader? Can they or should they show or not some kind of empathy, indeed can they prevent themselves from having and showing a deep emotional reaction? Emotional and cognitive actions and reactions are not as separable as we might find convenient (e.g. Dickson-Swift *et al*., 2007, 2008, 2009; Fahie, 2014), and indeed research is often an emotional experience.

Researching sensitive topics can be regarded as 'emotion work', i.e. that kind of activity which involves the management of emotions as an important element of work (in this case, of educational research) (Dickson-Swift *et al*., 2009; Hochschild, 2012). This typically includes work which involves much face-to-face or voice-to-voice interaction, particularly with those who are external to the organization as well as those who are internal to it, and which requires workers to produce an emotional state in others whilst managing their own emotions (p. 63).

As emotion workers, researchers have to manage their own emotions, yet emotions are fundamental to being human, and this poses a challenge: should the researcher remain emotionally relatively aloof and distant from the person, say, being interviewed, in order to maintain scientific or researcher objectivity, or should they allow their own emotions to be part of the process of, say, interviewing? Should they hold back or show their emotions? Indeed is it really possible to hold back if one is moved to tears? Researchers may not be able to stop themselves here, but is this acceptable (Dickson-Swift *et al*., 2007, 2008, 2009; Fahie, 2014)?

There are different responses to this: some would argue that it is perfectly acceptable for researchers to show their emotions, not least as, being perhaps coldly instrumental, this might stimulate an even richer response from those being researched. Further, it is important to respond to a research participant in human terms, and if this means not holding back the researcher's tears, anger or sadness, then so be it; as Ely *et al*. (1991) remark, if researchers are to study humans, then they have to be ready to 'face human feelings' (p. 49) and respond to the research participants as human beings, not robots, would respond.

When researching sensitive topics, natural empathy might establish a bond, a connection or rapport, between the researcher and the researched. Such reciprocity recognizes the essential humanity of a human situation (Dickson-Swift *et al.*, 2009). Indeed, when researching the marginalized and vulnerable, the research might be the only opportunity that they have had to tell their story to anyone, and for the researcher to show his/her emotional involvement here might support the catharsis that such participant disclosure might value (Dickson-Swift *et al.*, 2007).

By contrast, others would argue that for the researcher to introduce his or her own emotions onto an already emotionally charged, intense situation is somehow unworthy, improper, unscientific and a threat to rigour, sending inappropriate signals to the person being researched (or indeed even to his or her academic colleagues (Dickson-Swift *et al*., 2009)) and that any emotions should be held in check at least until after the encounter.

At issue here is the recognition that doing sensitive, emotionally charged research exacts its price on researchers (Dickson-Swift *et al*., 2007, 2008, 2009; Fahie, 2014). For example they may:

- feel emotionally and physically exhausted, become emotionally hardened and desensitized, for example, no longer able to be shocked;
- experience insomnia, nightmares, permanent tiredness and depression;
- feel guilty or angry in reporting but not taking action to alleviate or remediate the participant's situation;
- feel guilty in having affected the research participant;
- feel vulnerable (to their own emotions or to learning something about themselves);

- feel a failure or frustrated in not having managed to control their own emotions or not having maintained boundaries between themselves and the participants and becoming too friendly or empathetic;
- feel guilty at having entered intimately into the lives of others and then leaving them, i.e. a breach of trust, using others as a means to an end;
- feel that the establishing of rapport, indeed friendship, was somehow deceitful, for obtaining data only, again using others as a means to an end;
- feel that the research participants may not want to hear the self-disclosures of the researchers, as this could burden them even more;
- feel that they have let themselves down in breaching their own intention of not being too empathetic or emotional in the research situation (e.g. in an interview);
- have blurred the distinction between research and therapy;
- have failed to protect the research participants;
- feel that they, as keepers of secrets and private, privileged information, have betrayed the trust of the research participant. (Dickson-Swift *et al*. (2007) liken the trust and keeping of secrets to a religious confessional, thereby offending their own conscience.)

Dickson-Swift *et al*. (2007) note that, for some researchers, undertaking sensitive research can become a life-changing experience (p. 342) or an intense emotional, even traumatic encounter. Fahie (2014) illustrates this well, commenting on an interviewee recounting her story of being bullied by a school principal:

> Watching her cry in her own sitting room, listening to her describe the ritual humiliation she encountered in her place of work, and seeing her hands shake as she recalled the vitriolic abuse at the hands of her school principal, impacted upon me deeply by drawing me into the narrative. And I felt angry … the sheer injustice of it and unfairness of her experiences disturbed me profoundly, as did my own inability to 'make it better'. This impotence made me feel frustrated and helpless, as if, in some way, I had left Ann down.
>
> (Fahie, 2014, p. 25)

Here it is not enough simply to state that, ethically speaking, the research must not leave the participants worse off than before the research; rather it is to say that, in addressing sensitive research, care has to be given to support the researchers as well, even as a matter of Health and Safety requirements, both physically and psychologically, be this through, for example, counselling and support staff and services, peer support, mentoring and supervision, security services, social support or suchlike (McCosker *et al*., 2001). In this respect, ethics committees should also consider the possible effects of the research on all parties involved, including often-overlooked parties such as researchers, supervisors, transcribers and other members of the contact circle of those being researched.

McCosker *et al.* (2001) and Fahie (2014) also give practical advice for researchers conducting sensitive research, including: non-disclosure of personal details and personal contact details; conducting interviews in public places and informing another party of the likely starting and finishing times; checking the environment before agreeing the location of the interview; using a different SIM card from one's main SIM card in cellphone conversations with research participants; keeping a record of the time, place and duration of the interview; discussing and conducting debriefings on the research with a mentor and/or supervisor; closely monitoring the emotional impact of the research on the participants; consider spacing out the timing of interviews and the subsequent listening to recordings of interviews on sensitive topics, for example, only a limited number per week, in order to enable researchers not to be emotionally overwhelmed by, or desensitized by, emotionally charged interviews.

13.6 Researching powerful people

A branch of sensitive research concerns that which is conducted on, or with, powerful people, those in key positions, or elite institutions. In education, for example, this could include headteachers/principals and senior teachers, politicians, senior civil servants, decision makers, local authority officers and school governors. This is particularly the case in respect of research on policy and leadership issues (Walford, 1994a, p. 3, 2012). Researching the powerful is an example of 'researching up' rather than the more conventional 'researching down' (e.g. researching children, teachers, student teachers).

What makes the research sensitive is that it is often dealing with key issues of policy generation and decision making, or issues about which there are high-profile debate and contestation, or issues of a politically sensitive nature. Policy-related research is sensitive. This can also be one of the reasons why access is frequently refused. The powerful are those who exert control to secure what they want or can achieve, those with great responsibility and whose decisions have

significant effects on large numbers of people. Indeed they have considerable power in blocking access for researchers, thereby stopping the research, particularly if the issue is controversial or sensitive (e.g. contested fiercely by various parties) (Walford, 2012, p. 112).

Academic educational research on the powerful may be unlike other forms of educational research in that confidentiality may not be able to be assured. The participants are identifiable and public figures. This may produce 'problems of censorship and self-censorship' (Walford, 1994c, p. 229). It also means that information given in confidence and 'off the record' unfortunately may have to remain so. One issue raised in researching the powerful is the disclosure of identities, particularly if it is unclear what has been said 'on the record' and 'off the record' (Fitz and Halpin, 1994, pp. 35–6).

Fitz and Halpin (1994) indicate that the government minister whom they interviewed stated, at the start of the interview, what was to be attributable. They also report that they used semi-structured interviews in their research of powerful people, valuing both the structure and the flexibility of this type of interview, and that they gained permission to record the interviews for later transcription, for the sake of a research record. They also used two interviewers for each session, one to conduct the main part of the interview and the other to take notes (p. 47) and ask supplementary questions, helping to negotiate the way through the interview in which advisers to the interviewee were also present to monitor the proceedings and interject where it was deemed fitting (p. 44). Having two interviewers present also enabled a post-interview cross-check to be undertaken.

Fitz and Halpin comment on the considerable amount of gatekeeping that was present in researching the powerful (p. 40), in terms of access to people (with officers guarding entrances and administrators deciding whether interviews will take place), places ('élite settings'), timing (and scarcity of time with busy respondents), 'conventions that screen off the routines of policy-making from the public and the academic gaze' (p. 48), conditional access and conduct of the research ('boundary maintenance'; p. 49), monitoring and availability. Gewirtz and Ozga (1994, pp. 192–3) suggest that gatekeeping in researching the powerful can produce difficulties which include 'misrepresentation of the research intention, loss of researcher control, mediation of the research process, compromise and researcher dependence'.

Research with powerful people usually takes place on their territory, under their conditions and agendas (a 'distinctive civil service voice'; Fitz and Halpin, 1994, p. 42), working within discourses set by the powerful (and, in part, reproduced by the researchers; p. 40), and with protocols concerning what may or may not be disclosed (e.g. under a government's Official Secrets Act or privileged information), within a world which may be unfamiliar and, thereby, disconcerting for researchers and with participants who may be overly assertive, sometimes making the researcher have to pretend to know less than he or she actually knows. As Fitz and Halpin (1994, p. 40) commented: 'we glimpsed an unfamiliar world that was only ever partially revealed', and one in which they did not always feel comfortable. Similarly, Ball (1994b, p. 113) suggests that 'we need to recognize … the interview as an extension of the "play of power" rather than separate from it, merely a commentary upon it', and that, when interviewing powerful people, 'the interview is both an ethnographic … and a political event'. As Walford remarks:

> Those in power are well used to their ideas being taken notice of. They are well able to deal with interviewers, to answer and avoid particular questions to suit their own ends, and to present their own role in events in a favourable light. They are aware of what academic research involves, and are familiar with being interviewed and having their words tape-recorded. In sum, their power in the educational world is echoed in the interview situation, and interviews pose little threat to their own positions.
>
> (Walford, 1994c, p. 225)

McHugh (1994) comments that access to powerful people may take place not only through formal channels but through intermediaries who introduce researchers to them (p. 55). Here his own vocation as a priest helped him to gain access to powerful Christian policy makers and, as he was advised, 'if you say whom you have met, they'll know you are not a way-out person who will distort what they say' (p. 56). Access is a significant concern in researching the powerful, particularly if the issues being researched are controversial or contested (Walford, 2012).

Access may be difficult, because the very person whom the researcher wishes to meet may be busy or constrained by what he or she may or may not disclose, and the whole point of the meeting is to meet that particular person and not a substitute (cf. Walford, 2012, p. 115). Walford (1994c, p. 222) suggests that access can be eased through informal and personal 'behind the scenes' contacts: 'the more sponsorship that can be obtained, the better' (p. 223), be it institutional or personal. As he also remarks: '[o]ne obvious way of easing access is exploiting pre-existing links with those in power' (Walford, 2012, p. 112). Access can also be eased if the research is seen to be 'harmless' (p. 112); here he reports that female researchers may be at an advantage in that they are

viewed as more harmless and non-threatening (p. 112), particularly, he avers, if they are relatively young and not in a senior position in their own institution (though he also notes research which suggests that a female may not be 'taken as seriously as a male researcher'; p. 112). He also notes that gaining access to powerful people who have retired is easier than those who are still in office (p. 112), though the researcher would have to exercise caution here as the person may be seeking to 'write themselves into history' (p. 112). Walford (1994c) also makes the point that 'persistence pays' (p. 224); as he writes elsewhere (Walford, 2012, p. 115), 'access is a process rather than a one-off decision'.

McHugh (1994) reports the need for meticulous preparation for an interview with the powerful person, to understand the full picture and to be as fully informed as the interviewee, in terms of facts, information and terminology, so that it is an exchange between the informed rather than an airing of ignorance, i.e. to do one's homework. He also states the need for the interview questions to be thoroughly planned and prepared, with very careful framing of questions. He suggests (p. 60) that during the interview it is important for the interviewer to be as flexible as possible, to follow the train of thought of the respondent, but also to be persistent (p. 62) if the interviewee does not address the issue. However, he reminds us that 'an interview is of course not a courtroom' (p. 62) and so tact, diplomacy and – importantly – empathy are essential. Diplomacy in great measure is necessary when tackling powerful people about issues that might reveal their failure or incompetence, and powerful people may wish to control which questions they answer. Preparation for the conduct as well as the content of the interview is vital by the researcher, for example, the researcher must know the policies very fully and exactly, and not be intimidated by the power of the interviewee (Walford, 2012, p. 113). Further, powerful people, like other interviewees, may not answer questions fully; they may talk blandly or off the point, i.e. with their own agendas, as this may be typical of their usual, often required practice in office (Walford, 2012, p. 113), so the researcher has to ensure that they keep the interview on track, i.e. on their (the researcher's) agenda.

There are difficulties in reporting sensitive research with the powerful, as charges of bias may be difficult to avoid, not least because research reports and publications are placed in the public domain. Walford (2001, p. 141) indicates the risk of libel actions if public figures are named. He asks (1994b, p. 84), 'to what extent is it right to allow others to believe that you agree with them' even if you do not? Should the researcher's own political, ideological or religious views be declared? As Mickelson (1994, p. 147) states: 'I was not completely candid when I interviewed these powerful people. I am far more genuine and candid when I am interviewing non-powerful people'. Deem (1994, p. 156) reports that she and her co-researcher encountered 'resistance and access problems in relation to our assumed ideological opposition to Conservative government education reforms', where access might be blocked 'on the grounds that ours was not a neutral study'.

Mickelson (1994, p. 147) takes this further in identifying an ethical dilemma when 'at times, the powerful have uttered abhorrent comments in the course of the interview'. Should the researcher say nothing, thereby tacitly condoning the speaker's comments, or speak out, thereby risking closing the interview? She contends that, in retrospect, she wished that she had challenged these views and been more assertive (p. 148). She believes that the researcher should challenge different viewpoints, if necessary confrontationally, but this is a high-risk strategy, as the powerful person may simply terminate the interview. Walford (2001) reports the example of an interview with a church minister whose views included ones with which he disagreed:

> AIDS is basically a homosexual disease … and is doing a very effective job of ridding the population of undesirables. In Africa it's basically a non-existent disease in many places.… If you're a woolly woofter, you get what you deserve.… I would never employ a homosexual to teach at my school.
>
> (p. 137)

In researching powerful people Mickelson (1994, p. 132) observes that they are seldom women, yet researchers are often women. This gender divide might prove problematic. Deem (1994, p. 157) reports that, as a woman, she encountered greater difficulty in conducting research than did her male colleague, even though, in fact, she held a more senior position than him. On the other hand, she reports that males tended to be more open with female than male researchers, as female researchers were regarded as less important. Gewirtz and Ozga (1994) report that

> we felt [as researchers] that we were viewed as women in very stereotypical ways, which included being seen as receptive and supportive, and that we were obliged to collude, to a degree, with that version of ourselves because it was productive of the project.
>
> (p. 196)

Walford (2012) notes that, in reality, researching powerful people, approached for whom they are or for the positions that they hold or have held (p. 114), is little different from researching any other people,

except that access may be more problematic, and gaining reliable data may be more challenging. This also means that, unlike other research participants, it is unlikely that anonymity can be offered, indeed the powerful person may insist on being identified.

In approaching researching powerful people, then, it is wise to consider several issues. These are set out in Box 13.3.

13.7 Researching powerless and vulnerable people

Researching powerless people is also a sensitive matter, not least, as Munro *et al*. (2004, p. 299) point out, it is important not to add to their powerlessness. This also applies to vulnerable people: those who are unable to protect their own interests and who may suffer from negative labelling, stigmatization, exclusion or discrimination. (The great claim of participatory research is that it empowers otherwise powerless groups (Healy, 2001; see also Chapter 3).) Powerless people are easily negatively stereotyped and stigmatized (Fiske, 1993; Munro *et al*., 2004), for example: the poor, the unemployed, the homeless, travellers, the disabled, the psychologically disturbed, those with learning difficulties, minority groups, non-heterosexuals, females (Skelton *et al*., 2006) etc.

In conducting research it is important not to add to the disempowerment of already disempowered groups; indeed it may be important actively to promote their empowerment or not to leave them in the condition in which contact was first made (Munro *et al*., 2004, p. 299). (Hammersley (2002, 2014) explores this issue of 'partisan research'; see Chapter 3.)

What does the researcher do, for example, if she finds that women are 'talking down' their own achievements, lives, capabilities or career prospects, such that they will not achieve? If she simply notes this and reports it then she could be seen as complicit in the oppression of women; if she decides not to report it then she could be seen as distorting the research; if she decides to challenge it with the women in question then she could be seen as coming out of the role of the neutral researcher and invading the research site, or indeed to be raising expectations that are not realistic (see also Chapter 3).

Powerless groups may well feel resentful of the well-dressed researcher (Munro *et al*., 2004), even if the researcher's intentions are honourable, or they may feel unable to disclose their true feelings and opinions for fear of bringing yet further negativity to their own situation. They may feel antagonized if interviews are conducted in well-kept surroundings which are very different from their own. Indeed for many, an interview may be the first occasion in their lives that they have experienced such an activity.

Children may well feel powerless and insecure in the presence of a researcher (Greig and Taylor, 1999) and may say what they feel the researcher wishes to hear, what is the school's view, what is socially desirable (p. 131). They may be too shy or embarrassed to reveal their true feelings or to say what really happened in a situation (e.g. child abuse). The researcher must be acutely sensitive to this, and must recognize her/his

BOX 13.3 RESEARCHING POWERFUL PEOPLE

- What renders the research sensitive?
- How to gain and sustain access to powerful people.
- How much are the participants likely to disclose or withhold?
- What is on and off the record?
- How to prepare for interviews with powerful people.
- How to probe and challenge powerful people.
- How, and whether to gain informed consent.
- Is the research overt or covert, with or without deceit?
- How to conduct interviews that balance the interviewer's agenda and the interviewee's agenda and frame of reference.
- How to reveal the researcher's own knowledge, preparation and understanding of the key issues.
- The status of the researcher vis-à-vis the participants.
- Who should conduct interviews with powerful people?
- How neutral and accepting the researcher should be with the participant.
- Whether to identify the participants in the reporting.
- How to balance the public's right to know and the individual's right to privacy.
- What is in the public interest?

own limitations in conducting such research on sensitive matters with vulnerable participants, if necessary handing over such interviews (and, for example, handling projection or displacement techniques) to trained professionals.

The setting for such interviews should be familiar to the children, non-threatening and designed to put them at their ease, to make the strange familiar (Morrison, 2013a), an inversion of Blumer's famous dictum of 'making the familiar strange'. Morrison (2013a) reports on the process of interviewing children (aged 8–9) in a constrained setting in which they were urged to attend interviews in their own out-of-school time and with relative strangers. The interviews were conducted to gather their opinions about a major school innovation brought in by the senior staff of the school and which was evaluated by university staff. Strong asymmetries of power and age were operating in the interviews. Here the interview situation was sensitive in many different ways, and many steps were taken to render them less sensitive and less threatening, indeed enjoyable for the children (discussed in Chapters 14 and 25).

Researchers can conduct honest, sympathetic research on the participants' home ground (as did researchers examining poverty in Hong Kong, who conducted structured interviews in the participants' own homes (Sequeira *et al*., 1996)). They must take care to avoid sounding condescending, patronizing, powerful, domineering or high-handed. This concerns non-verbal behaviour, dress and choice of language (such that it becomes inclusive rather than exclusive, yet without being contrived or artificial). As mentioned in Chapter 7, data are gifts, not entitlements. The researcher has to conduct the research with respect, affording dignity to the participants, whilst not necessarily making promises which cannot be kept (e.g. to change their situation).

The researcher studying powerless and vulnerable groups should be inclusive (i.e. to enable all members of the group in question to participate on an equal footing and to feel valued), and to abide by the ethical principles outlined in Chapter 7 (e.g. informed consent, privacy and confidentiality, recognition of participants' time and efforts, consultation, keeping participants informed, maintaining and concluding relationships, addressing their well-being, indicating any possible adverse effects of participation, ensuring the safety and well-being of researchers) (Connolly, 2003). Powerless participants might feel 'used' in educational research, not only providing data but advancing the careers of the researchers whilst leaving themselves disempowered (see Chapter 7 on 'rape research'). The researcher must avoid this.

Box 13.4 summarizes some key issues in researching powerless and vulnerable people.

BOX 13.4 RESEARCHING POWERLESS AND VULNERABLE GROUPS

- What renders the research sensitive?
- How to gain and sustain access to powerless and vulnerable people.
- How much are the participants likely to disclose or withhold?
- What is on and off the record?
- How to prepare for interviews with powerless and vulnerable people.
- Where will the interviews/data collection take place?
- How to probe powerless and vulnerable people.
- How to ensure non-maleficence and beneficence, dignity and respect.
- How to avoid further stigmatization, negative stereotyping, and marginalization of participants.
- How to act in the interests of the participants.
- How, and whether, to gain informed consent.
- Is the research overt or covert, with or without deceit?
- How to conduct interviews that balance the interviewer's agenda and the interviewee's agenda and frame of reference.
- How to reveal the researcher's own knowledge, preparation and understanding of the key issues.
- How to equalize status between the researcher and the participants.
- How to ensure inclusiveness of participants.
- Who should conduct interviews with powerless and vulnerable people?
- Does the researcher have the expertise to conduct interviews with the participants?
- What protections are there for the participants?
- Whether to identify the participants in the reporting.
- How to balance the public's right to know and the individual's right to privacy.
- What is in the public interest?

Many of the issues raised in considering researching powerful groups are identical to those raised in researching powerless and vulnerable groups (Boxes 13.3 and 13.4). This is deliberate, as both concern ethical, sensitive behaviour, and, though perhaps interpreted differently for the two groups, they apply equally powerfully to both. The Joseph Rowntree Foundation publishes ethical guidelines for researchers working with vulnerable, marginalized groups, powerless people and children.

13.8 Asking questions

Even though an anonymized questionnaire may give participants the freedom to respond in private, in depth and with honesty, and even though a face-to-face interview may be very threatening in connection with some sensitive issues, such that honest or complete answers may be unlikely, as a general rule, the more sensitive the research, the more important it is to conduct face-to-face interviews for data collection. In asking questions in research, Sudman and Bradburn (1982, pp. 50–1) suggest that open questions may be preferable to closed questions and long questions may be preferable to short questions. Both of these enable respondents to answer in their own words, which might be more suitable for sensitive topics. Indeed they suggest that whilst short questions may be useful for gathering information about attitudes, longer questions are more suitable for asking questions about behaviour, and can include examples to which respondents may wish to respond. Longer questions may reduce the under-reporting of the frequency of behaviour addressed in sensitive topics (e.g. the use of alcohol or medication by stressed teachers). On the other hand, the researcher has to be cautious to avoid tiring, emotionally exhausting or stressing the participant by a long questionnaire or interview.

Lee (1993, p. 78) advocates using familiar words in questions as these can reduce a sense of threat in addressing sensitive matters and help the respondent to feel more relaxed. He also suggests the use of 'vignettes' (p. 79): short portrayals of people or situations which contain what are considered to be the important or key factors which affect those people's judgements, decisions or behaviours (p. 79); scenes or short stories about situations or people that can be composed in picture, video, written or spoken formats (Hurworth, 2012, p. 179). These can be part of an interview.

Simon and Tierney (2011) and Hurworth (2012) note that vignettes may be useful in sensitive educational research such as bullying, abuse, assessment, mental health, moral and ethical dilemmas, as participants in the research can give their own reactions to, and accounts of, the positions that they take. They enable the researcher to ask questions about participants' reactions to the situation portrayed, what they would do next or what others might do next. Focusing the discussion away from the individual participant and onto the vignette can 'take the heat out of' the sensitive situation being proposed, i.e. depersonalize it (Hurworth, 2012, p. 179) and reduce the likelihood of receiving only socially desirable or defensive responses by making the sensitivity of the research more unobtrusive (Simon and Tierney, 2011). For example S. Martin (2012, 2013, 2015) shows how this might be undertaken in virtual worlds when exploring sensitive issues of citizenship.

Simon and Tierney (2011) and Hurworth (2012) suggest that vignettes should comprise:

- quite short situations and scenarios that are not only close to the research topic but are rooted in everyday real life or that take real-life examples;
- situations that are credible;
- ordinary everyday situations with which the research participants can connect straightforwardly;
- engaging and interesting age-appropriate and language-appropriate situations which strike a balance between overload of detail (and its resultant complexity) and providing sufficient detail to be interesting;
- deliberately incomplete situations so that there is the potential to enable participants to expand on the situation portrayed;
- characters and events that are relevant and interesting to the participants.

Simon and Tierney (2011) also note that it is important to pilot these for suitability (widely defined) before using them in the research. Vignettes can not only encapsulate concretely the issues under study, but can also deflect attention away from personal sensitivities by projecting them onto another external object – the case or vignette – and the respondent can be asked to react to them personally, for example, 'what would you do in this situation?'.

Researchers investigating sensitive topics have to be acutely percipient of the situation themselves. For example, their non-verbal communication may be critical in interviews. They must, therefore, give no hint of judgement, support or condemnation. They must avoid counter-transference (projecting the researchers' own views, values, attitudes, biases, background onto the situation). Interviewer effects are discussed in Chapter 25 in connection with sensitive research, for example:

- the characteristics of the researcher (e.g. sex, race, age, status, clothing, appearance, rapport, background, expertise, institutional affiliation, political affiliation, type of employment or vocation, e.g. a priest). Females may feel more comfortable being interviewed by a female; males may feel uncomfortable being interviewed by a female; powerful people may feel insulted by being interviewed by a lowly, novice research assistant;
- the expectations that the interviewers may have of the interview (Lee, 1993, p. 99). For example, a researcher may feel apprehensive about, or uncomfortable with, an interview about a sensitive matter. Bradburn and Sudman (1979, in Lee, 1993, p. 101) report that interviewers who did not anticipate difficulties in the interview achieved a 5–30 per cent higher level of reporting on sensitive topics than those who anticipated difficulties. This suggests the need for interviewer training.

Lee (1993, pp. 102–14) suggests several issues in conducting sensitive interviews:

- How to approach the topic (in order to prevent participants' inhibitions and to help them address the issue in their preferred way). Here the advice is to let the topic 'emerge gradually over the course of the interview' (p. 103) and to establish trust and informed consent.
- How to deal with contradictions, complexities and emotions (which may require training and supervision of interviewers); how to adopt an accepting and non-judgemental stance, how to handle respondents who may not be people whom interviewers particularly like or with whom they agree.
- How to handle the operation of power and control in the interview: (a) where differences of power and status operate: where the interviewer has greater or lesser status than the respondent and where there is equal status between the interviewer and the respondent; (b) how to handle the situation in which the interviewer wants information but is in no position to command that this be given and where the respondent may or may not wish to disclose information; (c) how to handle a situation wherein powerful people use the interview as an opportunity for lengthy and perhaps irrelevant self-indulgence; (d) how to handle the situation in which the interviewer, by the end of the session, has information that is sensitive and could give the interviewer power over the respondent and make the respondent feel vulnerable; (e) what the interviewer should do with information that may act against the interests of the people who gave it (e.g. if some groups in society say that they are not clever enough to handle higher or further education); and (f) how to conduct the interview (e.g. conversational, formal, highly structured, highly directed).
- Handling the conditions under which the exchange takes place (Lee, 1993, p. 112) suggests that interviews on sensitive matters should 'have a one-off character', i.e. the respondent should feel that the interviewer and the interviewee may never meet again. This can secure trust, and can lead to greater disclosure than in a situation where a closer relationship between interviewer and interviewee exists. On the other hand, this does not support the development of a collaborative research relationship (Lee, 1993, p. 113).

Much educational research is more or less sensitive; it is for the researcher to decide how to approach the issue of sensitivities and how to address their many forms, allegiances, ethics, access, politics and consequences.

13.9 Conclusion

Educational research is far from a neat, clean, tidy, unproblematic and neutral process; it is shot through with actual and potential sensitivities. With this in mind we have resisted the temptation to provide an exhaustive list of sensitive topics, as this could be simplistic and overlook the fundamental issue which is that it is the *social and individual context* of the research that makes the research sensitive. What may appear to the researcher to be a bland and neutral study can raise deep sensitivities in the minds of the participants. We have argued that it is these that often render the research sensitive rather than, or as well as, the selection of topics of focus. Researchers have to consider the likely or possible effects of the research project, conduct, outcomes, reporting and dissemination not only on themselves but on the participants, on those connected to the participants and on those affected by, or with a stakeholder interest in, the research (i.e. 'consequential validity': the effects of the research). This suggests that it is wise to be cautious and to regard all educational research as potentially sensitive. There are several questions that can be asked by researchers, in their planning, conduct, reporting and dissemination of their studies, and we present these in Box 13.5.

These questions reinforce the importance of regarding ethics as 'situated' (Simons and Usher, 2000), i.e. contingent on particular situations. In this respect sensitive educational research is like any other research, but

BOX 13.5 KEY QUESTIONS IN CONSIDERING SENSITIVE EDUCATIONAL RESEARCH

- What renders the research sensitive?
- What are the obligations of the researcher, to whom, and how will these be addressed? How do these obligations manifest themselves?
- What is the likely effect of this research (at all stages) to be on participants (individuals and groups), stakeholders, the researcher, the community? Who will be affected by the research, and how?
- Who is being discussed and addressed in the research?
- What rights of reply and control do participants have in the research?
- What are the ethical issues that are rendered more acute in the research?
- Over what matters in the planning, focus, conduct, sampling, instrumentation, methodology, reliability, analysis, reporting and dissemination might the researcher have to compromise in order to effect the research? On what can there be compromise? On what can there be no compromise?
- What securities, protections (and from what), liabilities and indemnifications are there in the research, and for whom? How can these be addressed?
- Who is the research for? Who are the beneficiaries of the research? Who are the winners and losers in the research (and about what issues)?
- What are the risks and benefits of the research, and for whom? What will the research 'deliver' and do?
- Should the researcher declare his/her own values, and challenge those with which he/she disagrees or considers to be abhorrent?
- What might be the consequences, repercussions and backlash from the research, and for whom?
- What sanctions might there be in connection with the research?
- What has to be secured in a contractual agreement, and what is deliberately left out?
- What guarantees must and should the researcher give to the participants?
- What procedures for monitoring and accountability must there be in the research?
- What must and must not, should and should not, may or may not, could or could not be disclosed in the research?
- Should the research be covert, overt, partially overt, partially covert, honest in its disclosure of intentions?
- Should participants be identifiable and identified? What if identification is unavoidable?
- How will access and sampling be secured and secure respectively?
- How will access be sustained over time?
- Who are the gatekeepers and how reliable are they?

sharper in the criticality of ethical issues. Also, behind many of these questions of sensitivity lurks the nagging issue of power: who has it, who does not, how it circulates around research situations (and with what consequences) and how it should be addressed. Sensitive educational research is often as much a power play as it is substantive. We advise researchers to regard educational research as involving sensitivities which need to be identified and addressed.

Notes

1 See also Walford (2001, p. 38) in his discussion of gaining access to public schools in the UK, where an early question that was put to him was, 'are you one of us?'.

2 Walford (2001, p. 69) comments on the very negative attitudes of teachers to research on independent schools in the UK, the teachers feeling that researchers had been dishonest and had tricked them, looking only for salacious, sensational and negative data on the school (e.g. on bullying, drinking, drugs, gambling and homosexuality).

Companion Website

The companion website to the book provides PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Validity and reliability

CHAPTER 14

This chapter discusses validity and reliability in educational research. It suggests that both of these terms can be applied to these different types of research, though how validity and reliability are applied to different approaches varies. The chapter proceeds in several stages:

- defining validity
- validity in quantitative, qualitative and mixed methods research
- types of validity
- triangulation
- ensuring validity
- reliability
- reliability in quantitative and qualitative research
- validity and reliability in interviews, experiments, questionnaires, observations, tests, life histories and case studies

There are many different types of validity and reliability. Threats to validity and reliability can never be erased completely; rather the effects of these threats can be attenuated by attention to validity and reliability throughout the research.

Reliability is a necessary but insufficient condition for validity in research; it is a necessary precondition of validity. Brock-Utne (1996, p. 612) contends that the widely held view that reliability is the sole preserve of quantitative research must be exploded, and this chapter demonstrates the significance of her view.

Validity and reliability have different meanings in quantitative, qualitative and mixed methods research. It is important not only to indicate these clearly, but to demonstrate fidelity to the approach in which the researcher is working and to abide by the required principles of validity and reliability. We address this here, locating different interpretations of validity and reliability within different paradigms. One of the purposes of the opening three chapters of this book was to indicate the multiplicity of paradigms. Hence our reference to quantitative and qualitative paradigms here is for simple, heuristic purposes to gain some leverage on the matters involved.

14.1 Defining validity

Validity is an important key to effective research. If a piece of research is invalid then it is worthless. Addressing validity concerns the nature of what is valid, what validity means, how to know if one has achieved an acceptable level of validity, how to address validity in research terms and how validity enters design, inferences and conclusions.

Some versions of validity regard it as essentially a demonstration that a particular instrument in fact measures what it intends, purports or claims to measure, that an account accurately represents 'those features that it is intended to describe, explain or theorise' (Winter, 2000, p. 1).

Other definitions state that validity is the extent to which interpretations of data are warranted by the theories and evidence used (Ary *et al*., 2002, p. 267). The issue of warrants was explored in Chapter 11, arguing that researchers must indicate the grounds and the evidence that they will use to connect their data with the claims made from, or conclusions drawn from, the data. A warrant, as Chapter 11 noted, is the logical link made between data and proposition, between data and conclusions (Andrews, 2003, p. 30), which supports the weight given to the explanation offered in the face of alternative, rival explanations. We advise the reader to review the discussion of warrants in Chapter 11. A piece of research is valid if the warrants that underpin it are defensible and, thereby, if the conclusions drawn and the explanations given can stand their ground in the face of rival conclusions and explanations; validity and warrants are linked intimately.

As researchers, we must be certain that our instruments for understanding phenomena are as sound as possible, i.e. that they are valid. This is particularly the case for abstract, unclearly or indirectly observable, theoretical constructs such as 'intelligence', 'creativity', 'anxiety', 'motivation', 'extraversion' and 'empathy', for which no natural measures or units of measurement exist (cf. Shadish *et al*., 2002, p. 65). How can we be sure that our instruments for gathering data on these unseen, theoretical constructs are safe and

that the proxies we use to assess them are valid? How can we be sure that the observable tasks and features that we choose are fair representations and indicators of these abstract concepts? How can we defensibly construct, name and define an abstract concept, and how do we know that a particular construct is prototypical or socio-culturally and contextually bound (pp. 66–7)? This raises the issue of construct validity, and we address this important factor in this chapter.

In qualitative research, given that multiple views of 'reality' exist, whose is credible and 'correct', how do we know and how do we validate socially constructed knowledge (Flick, 2009, p. 389)? Ary *et al*. (2002) note that validity not only concerns the extent to which an instrument measures what it claims to measure, but that the meaning and interpretation of the results of the data collection and instrumentation are sound (p. 242).

This chapter, in discussing the limits of discourses on validity, argues for a need to move beyond technical issues of how to address it and to address the ontological and epistemological natures (plural) of validity. We engage these issues as well as how researchers can address and ensure validity.

Shadish *et al*. (2002, pp. 37–8) identify four main kinds of validity:

- construct validity: the validity of inferences made about the nature and manifestations of theoretical factors;
- statistical conclusion validity: the use of appropriate statistics to determine, for example, correlation between intervention and outcome;
- internal validity: the validity of inferred and found relationships between elements of the research design and outcomes;
- external validity: generalizability.

They note that both construct validity and external validity concern generalization: the former with regard to the derivation and operation of theoretical constructs, and the latter with regard to sampling. There are, however, several different kinds of validity which fall into the four categories above, for example:

- catalytic validity;
- concurrent validity;
- consequential validity;
- construct validity;
- content validity;
- criterion-related validity;
- convergent and discriminant validity;
- cross-cultural validity;
- cultural validity;
- descriptive validity;
- ecological validity;
- evaluative validity;
- external validity;
- face validity;
- internal validity;
- interpretive validity;
- jury validity;
- predictive validity;
- statistical conclusion validity;
- systemic validity;
- theoretical validity.

It is not our intention in this chapter to discuss all of these terms in depth. Rather the main types of validity will be addressed. The argument will be made that, whilst some of these terms are more comfortably the preserve of quantitative methodologies, this is not exclusively the case. Indeed validity is the touchstone of all types of educational research. Hence the researcher will need to locate her discussions of validity within the research paradigm that is being used. This is not to suggest, however, that research should be paradigm-bound, that is a recipe for stagnation and conservatism; rather validity should be fit for purpose.

Validity takes many forms. For example, in qualitative data validity might be addressed through the honesty, depth, authenticity, richness, trustworthiness, dependability, credibility and scope of the data achieved, the participants approached, the extent of triangulation and the disinterestedness or objectivity of the researcher (Winter, 2000; Flick, 2009). This also means that the matters reported, for example, in an interview, are correct, 'socially appropriate' (Flick, 2009, p. 388) and given sincerely, echoing Habermas's (1979, 1982) views introduced in Chapter 3 of the need for a communication to be true, sincere, legitimate, truthfully given and comprehensible. We pick up this point below, in discussions of mixed methods research.

It is impossible for research to be 100 per cent valid; that is the optimism of perfection. Validity should be seen as a matter of degree rather than as an absolute state (Gronlund, 1981). Hence at best we strive to minimize invalidity and maximize validity.

14.2 Validity in quantitative research

In much quantitative research, validity often (not always) strives to be faithful to several features, for example:

- controllability;
- replicability;

- consistency;
- predictability;
- the derivation of generalizable statements of behaviour;
- randomization of samples;
- neutrality/objectivity;
- observability.

In many cases validity involves being faithful to the assumptions underpinning the statistics used, the construct and content validity of the measures used, careful sampling and the avoidance of a range of threats to internal and external validity outlined later in this chapter.

Statistical conclusion validity (Shadish *et al*., 2002) may be threatened by, for example: low statistical power; violating assumptions in the statistics used (e.g. of normal distributions of data, of linearity, of sample size); measurement error; too limited a range in the data derived from the measures used; too much variation in the procedures for the treatments/interventions in question; extraneous variables (e.g. moderator and mediator variables); wide variability in the outcome measures; built-in error in the statistics used (e.g. their formulae); a false assumption of causality.

14.3 Validity in qualitative research

Much qualitative research abides by principles of validity which differ in many respects from those of quantitative methods. Validity in qualitative research has several principles (Lincoln and Guba, 1985; Bogdan and Biklen, 1992; Ary *et al*., 2002; Flick, 2009):

- the natural setting is the principal source of data;
- context-boundedness and 'thick description';
- data are socially situated, and socially and culturally saturated;
- the researcher is part of the researched world;
- as we live in an already interpreted world, a doubly hermeneutic exercise (Giddens, 1979) is necessary to understand others' understandings of the world; the paradox here is that the most sufficiently complex instrument to understand human life is another human (Lave and Kvale, 1995, p. 220), but this risks human error in all its forms;
- holism in the research;
- the researcher – rather than a research tool – is the key instrument of research;
- data are descriptive;
- there is a concern for processes rather than solely with outcomes;
- data are analysed inductively rather than using a priori categories;
- data are presented in terms of the respondents rather than the researcher;
- seeing and reporting the situation through the eyes of participants (Geertz, 1974);
- respondent validation is important;
- catching agency, meaning and intention are essential.

Maxwell (1992) argues that qualitative researchers should avoid working within the agenda of the positivists in arguing for the need for research to demonstrate concurrent, predictive, convergent, criterion-related, internal and external validity. However, the discussion below indicates that this need not be so. Guba and Lincoln (1989) argue for the need to replace positivist notions of validity in qualitative research with 'authenticity'. Maxwell (1992), echoing Mishler (1990), suggests that 'understanding' is a more suitable term than 'validity' in qualitative research. We, as researchers, are part of the world that we are researching, and we cannot be completely objective about that, hence other people's perspectives are equally as valid as our own, and the task of research is to uncover these. Validity, then, concerns the meanings that subjects give to data and inferences drawn from the data (Hammersley and Atkinson, 1983). 'Fidelity' (Blumenfeld-Jones, 1995) requires the researcher to be as honest as possible to the self-reporting of the researched.

Agar (1993) notes that, in qualitative data collection, the intensive personal involvement and in-depth responses of individuals secure a sufficient level of validity and reliability. This claim is contested by Hammersley (1992, p. 144, 2011) and Silverman (1993, p. 153), who argue that these are insufficient grounds for validity and reliability, and that the individuals concerned have no privileged position on interpretation. (Of course, neither are actors 'cultural dopes' who need a sociologist or researcher to tell them what is 'really' happening.) Silverman argues that, whilst immediacy and authenticity make for interesting journalism, ethnography must have different but equally rigorous notions of validity and reliability. This involves moving beyond selecting data simply to fit a preconceived or ideal conception of the phenomenon or because they are spectacularly interesting (Fielding and Fielding, 1986). Data selected must be representative of the sample, the whole data set and the field, i.e. they must address content, construct and concurrent validity.

Hammersley (1992, pp. 50–1, 2011) suggests that validity in qualitative research replaces certainty with confidence in our results, and that, as reality is independent of the claims made for it by researchers, our accounts will only be representations of that reality

rather than reproductions of it. Lincoln and Guba (1985) and Ary *et al*. (2002) suggest that key criteria of validity in qualitative research are:

- credibility: the truth value (replacing the quantitative concepts of internal validity);
- transferability: generalizability (replacing the quantitative concept of external validity);
- dependability: consistency (replacing the quantitative concept of reliability);
- confirmability: neutrality (replacing the quantitative concept of objectivity).

Lincoln and Guba (1985) argue that, within these criteria of validity, rigour can be achieved by careful audit trails of evidence, member checking/respondent validation (confirmation by participants) when coding or categorizing results, peer debriefing, negative case analysis, 'structural corroboration' (triangulation, discussed below) and 'referential material adequacy' (adequate reference to standard materials in the field). Trustworthiness, they suggest, can be addressed in the credibility, fittingness, auditability and confirmability of the data (see also Morse *et al*., 2002).

Whereas quantitative data place great store on both external validity and internal validity, the emphasis in much qualitative research is on internal validity, and in many cases external validity is an irrelevance for qualitative research (Winter, 2000, p. 8; Creswell, 2012) as it does not seek to generalize but only to represent the phenomenon being investigated, fairly and fully. Of course, some qualitative research, for example, Miles and Huberman (1994), does move towards generalizability, and indeed Chapter 2 indicates that qualitative data can be 'quantitized'. The overwhelming feature of qualitative research is its concern with the phenomenon or situation in question, and not generalizability (Hammersley, 2013). Hence issues such as random sampling, replicability, alpha coefficients of reliability, isolation and control of variables, and predictability simply do not matter in much qualitative research.

Maxwell (1992) argues for five kinds of validity as 'understanding' in qualitative methods:

- descriptive validity: the factual accuracy of the account, that it is not made up, selective or distorted (cf. Winter, 2000, p. 4); in this respect validity subsumes reliability; it is akin to Blumenfeld-Jones's (1995) notion of 'truth' in research – what actually happened (objectively factual) – and to Glaser's and Strauss's (1967) term 'credibility';
- interpretive validity: the ability of the research to catch the meaning, interpretations, terms and intentions that situations and events, i.e. data, have for the participants/subjects themselves, in their terms; it is akin to Blumenfeld-Jones's (1995) notion of 'fidelity' – what it means to the researched person or group (subjectively meaningful); interpretive validity has no clear counterpart in experimental/positivist methodologies;
- theoretical validity: the theoretical constructions that the researcher brings to the research (including those of the researched); theory here is regarded as explanation; theoretical validity is the extent to which the research explains phenomena; in this respect it is akin to construct validity (discussed below); in theoretical validity the constructs are those of all the participants;
- generalizability: the view that the theory generated may be useful in understanding other similar situations; generalizing here refers to generalizing within specific groups or communities, situations or circumstances validly, and, beyond, to specific outsider communities, situations or circumstance (external validity);
- evaluative validity: the application of an evaluative, judgemental stance towards that which is being researched, rather than a descriptive, explanatory or interpretive framework.

To these one can add Auerbach's and Silverstein's (2003) category of *transparency*, i.e. how far the reader can understand, and is informed of, the processes by which the interpretation made is actually reached (cf. Teusner, 2016). Indeed Teusner (2016), commenting on insider research, argues that by making the procedures of the research transparent, with results and conclusions demonstrating clarity and justifiability (rehearsing the comments below and Chapter 11 on 'warrants'), this renders external validation less important (p. 88).

Central to Teusner's views of transparency in insider research is the importance of reflexivity and disclosure; she argues for researchers to address concerns about: (a) whether the relationship between the researcher and participants has a negative impact on the participants' behaviour; (b) whether the researcher's tacit knowledge will risk misinterpreting data, making false assumptions or missing potentially important information; (c) whether the researcher's own politics, loyalties, perspectives, socio-cultural and moral standpoints and agendas will lead to misrepresentation or distortion; (d) whether the researcher's own emotional connections with participants will impact on the research; and (e) how far the researcher's and participants' status will impact on the research relationships (2016, pp. 90–4).

Validity in qualitative research concerns the purposes of the participants, the actors and the appropriateness of the data-collection methods used to catch those purposes (Winter, 2000, p. 7). Maxwell (2005) suggests that validity here can be enhanced by 'intensive long-term involvement', 'rich data', 'respondent validation', 'intervention' (e.g. in action research or case study research), 'searching for discrepant evidence and negative cases', 'triangulation' and 'comparison' (e.g. between a control group and an intervention group, or between groups in different sites and location) (pp. 110–14) and by considering alternative explanations of a phenomenon (p. 126).

Differences in the meanings and criteria for validity in quantitative and qualitative are summarized in Table 14.1.

Clearly the criteria are not the exclusive preserve of each of the two main types of research here (quantitative and qualitative). The intention of Table 14.1 is heuristic and to indicate emphases only.

Onwuegbuzie and Leech (2006b, pp. 239–46) set out many steps that researchers can take to ensure validity in qualitative research (several of which derive from Lincoln and Guba, 1985; see also Huberman and Miles, 1998; Ary *et al*., 2002; Teddlie and Tashakkori, 2009, pp. 295–7; Flick, 2009; Yin, 2009; Teusner, 2016). These include:

- prolonged engagement in the field (to gather rich and sufficient data);
- persistent observation (to identify key relevant issues and to separate these from comparative irrelevancies);
- triangulation (discussed later in this chapter: data, perspectives, instruments, time, methodologies, people etc.): 'structural corroboration';
- leaving an audit trail (documentation and records used in the study that include: raw data; records of analysis and data reduction; reconstructions and syntheses of data; 'process notes' (on how the research and analysis are proceeding; notes on 'intentions and dispositions' of the researcher as the study proceeds; information concerning the development of instruments for data collection));
- member checking/informant feedback (respondent validation, discussed below);
- weighting the evidence, ensuring that correct attention is paid to higher-quality data (e.g. those data gathered from long engagement, detailed study and trusted participants) and less attention is paid to low-quality data;
- checking for representativeness (ensuring that unsupported generalizability of the findings is avoided);
- checking for researcher effects/clarifying researcher bias (how far the personal biases, assumptions or values of the researcher, or how far the researcher's personal characteristics (e.g. clothing, appearance, sex, age, ethnicity) affect the research), premature closure of data collection, unexplored data which are contained in field notes and too close an empathy between researcher and subjects;

TABLE 14.1 COMPARING VALIDITY IN QUANTITATIVE AND QUALITATIVE RESEARCH

Bases of validity in quantitative research		*Bases of validity in qualitative research*
Controllability	⟷	Natural
Isolation, control and manipulation of required variables	⟷	Thick description and high detail on required or important aspects
Replicability	⟷	Uniqueness
Predictability	⟷	Emergence, unpredictability
Generalizability	⟷	Uniqueness
Context-freedom	⟷	Context-boundedness
Fragmentation and atomization of research	⟷	Holism
Randomization of samples	⟷	Purposive sample/no sampling
Neutrality	⟷	Value-ladenness of observations/double hermeneutic
Objectivity	⟷	Confirmability
Observability	⟷	Observability and non-observable meanings and intentions
Inference	⟷	Description, inference and explanation
'Etic' research	⟷	'Emic' research
Internal validity	⟷	Credibility
External validity	⟷	Transferability
Reliability	⟷	Dependability
Observations	⟷	Meanings

- making contrast/comparisons (e.g. between subgroups, sites, literature);
- theoretical sampling (following the data and where they lead, rather than leading the data, and ensuring that the research addresses all the required aspects of the theory);
- checking the meaning of outliers (rather than ignoring outliers and exceptions, researchers should examine them to see what leverage they provide into an understanding of the phenomenon in question);
- using extreme cases (e.g. to identify what is missing in the majority of cases);
- ruling out spurious relations (avoiding attributing causality or association where none exists);
- replicating a finding (identifying how far the findings might apply to other groups);
- referential adequacy (how well-referenced the findings are to benchmark or significant literature);
- following up surprises (avoiding ignoring surprise results);
- structural relationships (looking for consistency between the findings – with each other and with literature);
- peer review;
- peer debriefing (external evaluation of the research, its conduct and findings);
- reflexivity and control of bias;
- rich and thick description (providing detail to support and corroborate findings);
- the 'modus operandi' approach (specifically looking for possible sources of invalidity in the research);
- assessing rival explanations (looking for alternative interpretations and explanations of the data);
- negative case analysis (examining disconfirming cases to see if the hypotheses or findings need to be amended in light of them);
- checking that the findings are thoroughly grounded in data, that inferences made are logical, that strategies for analysis are used correctly and that the category structure is appropriate;
- confirmatory data analysis (conducting qualitative replication studies where possible);
- theoretical adequacy (by, for example, theory triangulation and extended fieldwork);
- effect sizes (avoiding simply 'binarizing' matters (e.g. strong/weak; present/absent; positive/negative) and replacing them with indications of size/power or strength of the findings).

This comprehensive list of ways of striving to ensure validity in qualitative research has similarities in some places with those of quantitative research (e.g. replication, avoidance of researcher bias, external evaluation, representativeness, suitable generalizability, theoretical sampling, triangulation, transparency, etc.). This suggests that, whilst there may be different canons of validity between quantitative and qualitative research, and whilst there may be different interpretations of the meaning of 'validity' in different kinds of research, nevertheless there is some common ground between them; they are not mutually exclusive.

14.4 Validity in mixed methods research

Though each of the methods in mixed methods research (MMR) has to conform to its specific validity requirements in quantitative and qualitative research, there is an argument for identifying specific validity requirements for MMR. Onwuegbuzie and Johnson (2006) argue that the term 'validity' should be replaced by 'legitimation' in MMR, and they identify nine main types of legitimation (discussed below). These nine methods, the authors aver (p. 52), constitute an attempt to overcome problems in MMR of:

- representation (using largely or only words and pictures to catch the dynamics of lived experiences and unfolding, emergent situations);
- legitimation (ensuring that the results are dependable, credible, transferable, plausible, confirmable and trustworthy);
- integration (using and combining quantitative and qualitative methods, each with their own, sometimes antagonistic canons of validity, e.g. quantitative data may use large random samples whilst qualitative data may use small, purposive samples, and yet they may be placed on an equal footing) (p. 54).

Their nine types of legitimation in MMR (Onwuegbuzie and Johnson, 2006, p. 57) are:

1. *Sample integration* (how far different kinds and sizes of sample in combination, or the same samples in quantitative and qualitative research, can enable high-quality inferences to be made).
2. *Inside-outside* (how far researchers use, combine and balance both insiders' views ('*emic*' research) and outsiders' views ('*etic*', objective research) in the research in describing and explaining).
3. *Weakness minimization* (how far any weaknesses that stem from one approach are compensated by the strengths of the other approach, together with suitably weighting such strengths and weaknesses).
4. *Sequential* (how far one can minimize order effects (quantitative to qualitative and vice versa) in

'meta-inferences' made from data collection and analysis, such that one could reverse the order of the inferences made, or the order of the quantitative and qualitative data, without loss of power to the 'meta-inferences').

5 *Conversion* (how far qualitizing numerical data or quantitizing qualitative data can assist in yielding robust 'meta-inferences').

6 *Paradigmatic mixing* (how successful is the combination of the ontological, epistemological, axiological, methodological and rhetorical beliefs and practices in yielding useful results, particularly if the paradigms are in tension with each other).

7 *Commensurability* (how far any 'meta-inferences' made from the data catch a 'mixed worldview' (i.e. rejecting the incommensurability of paradigms) that is enabled by 'Gestalt switching' and integration of paradigms and their methodologies).

8 *Multiple validities* (fidelity to the canons of validity for each of the quantitative and qualitative data gathered).

9 *Political* (how accepted to the audiences are the 'meta-inferences' stemming from the combination of quantitative and qualitative methods).

Collins *et al*. (2012) add two criteria which concern philosophical clarity, researchers' assumptions and connecting quality criteria from different communities involved in MMR:

10 *Holistic legitimation* (the inclusion of major works to demonstrate legitimation and quality); and

11 *Synergistic legitimation*, where combining the process and outcome of legitimation is superior to addressing these two separately; adopting a dialectical process of multiple perspectives, philosophical assumptions and stances; regarding as equally important the legitimation processes in quantitative and qualitative approaches; and balancing opposing quantitative and qualitative approaches (p. 855).

Long (2015), however, argues that discussions of validity in MMR is still at an early stage. Commenting on the work of Collins *et al*. (2012), she advocates taking the issue of validity in MMR wider than is typically found, suggesting that, to date, validity in MMR has been confined to matters of design, procedures, methods and techniques, i.e. 'the logic of justification'. She argues for a broader embrace of validity, to include fundamental issues in the ontology and epistemology of validity in MMR. Here, she draws on Habermas's criteria for speech-act validity claims in communicative action, arguing that validity comprises: sincerity, legitimacy, truthfulness, rightness and comprehensibility in 'action oriented to mutual understanding' (Habermas, 1972, p. 310). In turn, this addresses Habermas's *ideal speech situation* which is 'discursively redeemed' in intersubjective, dialogic speech acts (Habermas, 1979, p. 2, 1984, p. 10; Morrison, 1995a, p. 104). Validity in MMR, thus construed, concerns, for example (Morrison, 1995a, p. 105):

- orientation to a 'common interest ascertained without deception';
- freedom to enter a discourse and to check questionable claims;
- freedom to evaluate explanations and to modify a given conceptual framework;
- freedom to reflect on the nature of knowledge, to assess justifications and to alter norms;
- freedom to allow commands or prohibitions to enter discourse when they can no longer be taken for granted;
- freedom to reflect on the nature of political will;
- mutual understanding between participants;
- equal opportunity to select and employ speech acts and to join a discussion, with that discussion being free from domination and distorting or deforming influences;
- recognition of the legitimacy of each subject to participate in the dialogue as an autonomous and equal partner;
- the consensus resulting from discussion derives from the force of the better argument alone, and not from the positional or political power of the participants;
- all motives except the cooperative search for truth are excluded.

Though Long (2015) draws attention to some challenges in this conception of validity, she understates the critiques of Habermas's view (for an account of these, see Morrison, 1995a).

In the following sections, which describe types of validity, where it is useful to separate the interpretations of validity in quantitative and qualitative research, this has been done. In some cases (e.g. catalytic, consequential validity), as the issues remain the same regardless of the type of research, this separation has not been done. The scene is set by considerations of internal and external validity, and then other types of validity are considered.

14.5 Types of validity

Internal validity

Both qualitative and quantitative methods can address internal and external validity. Internal validity seeks to demonstrate that the explanation of a particular event, issue or set of data which a piece of research provides can actually be sustained by the data and the research (cf. Shadish *et al*., 2002, p. 37). This requires, inter alia, accuracy and correctness, which can be applied to both quantitative and qualitative research. The findings must describe accurately the phenomena being researched. Onwuegbuzie and Leech (2006b, p. 234) define internal validity as the 'truth value, applicability, consistency, neutrality, dependability, and/or credibility of interpretations and conclusions within the underlying setting or group'.

Internal validity in quantitative research

The following summaries adapted from Campbell and Stanley (1963), Bracht and Glass (1968), Lewis-Beck (1993), Shadish *et al*. (2002) and Creswell (2012) distinguish between 'internal validity' and 'external validity'. Internal validity is concerned with the question, do the experimental treatments, in fact, make a difference in the specific experiments under scrutiny? Is the research sufficiently free of errors or violations of validity? Is the research secure? External validity, on the other hand, asks the question, 'given these demonstrable effects, to what populations or settings can they be generalized?'.

There are several kinds of threat to internal validity in quantitative research (many of these apply strongly, though not exclusively, to experimental research), for example:

- *History*: Frequently in educational research, events other than the intervention treatments occur during the time between pre-test and post-test observations (e.g. in a longitudinal survey, experiment, action research). Such events produce effects that can mistakenly be attributed to differences in treatment.
- *Maturation*: Between any two observations, subjects change in a variety of ways. Such changes can produce differences that are independent of the research. The problem of maturation is more acute in protracted educational studies than in brief laboratory experiments.
- *Ambiguous temporal precedence*: It is important to disclose which variable is taken to be the cause and which the effect (the direction of causality).
- *Statistical regression*: Regression means simply that subjects scoring highest on a pre-test are likely to score relatively lower on a post-test; conversely, those scoring lowest on a pre-test are likely to score relatively higher on a post-test. In short, in pre-test–post-test situations, there is regression to the mean. Regression effects can lead the educational researcher mistakenly to attribute post-test gains and losses to low scoring and high scoring respectively. Like maturation effects, regression effects increase systematically with the time interval between pre-tests and post-tests (e.g. in action research, experiments or longitudinal research). Statistical regression occurs in educational research due to the unreliability of measuring instruments and to extraneous factors unique to each group, for example, in an experiment.
- *Testing*: Pre-tests at the beginning of research (e.g. experiments, action research, observational research) can produce effects other than those due to the research treatments. Such effects can include sensitizing subjects to the true purposes of the research and practice effects which produce higher scores on post-test measures.
- *Instrumentation*: Unreliable tests or instruments can introduce serious errors into research (e.g. testing, surveys, experiments). With human observers or judges or changes in instrumentation and calibration, error can result from changes in their skills and levels of concentration over the course of the research.
- *Selection*: Bias may be introduced as a result of differences in the selection of subjects for the comparison groups or when intact classes are employed as experimental or control groups. Selection bias may interact with other factors (history, maturation, etc.) to cloud further the effects of the comparative treatments.
- *Experimental mortality (attrition)*: The loss of subjects through dropout often occurs in long-running research (e.g. experiments, longitudinal research, action research) and may confound the effects of the variables, for whereas initially the groups may have been randomly selected, those who stay the course may be different from the unbiased sample that began it.
- *Instrument reactivity*: The effects that the data-collection instruments exert on the people in the study (e.g. observations, questionnaires, video recordings, interviews).
- *Selection-maturation interaction*: Where there is confusion between the research design effects and the variable's effects.
- *Type I and Type II errors*: A false positive and a false negative, respectively.

A Type I error can be addressed by setting a more rigorous level of significance (e.g. $\rho < 0.01$ rather than $\rho < 0.05$). Boruch (1997, p. 211) suggests that a Type II error may occur if: (a) the measurement of a response to the intervention is insufficiently valid; (b) the measurement of the intervention is insufficiently relevant; (c) the statistical power of the experiment is too low; (d) the wrong population was selected for the intervention. A Type II error can be addressed by reducing the level of significance (e.g. $\rho < 0.20$ or $\rho < 0.30$ rather than $\rho < 0.05$). The more one reduces the chance of a Type I error the more chance there is of committing a Type II error, and vice versa. We discuss Type I and Type II errors in Chapter 39.

Ary *et al*. (2002) suggest that one threat to internal validity stems from 'construct underrepresentation' (p. 243): the under-representation of a construct in instrumentation or data collection (e.g. too narrow, too selective), whilst another threat is from 'construct-irrelevance variance' (p. 243): the effect of other, extraneous factors on the factor or process in question.

Later in this chapter we address how these threats might be mitigated.

Internal validity in qualitative research

In ethnographic, qualitative research there are several main kinds of internal validity (LeCompte and Preissle, 1993, pp. 323–4):

- confidence in the data;
- the authenticity of the data (the ability of the research to report a situation through the eyes of the participants);
- the cogency of the data;
- the soundness of the research design;
- the credibility of the data;
- the auditability of the data;
- the dependability of the data;
- the confirmability of the data.

Writers on the issue of authenticity, argue for:

- fairness (that there should be a complete and balanced representation of the multiple realities in, and constructions of, a situation);
- ontological authenticity (the research should provide a fresh and more sophisticated understanding of a situation, e.g. making the familiar strange (Blumer, 1969), a significant feature in reducing 'cultural blindness' in a researcher, a problem which might be encountered in moving from being a participant to being an observer (Brock-Utne, 1996, p. 610));
- educative authenticity (the research should generate a new appreciation of these understandings);
- catalytic authenticity (the research gives rise to specific courses of action);
- tactical authenticity (the research should bring benefit to all involved: the ethical issue of 'beneficence').

Hammersley (1992, p. 71) suggests that internal validity for qualitative data requires attention to:

- plausibility and credibility;
- the kinds and amounts of evidence required (such that the greater the claim that is being made, the more convincing the evidence has to be for that claim);
- clarity on the kinds of claim made from the research (e.g. definitional, descriptive, explanatory, theory generative).

In ethnographic research internal validity can be addressed by using low-inference descriptors, multiple researchers, participant researchers, peer examination of data and mechanical means to record, store and retrieve data (LeCompte and Preissle, 1993, p. 338). By tracking and storing information clearly, it is possible for the ethnographer to eliminate rival explanations of events and situations.

Lincoln and Guba (1985, pp. 219, 301) suggest that credibility in naturalistic inquiry can be addressed by:

- prolonged engagement in the field;
- persistent observation (in order to establish the relevance of the characteristics for the focus);
- triangulation (of methods, sources, investigators and theories);
- peer debriefing (exposing oneself to a disinterested peer in a manner akin to cross-examination, in order to test honesty, working hypotheses and to identify the next steps in the research);
- negative case analysis (in order to establish a theory that fits every case, revising hypotheses retrospectively);
- member checking (respondent validation to assess intentionality, to correct factual errors, to offer respondents the opportunity to add further information or to put information on record, to provide summaries and to check the adequacy of the analysis).

Whereas in quantitative research, history and maturation are viewed as threats to the validity of the research, ethnographic research simply assumes that this will happen; ethnographic research allows for change over time – it builds it in. Internal validity in ethnographic research is also addressed by the reduction of observer

effects by having the observers sample widely and stay in the situation for such a long time that their presence is taken for granted.

Onwuegbuzie and Leech (2006b, pp. 235–7) identify twelve kinds of threat to internal validity in qualitative research:

1. *Ironic legitimation* (how far the research recognizes and is able to work with multiple realities and interpretations of the same situation, even if they are simultaneously contradictory).
2. *Paralogical legitimation* (how far the research is able to catch and address paradoxes in the claims to validity).
3. *Rhizomatic legitimation* (how much the research loses data when mapping of data rather than describing takes place).
4. *Voluptuous legitimation* (how far the interpretation placed on the data exceeds the capability of the researcher to support that interpretation from the data).
5. *Descriptive validity* (the accuracy of the account given by the researcher).
6. *Observational bias* (inadequate sampling of words, observations or behaviours in the study).
7. *Researcher bias* (discussed earlier).
8. *Reactivity* (how far the research alters the situation being researched or the participants in the research, e.g. the Hawthorne effect (discussed below) and the novelty effect).
9. *Confirmation bias* (the tendency for a piece of research to confirm existing findings or hypotheses).
10. *Illusory confirmation* (the tendency to find relationships, e.g. between people, behaviours or events, when in fact they do not exist).
11. *Causal error* (inferring causal relations when none exists or where no evidence has been provided of their existence).
12. *Effect size* (avoiding taking numerical effect sizes and qualitizing them, when such a step would enrich the analysis; failure to take into account effect sizes and the meaningfulness that they could bring to the interpretation of the data).

Researchers need to be alert to these potential sources of invalidity and take steps to avoid or minimize them.

External validity

External validity refers to the degree to which the results can be generalized to the wider population, cases, settings, times or situations, i.e. to the transferability of the findings. The issue of generalization is problematical. For some researchers generalizability is a *sine qua non*, whilst this is far less the case in other kinds of research (e.g. naturalistic research). For one school of thought, generalizability through stripping out contextual variables is fundamental, whilst, for another, generalizations which say little about the context have little that is useful to say about human behaviour. For positivists and post-positivists, variables must be isolated and controlled and samples randomized, whilst for ethnographers human behaviour is infinitely complex, irreducible, socially situated and unique.

External validity in quantitative research

External validity in quantitative research concerns generalizability: how far we can generalize from a sample to a population. In addressing external validity, attention must be paid to a range of challenges. These include, for example (Morrison, 2001; Shadish *et al*., 2002; Cartwright and Hardie, 2012):

- generalizing from a narrow sample or sub-groups to a broad population;
- generalizing from a sample to an even smaller sample (sub-group or individuals) (the ecological fallacy);
- generalizing from one situation to another similar situation without taking account of contextual and causal differences;
- generalizing from one situation to another dissimilar situation without taking account of differences of context and causal similarities;
- the exception fallacy: deriving a generalized statement on the basis of exceptional cases;
- generalizing from unstandardized, under-controlled variable treatments (e.g. the failure to keep to the same processes or the overlooking of other factors present in the situation);
- overlooking the range of outcomes of an intervention (too tight a focus on certain outcomes, to the neglect of other outcomes); for example, an intervention that puts greater pressure on students' measured performance in mathematics might overlook the negative fallout of this.

Threats to external validity are likely to limit the degree to which generalizations can be made from the particular – for example, experimental – conditions to other populations or settings. Below, we summarize a number of factors that jeopardize external validity (adapted from Campbell and Stanley, 1963; Bracht and Glass, 1968; Hammersley and Atkinson, 1983; Vulliamy, 1990; Lewis-Beck, 1993; Onwuegbuzie and Johnson, 2006; Creswell, 2012; Cartwright and Hardie, 2012).

- *Failure to describe independent variables explicitly*: unless independent variables are adequately described by the researcher, future replications of the research conditions are virtually impossible.
- *Lack of representativeness of available and target populations*: whilst participants in the research may represent an available population, they may not represent the population to which the researcher seeks to generalize her findings, i.e. poor sampling and/or randomization.
- *Hawthorne effect*: medical research has long recognized the psychological effects that arise out of mere participation in drug experiments, and placebos and double-blind designs are commonly employed to counteract the biasing effects of participation. Similarly, so-called Hawthorne effects threaten to contaminate research treatments in educational research when subjects realize their role as guinea pigs.
- *Inadequate operationalizing of dependent variables*: dependent variables that the researcher operationalizes must have validity in the non-research setting to which she wishes to generalize her findings. A questionnaire on career choice, for example, may have little validity in respect of the actual employment decisions made by undergraduates on leaving university.
- *Sensitization/reactivity to experimental/research conditions*: as with threats to internal validity, pretests may cause changes in the subjects' sensitivity to the intervention variables and thus cloud the true effects of the treatment.
- *Interaction effects of extraneous factors and experimental/research treatments*: all of the above threats to external validity represent interactions of various clouding factors with treatments. As well as these, interaction effects may also arise as a result of any or all of those factors in different combinations (see also threats to internal validity).
- *Invalidity or unreliability of instruments*: the use of instruments which yield data in which confidence cannot be placed (see below on tests).
- *Ecological validity, and its partner, the extent to which behaviour observed in one context can be generalized to another*: Hammersley and Atkinson (1983, p. 10) comment on the problems that surround attempts to relate inferences from responses gained under experimental conditions, or from interviews, to everyday life. Cartwright and Hardie (2012) comment in detail on the difficulties in applying the findings from an experiment in one context to a different location.
- *Multiple treatment validity*: applying several treatments simultaneously or in sequence may cause interaction effects between these treatments, such that it is difficult, if not impossible, to isolate the effects of particular treatments.

External validity in qualitative research

Generalizability in naturalistic research is interpreted as comparability and transferability (Lincoln and Guba, 1985; Eisenhart and Howe, 1992, p. 647). These writers suggest that it is possible to assess the typicality of a situation – the participants and settings – to identify possible comparison groups, and to indicate how data might translate into different settings and cultures (see also Strauss and Corbin, 1990; LeCompte and Preissle, 1993, p. 348). Schofield (1996, p. 200) comments that it is important in qualitative research to provide a clear, detailed and in-depth description so that others can decide the extent to which findings from one piece of research are generalizable to another situation, i.e. to address the twin issues of *comparability* and *translatability* (cf. Cartwright and Hardie's (2012) comments on the need for there to be similarly between the causal processes in the locations of the original research and those in other locations).

Qualitative research can be generalizable (Schofield, 1996, p. 209), by studying the typical for its applicability to other situations – the issue of *transferability* (see also LeCompte and Preissle, 1993, p. 324) – and by performing multi-site studies (e.g. Miles and Huberman, 1984), though it could be argued that this is injecting a degree of positivism into non-positivist research. Lincoln and Guba (1985, p. 316) caution the naturalistic researcher against this; they argue that it is not the researcher's task to provide an index of transferability. Rather, they suggest, researchers should provide sufficiently rich data for the readers and users of research to determine whether transferability is possible. In this respect transferability requires 'thick description'.

Bogdan and Biklen (1992, p. 45) argue that, in qualitative research, we are more interested not with the issue of whether the findings are generalizable in the widest sense but with the question of the settings, people and situations to which they might be generalizable. Yin (2009) notes that qualitative research may be generalizable in terms of conforming to, or contributing to, a generalizable theory (see the discussion on case study at the end of this chapter). He also supports the use of replication studies here.

In naturalistic research, threats to external validity include (Lincoln and Guba, 1985, pp. 189, 300):

- selection effects (where constructs selected are only relevant to a certain group);
- setting effects (where the results are largely a function of their context);

- history effects (where the situations have been arrived at by unique circumstances and, therefore, are not comparable);
- construct effects (where the constructs used are peculiar to a certain group).

Onwuegbuzie and Leech (2006b, pp. 237–8) identify several threats to external validity in qualitative research that lie in the following fields:

1. *catalytic validity* (how far the research empowers the research community, or the effects of a piece of research);
2. *action validity* (how much use is made of the research findings by stakeholders and decision makers);
3. *investigation validity* (the ethical rigour, expertise, quality control and, indeed, personality of the researcher);
4. *interpretive validity* (how far the research catches the meanings and interpretations of the participants in the study);
5. *evaluative validity* (how far an evaluative structure (rather than a descriptive, interpretive or explanatory structure) can be applied to the research);
6. *consensual validity* (how far the 'competent others' agree on the interpretations made the research);
7. *population generalizability/ecological generalizability/temporal generalizability* (how successfully the researchers have kept within the bounds of generalizability/non-generalizability of their findings);
8. *researcher bias* (as for internal validity in qualitative research);
9. *reactivity* (as for internal validity in qualitative research);
10. *order bias* (where the order of the questions posed in an interview/observation/questionnaire affect the dependability of the results);
11. *effect size* (as for internal validity in qualitative research).

Researchers should decide, then, if they really seek generalizability and, if so, how to address this in the design of their research and the warrants brought forward for generalizability.

Construct validity

Construct validity is a fundamental type of validity. It is argued (Loevinger, 1957) that, in fact, construct validity is the queen of the types of validity because it subsumes other types of validity and because it concerns constructs or explanations rather than methodological factors, i.e. the meaning, definition and operationalization of factors.

A construct is an abstract which is theoretically derived; this separates it from other types of validity which deal in actualities – pre-defined content. In construct validity, agreement is sought on the 'operationalized' forms of a construct, clarifying what we mean when we work with this abstract construct, for example, is my understanding of this construct acceptable, fair in operationalizing the abstract construct, similar to that which is generally accepted to be the construct? For example, let us say that I wished to assess a child's intelligence (assuming, for the sake of this example, that it is a unitary quality). Intelligence is an abstract construct. I could say that I construe intelligence to be demonstrated in the ability to sharpen a pencil. How acceptable a construction and operationalization of, or an indicator of, intelligence is this? Is not intelligence something else (e.g. that which is demonstrated by a high score in an intelligence test)? To establish construct validity I would need to be assured that *my construction* of a particular issue is warranted, that proxies and indicators that I use for it in my research are warranted and agree with other constructions or theories of the same underlying abstract issue, for example, intelligence, creativity, anxiety, motivation.

Demonstrating construct validity means not only confirming the construction with that given in relevant literature or by the consistency of measures of the construct with other measures of that same construct; it also requires me to look for counter-examples which might falsify my construction. When I have balanced confirming and refuting evidence, I am in a position to demonstrate construct validity. I can stipulate what I take this construct to be. In the case of conflicting interpretations of a construct, I might have to acknowledge that conflict and then stipulate the interpretation that I shall use.

Addressing construct validity comprises two main stages:

Stage 1: Ensure that the construct has been correctly and adequately defined, including its key elements. This may require expert opinion, comparison with other tests of the construct in question, an exhaustive literature review and review of research in the field, a rooting in relevant theories of the construct in question.
Stage 2: Operationalize the construct fairly, so that the data-collection instruments fairly cover the construct and only the construct, i.e. rule out the effects of other possible constructs, which can be addressed using discriminant validity (see below), to show that the construct in question is different from other, possibly

similar, constructs. This can also be addressed by comparing the instrument used for data collection with other instruments purporting to address the construct, and by conducting correlational analysis of data from the instrument in question with data from other, related instruments.

Construct validity in quantitative research

Campbell and Fiske (1959), Brock-Utne (1996) and Cooper and Schindler (2001) suggest that construct validity is addressed by convergent and discriminant techniques. *Convergent techniques* imply that different methods for researching the same construct should give a relatively high inter-correlation, whilst *discriminant techniques* suggest that using similar methods for researching different constructs should yield relatively low inter-correlations, i.e. that the construct in question is different from other potentially similar constructs. Discriminant validity can be yielded by factor analysis, which clusters together similar issues and separates them from others (see Chapter 43). We discuss discriminant validity below.

Construct validity in qualitative research

In qualitative/ethnographic research, construct validity must demonstrate that the categories which the researchers are using are meaningful *to the participants themselves* (Eisenhart and Howe, 1992, p. 648), i.e. that they reflect the way in which the participants actually experience and construe the situations in the research, that they see the situation through the actors' eyes.

Threats to construct validity

There are several threats to construct validity (cf. Shadish *et al*., 2002, pp. 73–81), for example:

- poor definition of the construct, leading to incorrect inferences being made in its operationalization;
- failure to include all the elements of a construct;
- failure to identify what is and is not included in the construct (the boundaries of the construct);
- poor operationalization of the construct and its indicators/proxies (e.g. an intelligence test on its own is a highly selective construction of intelligence);
- confounding constructs: failure to address the fact that different constructs may be at work when one construct is being operationalized;
- failure to control out different factors (e.g. an intervention in a school to improve students' mathematics performance may find an improvement in mathematics scores, but this might overlook the fact that many students were taking private lessons in mathematics outside the school; see also Chapter 6 on causation);
- failure to separate one construct from another;
- false assumption that a construct can be measured by a single instrument (mono-method bias);
- failure to recognize that treatment may change the structure of a measure being used;
- failure to take account of participant reactivity to a situation, its novelty and processes.

Researchers have to be vigilant to ensure that these threats are addressed adequately.

Content validity

To demonstrate content validity, the instrument must show that it fairly and comprehensively covers the domain or items that it purports to cover (Carmines and Zeller, 1979, p. 20). It is unlikely that each issue will be able to be addressed in its entirety simply because of the time available or, for example, respondents' motivation to complete a long questionnaire, hence the researcher must ensure that the elements of the main issue to be covered in the research are both a fair representation of the wider issue under investigation (and its weighting) and that the elements chosen for the research sample are themselves addressed in depth and breadth. Careful sampling of items is required to ensure their representativeness.

For example, if the researcher wished to see how well a group of students could spell 1,000 words in French but decided to have a sample of only fifty words for the spelling test, then that test would have to ensure that the fifty words chosen fairly represented the range of spellings in the 1,000 words – maybe by ensuring that the spelling rules had all been included or that possible spelling errors had been covered in the test, in the proportions in which they occurred in the 1,000 words. The researcher would ensure that the population (the 1,000 words) covered all the aspects of spelling in which she was interested. Then she would randomly sample from the 1,000 items and then check that her fifty items selected fairly covered the 1,000 items.

The challenge here is to identify those characteristics required in the population (however defined: e.g. people, spelling items), i.e. to define the universe of content from which the sample will be drawn. In this respect expert opinion (jury validity) might be useful.

Convergent and discriminant validity

Convergent and discriminant validity are two sides of the same coin, and are both facets of construct validity. Convergent validity is demonstrated when two related or similar factors or elements of a particular construct

are shown (e.g. by measures or indicators) to be related or similar to each other, i.e. the results converge or are consistent with each other. Convergent validity is demonstrated when factors that *should* be related to each other are found, by indicators, actually to be related. Measures of correlation, regression, or factor analysis, are often used in quantitative research to demonstrate convergent validity. In qualitative research, where convergent validity is required to be shown, the researcher (e.g. using NVivo analysis and 'proximity searches', see Chapter 34) can show, by collating and collecting together data from people, groups, samples and subsamples, whether convergence has been found.

By contrast, discriminant (divergent) validity requires two or more unrelated items, attributes, elements or factors to be shown (e.g. by measurement) to be unrelated to, or different from, each other, i.e. difference is found where it should be found, even if those items at first seem to be similar. In quantitative research, statistics such as difference-testing (e.g. t-tests, chi-square tests, analysis of variance) are calculated. In qualitative research where discriminant validity is required, the researcher can examine negative cases, deviant cases and compare data from sub-groups of people, samples and sub-samples, cases and factors, to determine if, indeed, differences are found in terms of key factors, constructs, sub-elements or issues.

Convergent and discriminant validity can be addressed by mixed methods research. Here one can examine whether a set of data from one method accords with the data found by another method which focused on the same issues, variables or constructs. For example, the researcher could investigate whether the findings on, say, social class uptake of higher education in terms of cost–benefit to working-class students yield similar results from both qualitative and quantitative data. If they do, and if this was either predicted or supported by the literature, then one could suggest that convergent validity has been demonstrated. By contrast, let us say that the researcher hypothesized that family income and upward mobility aspirations for working-class students were not significantly related (the former being an index of wealth and the latter being an index of culture), and the data found two different, discordant results, then discriminant validity has been shown.

Convergent and discriminant validity draw on triangulation of methods, instruments, samples and theories. These important features of test construction are addressed in Chapter 27.

Criterion-related validity

Criterion-related validity concerns the detection of the presence or absence of suitable criteria that represent the construct in question, i.e. the appropriacy and suitability of the proxy or indicator being used. This can be addressed, for example, by administering the data-collection instrument (e.g. a test) to one group that is known to possess the construct in question, for example, extraversion, with such knowledge deriving from, say, experts or other data, and then looking to see which answers to which items in the test *did* correspond to the construct in question and which *did not*, in those participants known to possess the construct. Those items which have low correspondence are weeded out, leaving only those items which do correspond.

Criterion validity relates the results of one particular instrument to another external criterion. Within this type of validity there are two principal forms: predictive validity and concurrent validity. Predictive validity is achieved if the data acquired at the first round of research correlate highly with data acquired at a future date. For example, if the results of examinations taken by sixteen-year-olds correlate highly with the examination results gained by the same students when aged eighteen, then we might wish to say that the first examination demonstrated strong predictive validity.

In concurrent validity the data gathered from using one instrument must correlate highly with data gathered from using another instrument. For example, suppose I wished to research a student's problem-solving ability. I might observe the student working on a problem, or I might talk to the student about how she is tackling the problem, or I might ask the student to write down how she tackled the problem. Here I have three different data-collection instruments – observation, interview and documentation respectively. If the results all agreed – concurred – that, according to given criteria for problem-solving ability, the student demonstrated a good ability to solve a problem, I would be able to say with greater confidence (validity) that the student was good at problem solving than if I had arrived at that judgement simply from using one instrument.

Concurrent validity is similar to its partner – predictive validity – in its core concept (i.e. agreement with a second measure); what differentiates concurrent and predictive validity is the absence of a time element in the former; concurrence can be demonstrated simultaneously with another instrument.

An important partner to concurrent validity, which is also a bridge into later discussions of reliability, is triangulation, discussed later in this chapter.

Catalytic validity

Catalytic validity embraces the paradigm of critical theory discussed in Chapter 3 and the discussions of partisan research in that chapter. Put neutrally, catalytic

validity simply strives to ensure that research leads to action, echoing the paradigm of participatory research in Chapter 3. However, the story does not end there, for discussions of catalytic validity are substantive; like critical theory, catalytic validity often suggests an agenda. Lincoln and Guba (1986) suggest here that, in pursuing 'fairness', research should augment and improve participants' experience of the world, and should improve their empowerment. Lather (1986, 1991) and Kincheloe and McLaren (1994) suggest that the agenda for catalytic validity is to help participants understand their worlds in order to transform them, to bring about social justice, equality and empowerment. Catalytic validity, then, is intended to act as a spur to social change and transformation; its agenda is explicitly political, and it suggests the need to expose whose definitions of the situation are operating in the situation.

Catalytic validity is a major feature in critical theory, feminist research, critical race theory etc. (see Chapter 3), and, in these, it requires solidarity in the participants, an ability of the research to promote emancipation, autonomy and freedom within a just, egalitarian and democratic society (Masschelein, 1991), to reveal the distortions, ideological deformations and limitations that reside in research, communication and social structures (see also LeCompte and Preissle, 1993). Validity, it is argued (Mishler, 1990; Scheurich, 1996), is no longer an ahistorical given, but contestable, with definitions of valid research residing in the academic communities of the powerful. Lather (1986) calls for research to be emancipatory and to empower those who are being researched, suggesting that catalytic validity, akin to Freire's notion of 'conscientization', should empower participants to understand and transform their oppressed situation (discussed in Chapter 3 and its discussions of partisan research).

How defensible it is to suggest that researchers should have such ideological intents is a moot point; not to address this area is to perpetuate inequality by omission and neglect. Catalytic validity reasserts the centrality of ethics in the research process, as it requires researchers to interrogate their allegiances, responsibilities and self-interests (Burgess, 1989). We discuss this fully in Chapter 3.

Consequential validity

Partially related to catalytic validity is consequential validity, which argues that the ways in which research data are used (the consequences of the research) must be in keeping with the capability or intentions of the research, i.e. the consequences of the research do not exceed the capability of the research, and the action-related consequences of the research are both legitimate and fulfilled. Clearly, once the research is in the public domain the researcher has little or no control over how it is used. However, and this is often a political matter, research should not be used in ways in which it was not intended to be used, for example by exceeding the capability of the research data to make claims, by acting on the research in ways that the research does not support (e.g. by using the research for illegitimate epistemic support), by making illegitimate claims by using the research in unacceptable ways (e.g. by selection, distortion), and by not acting on the research in ways that were agreed, i.e. errors of omission and commission.

Cross-cultural validity

A considerable body of educational research seeks to understand the extent to which there are similarities and differences between cultures and their members. Matsumoto and Yoo (2006) identify four main phases of cross-cultural research:

- The first phase of making comparatively coarse cross-cultural comparisons of similarities and differences between cultures, though there is no attempt to demonstrate empirically (a) that differences found between groups are the result of cultural factors (pp. 234–5), and (b) what are the elements of the culture that have given rise to the differences.
- The second phase of 'identifying meaningful dimensions of cultural variability' (p. 235) identifies important dimensions of culture, and tests across cultures for the applicability, universality, extent and strength of these. An example of this are Hofstede's (1980) well-known dimensions of individualism–collectivism (see also Triandis, 1994), power–distance, uncertainty avoidance, masculinity–femininity and, later, long-term to short-term orientation (Hofstede and Bond, 1984). These studies have been criticized (Matsumoto and Yoo, 2006) for the assumption that: (a) countries are the same as cultures; (b) individual behaviour is the same as group behaviour (the ecological fallacy, discussed later); (c) there is a single or main culture in a country (i.e. overlooking differences within countries as well as between countries); and (d) attributing the causes of differences found between cultures to cultural sources rather than to other factors (e.g. economic factors, psychological factors).
- The third phase of cultural studies, in which theoretical models of culture and their influence on individuals are used to explain differences found between cultures, for example, Markus and Kitayama (1991)

on cognition, emotion and motivation, Nisbett (2005) on thought processes and cognition. This phase has been criticized for the limited empirical testing of 'cultural ingredients' (Matsumoto and Yoo, 2006).

- The fourth phase of establishing 'linkages' between empirical research on cultural variables and the models that hypothesize such linkages (Matsumoto and Yoo, 2006, p. 236).

For cross-cultural research to demonstrate validity, it is important to ensure that appropriate models of cross-cultural features and phenomena are developed, making clear their causal rootedness in cultural variables (rather than, e.g., psychological, economic or personality variables), that these models are operationalized into specific variables that constitute elements of culture, and that these are then tested empirically.

A major question to be faced by the cross-cultural researcher is the extent to which an instrument which has been developed, tested and validated in one country can be used in another culture or country. Are there sufficient similarities between the cultures or cultural properties (e.g. cultural 'universals') to enable the same instrument to be applied meaningfully in the other culture, given the particularities, uniqueness and sensitivities of each culture (e.g. Hilton and Skrutkowski, 2002; Sumathipala and Murray, 2006).

In conducting cross-cultural research, another fundamental issue to be addressed is in whose terms, constructs and definitions the researcher is working. This rehearses the 'emic'/'etic' discussion in Chapter 15, i.e. does the researcher use objective constructs, definitions, variables and elements of culture ('etic' views), or those that arise from the participants themselves ('emic views') (Hammersley, 2006, p. 6, 2013). Whose 'definition of the situation' drives the research? Are participants sufficiently aware of their own culture to be able to articulate it or, if the researcher uses/imposes her or his own construction of culture, is this a form of 'symbolic violence' to participants (Hammersley, 2006, p. 6)? In practice, the researcher can conduct pilot research (e.g. ethnographic research) to establish the categories, items and variables that are relevant, important and meaningful to participants, and then convert these into measurement scales for further investigation.

'Emic' research may be essential in cross-cultural research, as it is the locals who know more about their environment than an outside researcher (cf. Brock-Utne, 1996, p. 607) and who may know which are the important questions to ask in any environment; indeed she argues for the researcher being a local person rather than an outsider, as a local researcher will have more experience of, and hence more insight into, the local culture, though, of course, this should not blind the local researcher to the situation (p. 610). She gives a fascinating example of the interpretation of riddles in an African society; the outsider expatriate interprets them as entertainment and amusement, whereas the locals saw them as essential teaching and educational tools and promoters of cognitive development (pp. 610–12).

Items that are present in one culture may not be present in another, or may have different relevance, meanings or importance (Banville *et al*., 2000, p. 374). Banville *et al*. (2000) suggest the use of a team of experts in both cultures to work in parallel in order to establish the 'etic' constructs, and then they formulate questions for study that are subsequently operationalized into 'emic' constructs for each culture. This, they aver, avoids the danger of imposing an 'emic' culture from one culture as an 'etic' construct on another culture (p. 375) (see also Aldridge and Fraser, 2000, p. 127). Essentially the authors are arguing for ensuring the relevance of the instrument for all the target cultures, by including 'emic' and 'etic' elements.

It is important to address meaningfulness and relevance in cross-cultural research: whilst a construct or element of culture may be found in two cultures, it may have different meanings, weight or significance in the two cultures, i.e. the *presence* alone of a factor may not be sufficient in cross-cultural research.

Threats to validity in cross-cultural research may lie in many areas, for example:

- failure to operationalize elements of cultures into researchable variables;
- problems of whose construction of 'culture' to adopt: 'emic' and/or 'etic' research;
- false attribution of causality for differences found between groups to cultural factors rather than non-cultural factors, for example, economic factors, affluence, demography, biological features of people, climate, personality, religion, educational practices, personal/subjective perceptions of the research, contextual but non-cultural variables (Alexander, 2000; Matsumoto and Yoo, 2006);
- the ecological fallacy: the error of the ecological fallacy is made where

  relationships that are found between aggregated data (e.g. mean scores) are assumed to apply to individuals, i.e. one infers an individual or particular characteristic from a generalization. It assumes that the individuals in a group exhibit the same features of the whole group taken together (a form of stereotyping).
  (Morrison, 2009, p. 62)

The caution here is to avoid assuming that what one finds at a group level is necessarily the same as that which one would find at an individual level;

- the directions of causality, for example, whether culture influences individual behaviour or vice versa, or both;
- sampling, for example, much cross-cultural research involves using groups of university students, or – as in the case of Hofstede (1980) – individual companies, and it is dangerous to generalize more widely from these. Further, some studies do not have samples that are matched in terms of size or characteristics of the sample;
- instrument problems: different groups may not understand, or have different understandings of, the language/issues/instruments used for gathering data;
- problems of convergent validity (where several items that are supposed to be measuring the same construct or variable do not yield strong inter-correlations);
- problems of discriminant validity (where items that are supposed to be measuring different constructs or variables yield strong inter-correlations);
- problems of equivalence (where the same meaning and significance is not given to concepts, constructs, language, sampling, methods in different cultures, such that meaningful comparisons cannot be made between cultures);
- problems of conceptual equivalence (where items are unrelated or relatively unimportant or meaningless to one or more groups) (e.g. Aldridge and Fraser, 2000, p. 111);
- problems of psychological equivalence, where the psychological connotations or referents in the original language may be different from those in the translated language, giving rise to differences in results that are attributable to factors other than cultural (Liu, 2002; Riordan and Vandenburg, 1994);
- problems of meaning equivalence: using similar words in the two languages but which connote different interpretations or meanings;
- failure of the instruments to take account of different frames of reference of the different cultural groups (Riordan and Vandenburg, 1994);
- failure of groups to understand the measures, instruments, language, meaning or research, i.e. the same items may be interpreted differently by different groups;
- failure to accord equal significance to items (factors might be found to be present in different cultures, but some cultures accord those factors much more importance than others, e.g. in measures of personality such as the Big Five factors of personality) (Matsumoto and Yoo, 2006, p. 240);
- failure to accord equal relevance and meaning to the same construct or item in different cultures;
- measurement equivalence;
- linguistic equivalence (where translated versions of an instrument carry the same meaning as in the original, and which will be understood in the same way by members of different cultures);
- response bias, in which members of different cultures respond in systematically different ways to items, elements, constructs or scales in the instrument in ways that are meaningful to their own cultures, situations or contexts (Riordan and Vandenburg, 1994; Aldridge and Fraser, 2000, p. 127). For example: (a) some cultures may give more weight to socially desirable responses or to responses that make the participants look good (Liu, 2002, p. 82); (b) some cultures may give more weight to categories of 'agree' rather than 'disagree' in responses; (c) some cultures may consider it undesirable to use extreme ends of a measurement scale such as 'strongly agree' or 'strongly disagree', or indeed some cultures may deliberately value the use of extreme categories, such as those that emphasize status, masculinity and power (Matsumoto and Yoo, 2006);
- preparation of participants – giving advance organizers or suggestions to participants before administering an instrument ('priming') (Matsumoto and Yoo, 2006) – may give rise to different responses;
- problems with the researcher who may not speak the language(s) of the participants, or whose participants may be insufficiently articulate or literate to engage in respondent validation.

There are several techniques that researchers can use to address validity in cross-cultural research. For instruments such as questionnaires, a common practice is to use 'back-translation', undertaken by bilinguals or those with a sound ability in the second as well as the first language (cf. Brislin, 1970; Vallerand *et al*., 1992; Banville *et al*., 2000; Cardinal *et al*., 2003). Here the original version of the instrument (say, a questionnaire in English) is translated into the other language required (say, Chinese). Then the Chinese version is given to a third party who does not have sight of the original English version, and that third party translates the Chinese version back into English. The two English versions (the original and the resultant back-translation) are then compared to check whether the meanings (and, in a few cases, the exact language) are the same. If the meanings in the two English versions are the same (semantic equivalence) then the Chinese version is said to be acceptable; if the meanings in the two English

versions are discrepant then there may be a problem in the Chinese, and the Chinese translation is revisited to make changes to it.

Liu (2002) suggests that translators should be familiar with the subject matter, and, if possible, instrumentation. Banville *et al*. (2000) report the use of professional translators instead of simply back-translation, in order to ensure discriminability of similar items in translation, and they indicate that translation should precede the conduct of the empirical research and that translated instruments should be piloted to determine their suitability for the target population.

A variant of this, to ensure even greater validity and reliability of the translated version, is to have more than one person doing the translation into the new language (each person is unknown to the other) and similarly for the back-translation into the original language, as this avoids possible bias in having only a single translator at each stage (Banville *et al*., 2000, p. 379). In this instance, the two translators at each stage should compare their translations and discuss any differences found in meaning or language.

Aldridge and Fraser (2000) note that there may be no equivalent words in the target translated language, and this may mean that there have to be rewordings of the original language in order to reach a compromise statement in the instrument (e.g. a questionnaire) that fits both languages. For example, in translating the English phrase 'how much' into Chinese, the Chinese characters change, depending on the topic in hand. Whilst back-translation keeps the original language as the language of reference, in fact compromises may have to be made in both the original and the translated language, in order to ensure commonality or equivalence of meaning, i.e. the original and the translated language are equally important and must be user-friendly to all groups (Liu, 2002, p. 81). Liu also suggests that it is useful to keep the original language in active rather than passive voice, simple and short sentences, avoiding colloquialisms, idioms and using specific terms and familiar rather than abstruse words (see also Hilton and Skrutkowski, 2002).

Banville *et al*. (2000) provide a useful seven-step approach from Vallerand (1989) to translating and using instruments in cross-cultural research:

Step 1: Prepare a preliminary version of the instrument using the back-translation technique.

Step 2: Evaluate the preliminary versions (to check that the back-translated version is acceptable, or to adjudicate between different versions of the back-translated items) and prepare an experimental version of the instrument using a committee of experts (3–5 persons) to conduct such a review, thereby avoiding possible bias by a single researcher (see also Vallerand *et al*., 1992; Liu, 2002, p. 82).

Step 3: Pre-test the experimental version using a random survey approach, to check the clarity of the instructions and the appropriateness of the instrument.

Step 4: Evaluate the content and concurrent validity of the instrument using bilingual participants to check whether they are answering both versions in the same way, and to check the appropriateness of the instrument (using between twenty and thirty participants). Participants answer both versions of the instrument (i.e. both languages). Content validity can be assessed qualitatively (expert review) and concurrent validity can be assessed quantitatively (e.g. by difference testing or correlational analysis).

Step 5: Conduct a reliability analysis to check for internal validity and stability over time (looking for high reliability coefficients: Cronbach alphas and correlations respectively), and to check the suitability of the instrument. Remove items with low reliability.

Step 6: Evaluate the construct validity of the instruments (through factor analysis, inter-scale correlations and to test the hypothesis that stems from theory).

Step 7: Establish norms of the scales/measures by selecting the population from which the sample will be drawn, by statistical indices, and by calculating means, standard deviations and standardized (z) scores, used with a large number of people in order to establish the stability of the norms (see Chapters 40–43 of the present volume).

Step 4 uses bilingual participants to undertake both versions (both languages), so that their two sets of answers can be compared for discrepancies (see also Liu, 2002, pp. 81–2). This may not be feasible for sole researchers, who may not have access to a sufficiently large group of bilingual participants, but only to people who can translate rather than who are fully bilingual and expert in both cultures. (For an example of the use of this technique, see Cothran *et al*., 2005.)

In order to avoid bias in cross-cultural research, the researcher can also use a multi-instrument approach with different-sized samples for different instruments (Aldridge and Fraser, 2000; Aldridge *et al*., 1999; Sumathipala and Murray, 2006). A multi-method approach provides triangulation and concurrent validity

and gives a closer, more authentic meaning to the phenomenon or culture (particularly when qualitative data combine with quantitative data).

Qualitatively speaking, the researcher has to ensure that: (a) the meanings, definitions and constructs which are being used are understood similarly by the members of the different cultures being investigated (the equivalence issue); (b) these are given sufficient relevance, meaningfulness and weight in the different cultures for them to be suitable for investigation (or, indeed, the research may be intended to discover the relevance, meaningfulness and weight of these in the different cultures); (c) the research includes items that are meaningful, relevant and significant to participants; and (d) the research draws on both 'emic' and 'etic' analysis and constructs as appropriate.

Quantitatively speaking, there are several ways in which the cross-cultural validity of measures can be addressed. We discuss these below. Essentially the purpose is to test the instrument on the different cultures to see if the reliability, items, clusters of items into factors and suitability of the items are acceptable in both cultures; an instrument that is suitable, reliable and valid in one culture may not be in another (Cothran *et al*., 2005, p. 194).

Factor analysis enables the researcher to examine the factor structure of the instrument. A suitable instrument for cross-cultural research should ensure that: (a) the same *factors* are extracted from the same instrument with the different groups of participants; (b) the same *variables* are included in these factors with the different groups of participants; (c) the same *loadings* (e.g. weightings) of each variable are loaded onto each factor (see Chapter 43). One has to exercise discretion here, as, clearly, the results will not be identical for each group of participants. However, if there are gross discrepancies found between factors, variables included, and loadings of each variable, then the researcher will need to consider whether the instrument is sufficiently valid, or whether some items will need to be excluded or replaced.

Inter-correlations of variables (alphas) (discussed below in section on 'Reliability') can be conducted to see whether: (a) the item-to-whole reliability correlation coefficient is the same for the different groups of participants; (b) the overall reliability level (the alpha) is sufficiently high for items to be included (see Chapter 40). A suitable instrument will ensure that the coefficient of correlation for each item to the whole is sufficiently high (e.g. ≥ 0.67), or the overall alphas for the sections of the instrument are sufficiently high (e.g. ≥ 0.67) to be retained. Items with low correlations should be considered for removal. Hence the researcher will need to test his/her instrument in the groups concerned (e.g. groups of members of different cultures) in order to conduct such pilot testing. In this case it is advisable to include no fewer than thirty people in each of the pilot groups.

Items which, the researcher hypothesizes, should be strongly correlated, i.e. convergent validity: measuring the same construct, factor or trait (Rohner and Katz, 1970, p. 1069), should have high correlation coefficients. Items which, the researcher hypothesizes, should have very low correlation coefficients, i.e. discriminant validity: measuring unrelated constructs, factors or traits (p. 1069), should have low correlation coefficients. Alternatively, instead of using correlations, the researcher can conduct difference testing (e.g. t-tests, ANOVA see Chapter 41) to discover: (a) whether items which, he/she hypothesizes, should be similar to each other (convergent validity), in reality show no statistically significant difference or very small effect size; and (b) whether items which, he/she hypothesizes, should be different from each other (discriminant validity), in reality are statistically significantly different from each other or have high effect sizes (see Keet *et al*. (1997) for an example of using correlational analysis, t-tests and factor analysis to establish validity in cross-cultural research).

Watkins (2007, pp. 305–6) suggests that meta-analysis can be used to examine the cross-cultural relevance of variables to the participating groups. This is a statistical procedure in which the researcher selects and combines empirical studies that satisfy criteria for inclusion in respect of the hypotheses under investigation (e.g. they are quantitative, include relevant variables, include scales and measures that can be combined from different studies, include identified samples and include correlational analysis of items). Then the researcher calculates average correlations and effect sizes from the studies (bearing in mind the likely different sample sizes), and then judges whether the correlations and effect sizes found are sufficiently strong for items to be retained in the researcher's own research (on how to conduct a meta-analysis, see Glass *et al*., 1981; Hattie, 2009; Cumming, 2012).

Cross-cultural validity, like other forms of research, should be cautious in making generalizations from small samples, in avoiding claims about whole cultures or countries from limited or selective samples and in imposing instruments from one culture on another – however well they might be translated. Matsumoto and Yoo (2006) suggest that cross-cultural data are 'nested' (p. 246), i.e. there are data at several levels: individual, group, cultures, societies, ecologies. This points us to the statistical technique of multilevel modelling.

Cultural validity

Related to cross-cultural research and ecological validity (see below) is cultural validity (Morgan, 1999). This is particularly an issue in cross-cultural, intercultural and comparative kinds of research, where the intention is to shape research so that it is appropriate to the culture of the researched, and where the researcher and the researched are members of different cultures. Cultural validity is defined as 'the degree to which a study is appropriate to the cultural setting where research is to be carried out' (Joy, 2003, p. 1; see also Stuchbury and Fox, 2009, p. 494). Cultural validity, Morgan (1999) suggests, applies at all stages of the research, and affects its planning, implementation and dissemination. It involves a degree of sensitivity to the participants, cultures and circumstances being studied. Morgan (2005) writes that:

> cultural validity entails an appreciation of the cultural values of those being researched. This could include: understanding possibly different target culture attitudes to research; identifying and understanding salient terms as used in the target culture; reviewing appropriate target language literature; choosing research instruments that are acceptable to the target participants; checking interpretations and translations of data with native speakers; and being aware of one's own cultural filters as a researcher.
>
> (Morgan, 2005, p. 1)

Joy (2003, p. 1) presents twelve important questions that researchers in different cultural contexts may face, to ensure that research is culture-fair and culturally sensitive:

1. Is the research question understandable and of importance to the target group?
2. Is the researcher the appropriate person to conduct the research?
3. Are the sources of the theories that the research is based on appropriate for the target culture?
4. How do researchers in the target culture deal with the issues related to the research question (including their method and findings)?
5. Are appropriate gatekeepers and informants chosen?
6. Are the research design and research instruments ethical and appropriate according to the standards of the target culture?
7. How do members of the target culture define the salient terms of the research?
8. Are documents and other information translated in a culturally appropriate way?
9. Are the possible results of the research of potential value and benefit to the target culture?
10. Does interpretation of the results include the opinions and views of members of the target culture?
11. Are the results made available to members of the target culture for review and comment?
12. Does the researcher accurately and fairly communicate the results in their cultural context to people who are not members of the target culture?

Ecological validity

In education, ecological validity is particularly important and useful in charting how policies are actually happening 'at the chalk face' (Brock-Utne, 1996, p. 617). It concerns examining and addressing the specific characteristics of a particular situation, for example, how policies are actually impacting in practice (p. 617) rather than simply assuming that policies are implemented in the ways intended or in the ways that the powerful groups intended (those at 'the top of the hierarchy of credibility'; p. 618).

Ecological validity requires the specific factors of research sites – schools, universities, regions etc. – to be included and taken into account in the research. In this respect it is more sympathetic to qualitative research and 'thick description' (Geertz, 1973) than those forms of quantitative research variables which seek to isolate, control out and manipulate variables in contrived settings. The ethical tension is raised in ecological validity between the need to provide rich descriptions of characteristics of a situation or institution and the increased likelihood that this will lead to the situation or institution being able to be identified and anonymity breached (Brock-Utne, 1996, p. 618).

To demonstrate ecological validity, it is important to include and address in the research as many as possible of the characteristics and factors of a given situation. The intention is to give accurate portrayals of the realities of social situations in their own terms, in their natural or conventional settings. The difficulty with this is that the more characteristics are included and described, the harder it is to abide by central ethical tenets of much research – non-traceability, anonymity and non-identifiability.

Ecological validity raises the issues of external validity: the extent to which characteristics of one situation or behaviour observed in one setting can be transferred or generalized to another situation; how far fidelity to one specific set of circumstances can apply to others.

14.6 Triangulation

In its original and literal sense, triangulation is a technique of physical measurement: maritime navigators, military strategists and surveyors, for example, use (or used to use) several locational markers in their endeavours to pinpoint a single spot or objective. By analogy, triangular techniques in the social sciences attempt to map out, or explain more fully, the richness and complexity of human behaviour by studying it from more than one standpoint and, in so doing, by making use of both quantitative and qualitative data. Triangulation is a powerful way of demonstrating concurrent validity.

For example, the advantages of the mixed methods approach in social research are manifold and we examine two of them. First, it has been observed that as research methods act as filters through which the environment is selectively experienced, they are never atheoretical or neutral in representing the world of experience (see Chapter 1). Exclusive reliance on one method, therefore, may bias or distort the researcher's picture of the particular slice of reality she is investigating. She needs to be confident that the data generated are not simply artefacts of one specific method of collection (Lin, 1976). Such confidence can be achieved, as far as nomothetic research is concerned, when different methods of data collection yield substantially the same results. (Where triangulation is used in interpretive research to investigate different actors' viewpoints, the same method, e.g. accounts, will naturally produce different sets of data.)

Second, the more the methods contrast with each other, the greater is the researcher's confidence. If, for example, the outcomes of a questionnaire survey correspond to those of an observational study of the same phenomenon, the more the researcher can be confident about the findings. Or, more extremely, where the results of a rigorous experimental investigation are replicated in, say, a role-playing exercise, the researcher will experience even greater assurance. If findings are artefacts of method, then the use of contrasting methods considerably reduces the chances of any consistent findings being attributable to similarities of method (Lin, 1976). The use of triangular techniques, it is argued, can help to overcome the problem of 'method-boundedness'; indeed Chapter 2 demonstrates the value of combining qualitative and quantitative methods. In its use of mixed methods, triangulation may utilize either normative or interpretive techniques, or it may draw on methods from both these approaches and use them in combination.

Types of triangulation and their characteristics

Triangulation is often characterized by a mixed methods approach to a problem in contrast to a single-method approach. Denzin (1970) has, however, extended this view of triangulation to take in several other types as well as the mixed methods kind which he terms 'methodological triangulation', including:

- time triangulation: this takes into consideration the factors of change and process by utilizing cross-sectional and longitudinal designs. Kirk and Miller (1986) suggest that diachronic reliability seeks stability of observations over time, whilst synchronic reliability seeks similarity of data gathered in the same time;
- space triangulation: this attempts to overcome the parochialism of studies conducted in the same country or within the same subculture by making use of cross-cultural techniques;
- combined levels of triangulation: this uses more than one level of analysis from the three principal levels used in the social sciences, namely, the individual level, the interactive level (groups) and the level of collectivities (organizational, communitarian, cultural or societal);
- theoretical triangulation: this draws upon alternative or competing theories in preference to utilizing one viewpoint only;
- investigator triangulation: this engages more than one observer, and data are discovered independently by more than one observer (Silverman, 1993, p. 99);
- methodological triangulation: this uses either (a) the same methodology on different occasions or (b) different methods on the same object of study.

We can add to these:

- paradigm triangulation: different paradigms used in the same study;
- instrument triangulation: data-collection instruments;
- sampling triangulation: different samples and subsamples.

Many studies in the social sciences are conducted at one point only in time, thereby excluding effects of social change and process. Time triangulation goes some way to rectifying these omissions by making use of longitudinal approaches. Longitudinal studies collect data from the same group at different points in time. The use of panel studies and trend studies also address the time dimension (see Chapter 17). The former

compare the same measurements for the same individuals in a sample at several different points in time, and the latter examine selected processes continually over time. The weaknesses of each of these methods can be strengthened by using a combined approach to a given problem.

Space triangulation attempts to overcome the limitations of studies conducted within one culture or subculture (cf. Smith, 1975), as behavioural sciences are culture-bound and subculture-bound rather than being automatically true of any societies. Cross-cultural studies may involve testing theories among different people, as in Piagetian psychology, or they may measure differences between populations by using several different measuring instruments. We have addressed cultural validity earlier.

Social scientists are concerned with the individual, the group and society. These reflect three levels of analysis adopted by researchers. Those who are critical of research argue that some of it uses the wrong level of analysis, for example individual when it should be societal, or that it limits itself to one level only when a more meaningful picture would emerge by using more than one level. Smith (1975) extends this analysis and identifies seven possible levels: the aggregative or individual level, and six levels which characterize the collective as a whole, and do not derive from an accumulation of individual characteristics. The six are:

- group analysis (the interaction patterns of individuals and groups);
- organizational units of analysis (units which have qualities not possessed by the individuals making them up);
- institutional analysis (relationships within and across the legal, political, economic and familial institutions of society);
- ecological analysis (concerned with spatial explanation);
- cultural analysis (concerned with the norms, values, practices, traditions and ideologies of a culture); and
- societal analysis (concerned with gross factors such as urbanization, industrialization, education, wealth, etc.).

Studies combining several levels of analysis are useful.

Theoretical triangulation requires researchers to look at a phenomenon through different theoretical lenses. Researchers are sometimes taken to task for their rigid adherence to one particular theory or theoretical orientation to the exclusion of competing theories. Indeed a major function of research is to test competing theories.

Investigator triangulation refers to the use of more than one observer (or participant) in a research setting. Observers working on their own each have their own observational styles and this is reflected in the resulting data. The careful use of two or more observers or participants independently can lead to more valid and reliable data, checking divergences between researchers and leading to minimal divergence, i.e. reliability.

Denzin (1970) identifies two categories in methodological triangulation: 'within methods' triangulation and 'between methods' triangulation. Triangulation within methods concerns the replication of a study as a check on reliability and theory confirmation. Triangulation between methods involves the use of more than one method in the research. As a check on validity, the 'between methods' approach embraces the notion of convergence between independent measures of the same objective (Campbell and Fiske, 1959). Triangulation bridges issues of reliability and validity.

Triangular techniques are suitable when a more holistic view of educational outcomes is sought, or where a complex phenomenon requires elucidation. Triangulation is useful when an established approach yields a limited and frequently distorted picture. It can also be useful where a researcher is engaged in case study, a particular example of complex phenomena (Adelman *et al*., 1980).

Triangulation is not without its critics. For example, Silverman (1985) suggests that the very notion of triangulation is positivistic, and that this is exposed most clearly in *data triangulation*, as it suggests that a multiple data source (concurrent validity) is superior to a single data source or instrument. The assumption that a single unit can always be measured more than once violates the interactionist principles of emergence, fluidity, uniqueness and specificity (Denzin, 1997, p. 320). Further, Patton (1980) suggests that even having multiple data sources, particularly of qualitative data, does not ensure consistency or replication. Fielding and Fielding (1986) hold that methodological triangulation does not necessarily increase validity, reduce bias or bring objectivity to research. Further, triangulation suggests that there is only one correct final position, conclusion or focus (Tracy, 2010); in qualitative research this may not be the case.

With regard to investigator triangulation, Lincoln and Guba (1985, p. 307) contend that it is erroneous to assume that one investigator will corroborate another, nor is this defensible, particularly in qualitative, reflexive inquiry. They extend their concern to include theory and methodological triangulation, arguing that the search for theory and methodological triangulation is

epistemologically incoherent and empirically empty (see also Patton, 1980). No two theories, it is argued, will ever yield a sufficiently complete explanation of the phenomenon being researched.

These criticisms are trenchant, but they have been answered equally trenchantly by Denzin (1997). In naturalistic inquiry, Lincoln and Guba (1985, p. 315) suggest that triangulation is intended as a check on data, whilst member checking, an element of credibility, can be used as a check on members' constructions of data.

14.7 Ensuring validity

It is easy to slip into invalidity; it can enter at every stage of a piece of research. The attempt to build out invalidity is essential if the researcher is to have confidence in the elements of the research plan, data acquisition, data-processing analysis, interpretation and its ensuing judgement.

At the *design stage*, threats to validity can be minimized by:

- choosing an appropriate timescale;
- ensuring that there are adequate resources for the required research to be undertaken;
- selecting an appropriate methodology for investigating and answering the research questions;
- selecting appropriate instrumentation for gathering the type of data required;
- using an appropriate sample (e.g. which is representative, not too small nor too large);
- demonstrating internal, external, content, concurrent and construct validity; 'operationalizing' the constructs fairly;
- ensuring reliability in terms of stability (consistency, equivalence, split-half analysis of test material);
- selecting appropriate foci to answer the research questions;
- devising and using appropriate instruments (e.g. to catch accurate, representative, relevant and comprehensive data; ensuring that readability levels are appropriate; avoiding any ambiguity of instructions, terms and questions; using instruments that will catch the complexity of issues; avoiding leading questions; ensuring that the level of test is appropriate – neither too easy nor too difficult; avoiding test items with little discriminability; avoiding making the instruments too short or too long; avoiding too many or too few items for each issue);
- avoiding a biased choice of researcher or research team (e.g. insiders or outsiders as researchers).

At the *data-gathering stage*, threats to validity can be minimized by:

- reducing the Hawthorne effect (see the accompanying website);
- minimizing reactivity effects (respondents behaving differently when subjected to scrutiny or being placed in new situations, e.g. the interview situation – we distort people's lives in the way we go about studying them (Lave and Kvale, 1995, p. 226));
- trying to avoid dropout rates among respondents;
- taking steps to avoid non-return of questionnaires;
- avoiding having too long or too short an interval between pre-tests and post-tests;
- ensuring inter-rater reliability;
- matching control and experimental groups fairly;
- ensuring standardized procedures for gathering data or for administering tests;
- building on the motivations of the respondents;
- tailoring the instruments to the concentration span of the respondents and addressing other situational factors (e.g. health, environment, noise, distraction, threat);
- addressing factors concerning the researcher (particularly in an interview situation), for example, the attitude, gender, ethnicity, age, personality, dress, comments, replies, questioning technique, behaviour, style and non-verbal communication of the researcher.

At the *data-analysis stage*, threats to validity can be minimized by:

- using respondent validation;
- avoiding subjective interpretation of data (e.g. being too generous or too ungenerous in the award of marks), i.e. lack of standardization and moderation of results;
- reducing the halo effect, where the researcher's knowledge of the person or knowledge of other data about the person or situation exerts an influence on subsequent judgements;
- using appropriate statistical treatments for the level of data (e.g. avoiding applying techniques from ratio scales data to ordinal data or using incorrect statistics for the type, size, complexity, sensitivity of data);
- recognizing spurious correlations and extraneous factors which may be affecting the data;
- avoiding poor coding of qualitative data;
- avoiding making inferences and generalizations beyond the capability of the data to support such statements;

- avoiding the equating of correlations and causes;
- avoiding selective use of data;
- avoiding unfair aggregation of data (particularly of frequency tables);
- avoiding unfair telescoping of data (degrading the data);
- avoiding Type I and/or Type II errors.

At the *data-reporting stage*, threats to validity can be minimized by:

- avoiding using data selectively and unrepresentatively (e.g. accentuating the positive and neglecting or ignoring the negative);
- indicating the context and parameters of the research in the data collection and treatment, the degree of confidence which can be placed in the results, the degree of context-freedom or context-boundedness of the data (i.e. the level to which the results can be generalized);
- presenting the data without misrepresenting its message;
- making claims which are sustainable by the data;
- avoiding inaccurate or wrong reporting of data (technical or orthographic errors);
- ensuring that the research questions are answered; releasing research results neither too soon nor too late.

Having identified where invalidity might obtain, the researcher can take steps to ensure that, as far as possible, it has been minimized in all areas of the research.

14.8 Reliability

Reliability is essentially an umbrella term for dependability, consistency and replicability over time, over instruments and over groups of respondents. Can we believe the results? Reliability is concerned with precision and accuracy: some features, for example, height, can be measured precisely, whilst others, for example, musical ability, cannot. For research to be reliable it must demonstrate that if it were to be carried out on a similar group of respondents in a similar context (however defined), then similar results would be found. Guba and Lincoln (1994) suggest that the concept of reliability is largely positivist. Whilst widely held views of reliability may seem to adhere to positivism rather than to qualitative research, it is not exclusively so; qualitative research must be as reliable as positivist and post-positivist research, though in different ways: the canons of reliability and the types of reliability differ in quantitative and qualitative research. Similarly, it is simply not the case that qualitative or quantitative research, per se, guarantees reliability or that it is an irrelevance in qualitative research (Brock-Utne, 1996, p. 613). Reliability is relevant to both quantitative and qualitative research.

14.9 Reliability in quantitative research

In quantitative research and qualitative research which seeks trends, patterns, predictability and control (e.g. Miles and Huberman, 1994), there are three principal types of reliability: stability, equivalence and internal consistency (Carmines and Zeller, 1979). Here reliability concerns the research situation (e.g. the context of, or the conditions for, a test), factors affecting the researcher or participants, and the instruments for data collection themselves.

Reliability as stability

Reliability as stability is a measure of consistency over time, over similar samples and over the uses of the instrument in question. A reliable instrument in a piece of research yields similar data from similar respondents over time. A leaking tap which leaks one litre each day is leaking reliably, whereas a tap which leaks one litre some days and two litres on another, is not. In the experimental and survey models of research this would mean that if a test and then a re-test were undertaken within an appropriate time span, with no changes having occurred, then similar results should be obtained. The researcher has to decide what is an appropriate length of time; too short a time and respondents may remember what they said or did in the first test situation; too long a time and there may be extraneous effects operating to distort the data (e.g. maturation in students, outside influences on the students). A researcher seeking to demonstrate this type of reliability will have to choose an appropriate timescale between the test and re-test. Correlation coefficients can be calculated for the reliability of pre- and post-tests, using formulae which are readily available in texts on statistics and test construction and on Internet sites.

In addition to stability over time, reliability as stability can also be stability over a similar sample. For example, we would assume that if we were to administer a test or a questionnaire simultaneously to two groups of students who were very closely matched on significant characteristics (e.g. age, gender, ability etc. – whatever characteristics are deemed to have a significant bearing on the responses), then similar results (on a test) or responses (to a questionnaire) would be obtained. The

correlation coefficient on this form of the test/re-test method can be calculated either for the whole test or for sections of the questionnaire (e.g. by using a correlation statistic or a t-test as appropriate). The correlation coefficient can be found and should be high for reliability to be guaranteed. This form of reliability over a sample is particularly useful in piloting tests and questionnaires.

In using the test/re-test method, care has to be taken to ensure the following (Cooper and Schindler, 2001, p. 216):

- the time period between the test and re-test is not so long that situational factors may change;
- the time period between the test and re-test is not so short that the participants will remember the first test or that intervention effects will be too strong to be reliable (e.g. the Hawthorne effect and the immediacy effect);
- the participants may have become interested in the field and may have followed it up themselves between the test and the re-test times.

Reliability as equivalence

There are two main kinds of reliability as equivalence. Reliability may be achieved, first, through using equivalent forms (also known as 'alternative forms') of a test or data-gathering instrument. If an equivalent form of the test or instrument is devised and yields similar results, then the instrument can be said to demonstrate this form of reliability. For example, the pre-test and post-test in an experiment are predicated on this type of reliability, being alternate forms of instrument to measure the same issues. This type of reliability might also be demonstrated if the equivalent forms (e.g. items) of a test or other instrument yield consistent results if applied simultaneously to matched samples (e.g. two random samples in a survey). Here reliability can be measured through a difference test (e.g. a t-test or a Mann–Whitney U test), through the demonstration of a high correlation coefficient, similar means and standard deviations between two groups.

Second, reliability as equivalence may be achieved through inter-rater reliability. If more than one researcher is taking part in a piece of research then, human judgement being fallible, agreement between all researchers must be achieved, through ensuring that each researcher enters data in the same way. This is particularly pertinent to a team of researchers gathering structured observational or semi-structured interview data where each member of the team must agree on which data to enter into which categories. For observational data, such reliability is addressed in training sessions for researchers, for example, working on video material to ensure parity in how to enter data.

At a simple level one can calculate the inter-rater agreement as a percentage:

$$\frac{\text{Number of actual agreements}}{\text{Number of possible agreements}} \times 100$$

Robson (2002, p. 341) sets out a more sophisticated way of measuring inter-rater reliability in coded observational data, and his method can be used with other types of data.

Reliability as internal consistency

Whereas the test/re-test method and the equivalent forms method of demonstrating reliability require the tests or instruments to be done twice, demonstrating internal consistency demands that the instrument or tests be run once only through the split-half method.

Let us imagine that a test is to be administered to a group of students. Here the test items are divided into two halves, ensuring that each half is matched in terms of item difficulty and content. Each half is marked separately. If the test demonstrates split-half reliability, then the marks obtained on each half should correlate highly with each other. Any student's marks on the one half should match his or her marks on the other half. This can be calculated using the Spearman-Brown formula:

$$\text{Reliability} = \frac{2r}{1+r}$$

where r = the actual correlation between the halves of the instrument.

This calculation requires a correlation coefficient to be calculated, for example, a Spearman rank order correlation or a Pearson product moment correlation (Chapter 40). Let us say that using the Spearman-Brown formula, the correlation coefficient is 0.85; in this case the formula for reliability is set out thus:

$$\text{Reliability} = \frac{2x0.85}{1+0.85} = \frac{1.70}{1.85} = 0.919$$

Given that the maximum value of the coefficient is 1.00, we can see that the reliability of this instrument, calculated using the split-half reliability testing, is very high.

This type of reliability assumes that the test can be split into two matched halves; many tests have a gradient of difficulty or different items of content in each half. If this is the case and, for example, the test contains twenty items, then the researcher, instead of splitting the test into two by assigning items 1–10 to one half and items 11–20 to the second half, may assign all the even-numbered items to one group and all the odd-numbered items to another. This moves to the two

halves being matched in terms of content and cumulative degrees of difficulty.

An alternative measure of reliability as internal consistency is the Cronbach alpha, frequently referred to simply as the alpha coefficient of reliability, or simply the alpha. The Cronbach alpha provides a coefficient of inter-item correlations, i.e. the correlation of each item with the sum of all the other relevant items. This is useful for multi-item scales and is a measure of the internal consistency among the *items* (not, for example, the people). We address the alpha coefficient and its calculation in Chapter 40.

Ary *et al*. (2002, pp. 262–3) suggest that reliability of a data-collection instrument is a function of:

- the length of the data-collection instrument (e.g. a test);
- the heterogeneity of the group being investigated (the greater the heterogeneity, the greater the reliability);
- the abilities of the participants;
- the methods of testing for reliability;
- the nature of the variable that is being measured or investigated.

Reliability, thus construed, makes several assumptions, for example, that instrumentation, data and findings should be controllable, predictable, consistent and replicable. This pre-supposes a particular style of research, for example, positivist or post-positivist. Cooper and Schindler (2001, p. 218) suggest that, here, reliability can be improved by: minimizing any external sources of variation – standardizing and controlling the conditions under which the data collection and measurement take place; training the researchers in order to ensure consistency (inter-rater reliability); widening the number of items on a particular topic; excluding extreme responses from the data analysis (e.g. outliers, which can be done with SPSS).

14.10 Reliability in qualitative research

The suitability of the term 'reliability' for qualitative research is contested (e.g. Winter, 2000; Stenbacka, 2001; Golafshani, 2003). Lincoln and Guba (1985) prefer to replace 'reliability' with terms such as 'credibility', 'neutrality', 'confirmability', 'dependability', 'consistency', 'applicability', 'trustworthiness' and 'transferability', in particular the notion of 'dependability'.

LeCompte and Preissle (1993, p. 332) suggest that the canons of reliability for quantitative research may be unworkable for qualitative research. Quantitative research may strive for replication: if the same methods are used with the same sample then the results should be the same. Further, some quantitative methods require a degree of control and manipulation of phenomena. This distorts the natural occurrence of phenomena (see section above on 'Ecological validity'). Indeed the premises of naturalistic studies include the uniqueness and idiosyncrasy of situations, such that the study cannot be replicated; that is their strength rather than their weakness.

On the other hand, this is not to say that qualitative research need not strive for replication in generating, refining, comparing and validating constructs. Indeed LeCompte and Preissle (1993, p. 334) argue that such replication might include repeating:

- the status position of the researcher;
- the choice of informant/respondents;
- the social situations and conditions;
- the analytic constructs and premises that are used;
- the methods of data collection and analysis.

Further, Denzin and Lincoln (1994) suggest that reliability as replicability in qualitative research can be addressed in several ways:

- stability of observations (whether the researcher would have made the same observations and interpretation of these if they had been observed at a different time or in a different place);
- parallel forms (whether the researcher would have made the same observations and interpretations of what had been seen if she had paid attention to other phenomena during the observation);
- inter-rater reliability (whether another observer with the same theoretical framework and observing the same phenomena would have interpreted them in the same way).

This is a contentious issue, for it is seeking to apply to qualitative research the canons of reliability of quantitative research. Purists might argue against the legitimacy, relevance or need for this in qualitative studies.

In qualitative research, reliability can be regarded as a fit between what researchers record as data and what actually occurs in the natural setting that is being researched, i.e. a degree of accuracy and comprehensiveness of coverage (Bogdan and Biklen, 1992, p. 48). This is not to strive for uniformity: two researchers who are studying a single setting may come up with very different findings, but both sets of findings might be reliable. Indeed Kvale (1996, p. 181) suggests that there might be as many different interpretations of

qualitative data as there are researchers. An example of this is the study of the Nissan automobile factory in the UK, where Wickens (1987) found a 'virtuous circle' of work organization practices that demonstrated flexibility, teamwork and quality consciousness, whereas the same practices were reported by Garrahan and Stewart (1992) to be a 'vicious circle' of exploitation, surveillance and control respectively. Both versions of the same reality coexist because reality is not unitary. This argues for reliability to adopt an eclectic use of instruments, researchers, perspectives and interpretations (echoing the comments earlier about triangulation).

Brock-Utne (1996) argues that qualitative research, being holistic, strives to record the multiple interpretations of, intentions in and meanings given to situations and events. Here reliability is construed as *dependability* (Lincoln and Guba, 1985, pp. 108–9; Anfara *et al*., 2002), recalling the earlier discussion on internal validity. Dependability involves member checks (respondent validation), debriefing by peers, triangulation, prolonged engagement in the field, persistent observations in the field, reflexive journals, negative case analysis and independent audits (identifying acceptable processes of conducting the inquiry so that the results are consistent with the data). Audit trails enable the research to address the issue of confirmability of results, in terms of process and product (Golafshani, 2003, p. 601).

Dependability raises the important issue of *respondent validation* (researchers take back their research report to the respondents and record their reactions to that report). Whilst dependability might suggest that researchers should go back to respondents to check that their findings are dependable, researchers also need to be cautious in placing exclusive store on respondents, for, as Hammersley and Atkinson (1983) suggest, they are not in a privileged position to be sole commentators on their actions.

Kleven (1995) suggests that qualitative research can address reliability in part by asking three questions, particularly in observational research:

1. Would the same observations and interpretations have been made if observations had been conducted at different times? (The 'stability' version of reliability.)
2. Would the same observations and interpretations have been made if other observations had been conducted at the time? (The 'parallel forms' version of reliability.)
3. Would another observer, working in the same theoretical framework, have made the same observations and interpretations? (The 'inter-rater' version of reliability.)

The debate on reliability in quantitative and qualitative research rehearses the discussion of paradigms in the opening chapters: quantitative measures are criticized for combining sophistication and refinement of process with crudity of concept (Ruddock, 1981) and for failing to distinguish between educational and statistical significance (Eisner, 1985); qualitative methodologies, whilst possessing immediacy, flexibility, authenticity, richness and candour, are criticized for being impressionistic, biased, commonplace, insignificant, ungeneralizable, idiosyncratic, subjective and short-sighted (Ruddock, 1981). This is an arid debate; rather the issue is one of fitness for purpose. For our purposes here, we need to note that criteria of reliability in quantitative methodologies may differ from those in qualitative methodologies. In qualitative methodologies, reliability includes fidelity to real life, context- and situation-specificity, authenticity, comprehensiveness, detail, honesty, depth of response and meaningfulness to the respondents.

We summarize some similarities and differences between reliability in quantitative and qualitative research in Table 14.2.

Table 14.2 shows that, whilst there are some areas of reliability which are exclusive to quantitative research (split-half testing, equivalent forms and Cronbach alphas), many features of reliability apply, *mutatis mutandis*, to both quantitative and qualitative research. Further, Table 14.2 also shows that some features of validity (Table 14.1) also appear in reliability (e.g. content validity appears as coverage of domain and comprehensiveness, and concurrent validity appears as triangulation). This suggests some blurring of the edges between validity and reliability in the literature.

14.11 Validity and reliability in interviews

In interviews, inferences about validity are made too often on the basis of face validity (Cannell and Kahn, 1968), that is, whether the questions asked look as if they are measuring what they claim to measure. One cause of invalidity is bias, defined as 'a systematic or persistent tendency to make errors in the same direction, that is, to overstate or understate the "true value" of an attribute' (Lansing *et al*., 1961, pp. 120–1). One way of validating interview measures is to compare the interview measure with another measure that has already been shown to be valid, i.e. 'convergent validity', discussed earlier. If the two measures agree, it can be assumed that the validity of the interview is comparable with the proven validity of the other measure.

A practical way of achieving greater validity in interviews is to minimize bias as much as possible. Sources

TABLE 14.2 COMPARING RELIABILITY IN QUANTITATIVE AND QUALITATIVE RESEARCH

Bases of reliability in quantitative research		*Bases of reliability in qualitative research*
Reliability	⟷	Dependability
Demonstrability	⟷	Trustworthiness
Stability	⟷	Stability
Isolation, control and manipulation of required variables	⟷	Fidelity to the natural situation and real life
Identification, control and manipulation of key variables	⟷	Thick description and high detail on required or important aspects
Singular, objective truths	⟷	Multiple interpretations/perceptions
Replicability	⟷	Replicability
Parallel forms	⟷	Parallel forms
Generalizability	⟷	Generalizability
Context-freedom	⟷	Context-specificity
Objectivity	⟷	Authenticity
Coverage of domain	⟷	Comprehensiveness of situation
Verification of data and analysis	⟷	Honesty and candour
Answering research questions	⟷	Depth of response
Meaningfulness to the research	⟷	Meaningfulness to respondents
Parsimony	⟷	Richness
Objectivity	⟷	Confirmability
Fidelity to 'etic' research	⟷	Fidelity to 'emic' research
Internal consistency	⟷	Credibility
Generalizability	⟷	Transferability
Parallel forms	⟷	Parallel forms
Inter-rater reliability	⟷	Inter-rater reliability
Accuracy	⟷	Accuracy
Precision	⟷	Accuracy
Replication	⟷	Replication
Neutrality	⟷	Multiple interests represented
Consistency	⟷	Consistency
Theoretical relevance	⟷	Applicability
Triangulation	⟷	Triangulation
Alternative forms (equivalence)		
Split-half		
Inter-item correlations (alphas)		

of bias are: the characteristics of the interviewer and the respondent; and the substantive content of the questions. Researcher bias (Maxwell, 2005, p. 108), which has an effect on the interview (e.g. reactivity), can include, for example:

- the attitudes, opinions and expectations of the interviewer;
- a tendency for the interviewer to see the respondent in her own image;
- a tendency for the interviewer to seek answers that support her preconceived notions or theory;
- misperceptions on the part of the interviewer of what the respondent is saying;
- misunderstandings on the part of the respondent of what is being asked.

Studies have also shown that ethnicity, religion, gender, sexual orientation, status, social class and age in certain contexts can be potent sources of bias, i.e. interviewer effects (Lee, 1993; Scheurich, 1995). Interviewers and interviewees alike bring their own, often unconscious experiential and biographical baggage with them into the interview situation. Indeed Hitchcock and Hughes (1989) argue that because interviews are interpersonal, humans interacting with humans, it is inevitable that the researcher will have some influence on the interviewee and, thereby, on the data. Interviewer neutrality is a chimera (Denscombe, 1995, 2014).

Lee (1993) indicates problems of reliability in conducting interviews very sharply, where the researcher is researching sensitive subjects, i.e. research that might

pose a significant threat to interviewers and interviewees. Here the interview might be seen as an intrusion into private worlds, or the interviewer might be regarded as someone who can impose sanctions on the interviewee, or as someone who can exploit the powerless; the interviewee is in the interviewer's searchlight (see also Scheurich, 1995), so may be cautious in what is revealed. Indeed Gadd (2004) reports that an interviewee may reduce his/her willingness to 'open up' to an interviewer if the dynamics of the interview situation are too threatening, taking the role of the 'defended subject'. This raises issues of *transference* and *counter-transference*, which have their basis in psychoanalysis. In transference, interviewees project onto the interviewer their feelings, fears, desires, needs and attitudes that derive from their own experiences (Scheurich, 1995). In counter-transference the process is reversed. Both affect reliability.

One way of addressing reliability is to have a highly structured interview, with the same format and sequence of words and questions for each respondent (Silverman, 1993), though Scheurich (1995, pp. 241–9) suggests that this is to misread the infinite complexity and open-endedness of social interaction. Controlling the wording is no guarantee of controlling the interview. Oppenheim (1992, p. 147) argues that wording is a particularly important factor in attitudinal rather than factual questions. He suggests that changes in wording, context and emphasis undermine reliability, because it ceases to be the same question for each respondent. Indeed he argues that error and bias can stem from alterations to wording, procedure, sequence, recording and rapport, and that training for interviewers is essential to minimize this. Silverman (1993) suggests that it is important for each interviewee to understand the question in the same way. He suggests that the reliability of interviews can be enhanced by: careful piloting of interview schedules; training of interviewers; inter-rater reliability in the coding of responses; and the extended use of closed questions.

On the other hand, Silverman (1993) argues for the importance of open-ended interviews, as this enables respondents to demonstrate their unique way of looking at the world – their definition of the situation. It recognizes that what is a suitable sequence of questions for one respondent might be less suitable for another, and open-ended questions enable important but unanticipated issues to be raised.

Oppenheim (1992, pp. 96–7) suggests several causes of bias in interviewing:

- biased sampling (sometimes created by the researcher not adhering to sampling instructions);
- poor rapport between interviewer and interviewee;
- changes to question wording (e.g. in attitudinal and factual questions);
- poor prompting and biased probing;
- poor use and management of support materials (e.g. show cards);
- alterations to the sequence of questions;
- inconsistent coding of responses;
- selective or interpreted recording of data/transcripts;
- poor handling of difficult interviews.

One can add to this the issue of 'acquiescence' (Breakwell, 2000, p. 254), the tendency of respondents to say 'yes', regardless of the question or, indeed, regardless of what they really feel or think.

There is also the issue of *leading questions*. A leading question is one which makes assumptions about interviewees or 'puts words into their mouths', i.e. where the question influences the answer perhaps illegitimately. For example (Morrison, 1993, pp. 66–7), the question 'when did you stop complaining to the headteacher?' assumes that the interviewee had been a frequent complainer, and the question 'how satisfied are you with the new Mathematics scheme?' assumes a degree of satisfaction with the scheme. The leading questions here might be rendered less leading by rephrasing, for example: 'how frequently do you have conversations with the headteacher?' and 'what is your opinion of the new Mathematics scheme?' respectively.

In discussing the issue of leading questions we are not necessarily suggesting that there is not a place for them. Indeed Kvale (1996, p. 158) makes a powerful case *for* leading questions, arguing that they may be necessary in order to obtain information that the interviewer suspects the interviewee might be withholding. Here it might be important to put the 'burden of denial' onto the interviewee (e.g. 'when did you stop cheating in examinations?'). Leading questions, frequently used in police interviews, may be used for reliability checks with what the interviewee has already said, or may be deliberately used to elicit particular non-verbal behaviours that provide an indication of the sensitivity of the interviewee's remarks.

The researcher must also be aware of possible bias in interviewees giving what they think are socially desirable answers to questions (Fowler, 2009), i.e. answers to please the interviewer or not to appear different from what is socially acceptable or desirable.

Reducing bias in interviews requires: (a) careful formulation of questions so that the meaning is crystal clear; (b) thorough training procedures so that an interviewer is more aware of the possible problems; (c) probability sampling of respondents; and (d) matching

interviewer characteristics with those of the sample being interviewed (where appropriate). Oppenheim (1992, p. 148) argues, for example, that interviewers seeking attitudinal responses have to ensure that people with known characteristics are included in the sample – the criterion group. Researchers must recognize that the interview is a shared, negotiated and dynamic social moment.

Power is significant in the interview situation, for the interview is not simply a data-collection situation but a social and frequently a political situation. Literally the word 'inter-view' is a view *between* people, mutually, not the interviewer alone, extracting data one way from the interviewee. Power resides with interviewer and interviewee alike (Thapar-Björkert and Henry, 2004), though Scheurich (1995, p. 246) argues that, typically, more power resides with the interviewer (see also Lee, 1993; Morrison, 2013a): the interviewer generates the questions and the interviewee answers them; the interviewee is under scrutiny whilst the interviewer is not. Kvale (1996, p. 126), too, suggests that there are definite asymmetries of power as the interviewer tends to define the situation, the topics and the course of the interview. Of course, the interviewee is powerful as he/she has data that the interviewer wants, and has power to withhold such data (discussed below).

Cassell (cited in Lee, 1993) and Walford (2012) suggest that elites and powerful people might feel demeaned or insulted when being interviewed by those with a lower status or less power. Further, those with power, resources and expertise might be anxious to maintain their reputation, and so will be more guarded in what they say, wrapping this up in well-chosen, articulate phrases (Walford, 2012). Interviewers need to be aware of the potentially distorting effects of power, a significant feature of critical theory (see Chapter 3).

Neal (1995) draws attention to the feelings of powerlessness and anxieties about the physical presentation and status of interviewers when interviewing powerful people. This is particularly so for frequently lone, low-status research students interviewing powerful people; a low-status female research student might find that an interview with a male in a position of power (e.g. a university vice-chancellor, a senior politician or a senior manager) might turn out to be very different from an interview with the same person if conducted by a male university professor, which is perceived by the interviewee to be more of a dialogue between equals (see also Connell *et al*., 1996; Gewirtz and Ozga, 1993, 1994). Ball (1994b) comments that, when powerful people are being interviewed, interviews must be seen as an extension of the 'play of power' – with its game-like connotations. He suggests that powerful people control the agenda and course of the interview, and are usually very adept at this because they have both a personal and professional investment in being interviewed (see also Batteson and Ball, 1995; Phillips, 1998; Walford, 2012).

The effect of power can be felt even before the interview commences. Neal (1995) instances being kept waiting, and subsequently being interrupted, patronized and interviewed by the interviewee (see also Walford, 1994b, 2012). Scheurich (1995) suggests that many powerful interviewees will rephrase or not answer the question. Limerick *et al*. (1996) report interviews in which interviewers have felt themselves to be passive, vulnerable, helpless and indeed manipulated. One way of overcoming this is to have two interviewers conducting each interview (Walford, 1994c, p. 227). On the other hand, Hitchcock and Hughes (1989) observe that if the researchers are known to the interviewees and they are peers, however powerful, then a degree of reciprocity might be taking place, with interviewees giving answers that they think the researchers might want to hear.

The issue of power features in feminist research (e.g. Thapar-Björkert and Henry, 2004), i.e. research which emphasizes subjectivity, equality, reciprocity, collaboration, non-hierarchical relations and emancipatory potential (catalytic and consequential validity) (Neal, 1995), echoing the comments on research that is influenced by critical theory (Chapter 3). Here feminist research addresses a dilemma of interviews which are constructed in the dominant, male paradigm of pitching questions that demand answers from a passive respondent.

Limerick *et al*. (1996) suggest that, in fact, it is wiser to regard the interview as a gift (and 'data' means 'things that are given'), as interviewees have the power to withhold information, to choose the location of the interview, to choose how seriously to attend to the interview, how long it will last, when it will take place, what will be discussed – and in what and whose terms – what knowledge is important, even how the data will be analysed and used (see also Thapar-Björkert and Henry, 2004). Echoing Foucault, they argue that power is fluid and is discursively constructed through the interview rather than being the province of either party.

Miller and Cannell (1997) identify particular problems in conducting telephone interviews, where reducing the interview situation to just auditory sensory cues can be challenging (see Chapter 25). For example, the interviewee can only retain a certain amount of information in her/his short-term memory, so bombarding the telephone interviewee with too many choices (the

non-written form of 'show cards' of possible responses) becomes unworkable. Here the reliability of responses is subject to the memory capabilities of the interviewee – how many scale points and descriptors, for example, can an interviewee retain in her head about a single item? Further, the absence of non-verbal cues, for example, facial expression, gestures, posture, the significance of silences and pauses (Robinson, 1982), is important, as interviewees may be unclear about the meaning behind words and statements. This problem is compounded if the interviewer is unknown to the interviewee.

Miller and Cannell (1997) report important research evidence to support the significance of the non-verbal mediation of verbal dialogue. As discussed earlier, the interview is a social situation; in telephone interviews the absence of essential social elements could undermine the salient conduct of the interview, and hence its reliability and validity. Non-verbal paralinguistic cues affect the conduct, pacing and relationships in the interview and the support, threat and confidence felt by the interviewees. Telephone interviews can easily slide into becoming mechanical and cold. Further, the problem of loss of non-verbal cues is compounded by the asymmetries of power that often exist between interviewer and interviewee; the interviewer will need to take immediate steps to address these issues (e.g. by putting interviewees at their ease, as the interviewee might simply put down the telephone).

On the other hand, Nias (1991), Miller and Cannell (1997) and Ary *et al*. (2002) suggest that the very fact that interviews are not face-to-face may strengthen their reliability, as the interviewee might disclose information that may not be so readily forthcoming in a face-to-face, more intimate situation. Hence, telephone interviews have their strengths and weaknesses; their use should be governed by the criterion of fitness-for-purpose. They tend to be shorter, more focused and useful for contacting busy people (Harvey, 1988; Miller, 1995).

A cluster of problems surround the person being interviewed. Tuckman (1972), for example, observed that, when formulating questions, an interviewer has to consider the extent to which a question might influence the respondent to show herself in a good light; or the extent to which a question might influence the respondent to be unduly helpful by attempting to anticipate what the interviewer wants to hear; or the extent to which a question might be asking for information about a respondent that she is not certain or likely to know herself. Interviews may be based on the assumption that the person interviewed has insight into the cause of her behaviour, and this may not be possible.

In educational circles interviewing might be a particular problem in working with children (Morrison, 2013a) (see also Chapters 13 and 25). Simons (1982), McCormick and James (1988) and Greig and Taylor (1999) comment on particular problems involved in interviewing children which affect reliability, for example:

- establishing trust;
- overcoming shyness and reticence;
- maintaining informality;
- avoiding assuming that children 'know the answers';
- overcoming the problems of inarticulate children;
- pitching the question at the right level;
- choice of vocabulary;
- non-verbal cues;
- moving beyond the institutional response or receiving what children think the interviewer wants to hear;
- avoiding the interviewer being seen an authority spy or plant;
- keeping to the point;
- breaking silences on taboo areas and those which are reinforced by peer-group pressure;
- children being seen as of lesser importance than adults (maybe in the sequence in which interviews are conducted, e.g. the headteacher, then the teaching staff, then the children).

These are not new matters. Studies by Labov in the 1960s and 1970s showed how students reacted very strongly to contextual matters in an interview situation (Labov, 1969). The language of children varied according to the ethnicity of the interviewee, the friendliness of the surroundings, the opportunity for the children to be interviewed with friends, the ease with which the scene was set for the interview, the demeanour of the adult (e.g. whether the adults was standing or sitting), the nature of the topics covered. The interview is a social encounter, and children may be very sensitive to the social context of the interview (Morison *et al*., 2000; Morrison, 2013a); Maguire (2005, p. 4) suggests that 'children have good social radar'. The differences can be significant, varying from monosyllabic responses by children in unfamiliar and uncongenial surroundings to extended responses in the more congenial and less threatening surroundings – more sympathetic to the children's everyday world. The language, argot and jargon, social and cultural factors of the interviewer and interviewee all exert a powerful influence on the interview situation.

Lee (1993) raises the further issue of whether there should be a single interview that maintains the detachment of the researcher (perhaps particularly useful in

addressing sensitive topics), or whether there should be repeated interviews to gain depth and to show fidelity to the collaborative nature of research (a feature, as noted above, which is significant for feminist research (Oakley, 1981)).

Kvale (1996, pp. 148–9) suggests that, in order to obtain reliable and valid data, a skilled interviewer should:

- know his/her subject matter in order to conduct an informed conversation;
- structure the interview well, so that each stage of the interview is clear to the participant;
- be clear in the terminology and coverage of the material;
- allow participants to take their time and answer in their own way;
- be sensitive and empathic, using active listening and being sensitive to how something is said and the non-verbal communication involved;
- be alert to those aspects of the interview which may hold significance for the participant;
- keep to the point and the matter in hand, steering the interview where necessary in order to address this;
- check the reliability, validity and consistency of responses by well-placed questioning;
- be able to recall and refer to earlier statements made by the participant;
- be ready to clarify, confirm and modify the participant's comments with the participant.

Walford (1994c, 2012) adds to this the need for the interviewer to have done her homework when interviewing powerful people, as such people could well interrogate the interviewer – they will assume up-to-dateness, competence and knowledge in the interviewer. Powerful interviewees are usually busy people and will expect the interviewer to have read relevant material in the public domain.

The issues of reliability do not reside solely in the preparations for and conduct of the interview; they extend to the ways in which interview data are analysed. For example, Lee (1993) and Kvale (1996, p. 163) comment on the issue of 'transcriber selectivity'. Here transcripts of interviews, however detailed and full they might be, remain selective, since they are interpretations of social situations. They become decontextualized, abstracted, even if they record silences, intonation, non-verbal behaviour etc. The issue, then, is how useful they are to researchers overall rather than whether they are completely reliable.

One problem in using open-ended questions in interviews is that of developing a satisfactory, reliable method of recording replies. One way is to summarize responses in the course of the interview. This has the disadvantage of breaking the continuity of the interview and may result in bias because the interviewer may unconsciously emphasize responses that agree with her expectations and fail to note those that do not. It is sometimes possible to summarize an individual's responses at the end of the interview. Although this preserves the continuity of the interview, it is likely to induce greater bias because the delay may lead to the interviewer forgetting some of the details. It is these forgotten details that are most likely to be those which disagree with his or her own expectations. We advise the reader also to review Chapter 25 of the present volume.

14.12 Validity and reliability in experiments

One fundamental purpose of experimental design is to impose control over conditions that would otherwise cloud the true effects of the independent variables on the dependent variables, so that causality can be attributed to the intervention in question. Clouding conditions that threaten to jeopardize the validity of experiments have been identified by Campbell and Stanley (1963), Bracht and Glass (1968), Lewis-Beck (1993), Shadish *et al*. (2002) and Torgerson and Torgerson (2008), conditions that are of greater consequence to the validity of quasi-experiments (more typical in educational research) than to true experiments in which random sampling and assignment to treatments occurs and where both treatment and measurement can be more adequately controlled by the researcher.

The following summaries distinguish between 'internal validity' and 'external validity'. Internal validity is concerned with the question, do the experimental treatments, in fact, make a difference in the specific experiments under scrutiny? External validity, on the other hand, asks the question, given these demonstrable effects, to what populations or settings can they be generalized?

Threats to internal validity were introduced earlier in this chapter, and comprise:

- history
- maturation
- statistical regression
- testing
- instrumentation
- selection
- experimental mortality
- instrument reactivity
- selection–maturation interaction.

Shadish *et al*. (2002), Torgerson and Torgerson (2008) and Creswell (2012) add to these: (a) contamination, in that control and experimental groups may communicate with each other, affecting what happens with each group; and (b) compensatory rivalry: a control group may feel resentful about being deprived of the intervention (if they are told what the intervention comprises) and this may affect their behaviour.

Several threats to external validity were discussed earlier in this chapter (Section 14.5) and the reader is advised to review these. As in clinical trials, educational experiments require attention to the educational equivalents of: effects on different sub-groups of a sample; side effects; contra-indications; effects of personal characteristics of participants; dose-response (e.g. attention to amount, quality, strength, frequency, intensity, duration of the intervention); recognition that a person is a complex system which combines and connects very many elements whose interactions and outcomes change over time (with commensurate changes to interventions over time); patients who forget to, or refuse to, take medicine or take it irregularly (i.e. changes to the intervention affect reliability); comorbidity (other problems may exist at the time of the intervention); patients taking multiple medications (several other events may be happening at the same time as the intervention); and doctor–patient (teacher–student) relations.

In clinical trials, some treatments may require initial intensive medication, tailing off to a maintenance level (e.g. many people start antibiotics with a double dose and then maintain a single dose for several days); some medication may require a gentle start, with an increasing, cumulative dosage as the body responds to treatment. The equivalents in educational research also apply. Further, some drugs may require ongoing, regular, very close monitoring, whilst others require less frequent monitoring. The point here is that medication is not a single event but, as the career of a disease and a patient changes over time, so does the treatment. Translating these practices from clinical research to educational research suggests that educational experiments need greater sensitivity to many confounding factors and to the need to address many kinds of threats to validity and reliability.

Though the analogy between clinical trials and educational experiments may not hold too strongly, for example, the former operating on a one-to-one patient–doctor relation and the latter typically operating on a one-to-many basis, and the former adopting a pathological model and the latter adopting a non-pathological model, nevertheless in educational experiments, this argues against a too-simplistic operation of randomized controlled trials, with its focus on average effects and its risk of overlooking the importance of outliers and sub-groups. This suggests that, to ensure validity and reliability in educational experiments, attention must be paid to: the whole person; contexts and other interventions and practices that are taking place in the educational experiences of students at the time of the experiment; duration, intensity and differential inputs into, operations of and responses to the intervention; and to the often non-linear and dynamical systems nature of the 'careers' of participants.

An experiment can be said to be internally valid to the extent that, within its own confines, its results are credible; but for those results to be useful, they must be generalizable beyond the confines of the particular experiment; in a word, they must be externally valid also (for a critique of randomized controlled experiments and the problems of generalizability, see Morrison, 2001; Cartwright and Hardie, 2012). Without internal validity an experiment cannot be externally valid, but the converse does not necessarily follow; an internally valid experiment may or may not have external validity.

It follows, then, that the way to reliable and valid educational experimentation lies in maximizing both internal validity and, where relevant, external validity.

14.13 Validity and reliability in questionnaires

Questionnaires feature in many types of research, from surveys to action research. Validity of questionnaires (however administered, e.g. face-to-face, postal, telephone, Internet) can be seen from two viewpoints (Belson, 1986). First, whether respondents who complete questionnaires do so accurately, honestly and correctly; and second, whether those who fail to return their questionnaires would have given the same distribution of answers as did the returnees.

As more and more questionnaires are conducted online, this brings with it the problem of honesty: are respondents really telling the truth about themselves and about the matters to which they have been asked to respond? Fowler (2009) gives the example of people under-reporting how many cigarettes they smoke each day or how much alcohol they drink (p. 16). Fowler also reports that respondents may not understand or may misunderstand a question, or they may not know the answer, or they may not be able to recall accurately, or they may not want to disclose information, or they may give what they believe to be the socially desirable answer rather than a 'true' answer, and all of these affect reliability (p. 105). Here the piloting of the

questionnaire and the guarantees of anonymity and non-traceability might attenuate such problems.

The question of accuracy can be checked by the intensive interview method, a technique consisting of tactics that include familiarization, temporal reconstruction, probing and challenging (cf. Belson, 1986, pp. 35–8).

The problem of non-response is addressed in Chapters 17 and 40. Hudson and Miller (1997) suggest several strategies for maximizing the response rate to questionnaires (and, thereby, to increase reliability), which involve:

- including stamped addressed envelopes (for postal questionnaires);
- multiple rounds of follow-up to request returns (maybe up to three follow-ups);
- stressing the importance and benefits of the questionnaire;
- stressing the importance of, and benefits to, the client group being targeted (particularly if it is a minority group that is struggling to have a voice);
- providing interim data from returns to non-returners to involve and engage them in the research;
- checking addresses and changing them if necessary;
- following up questionnaires with a personal telephone call;
- tailoring follow-up requests to individuals (with indications to them that they are personally known and/or important to the research – including providing respondents with clues by giving some personal information to show that they are known) rather than blanket generalized letters;
- features of the questionnaire itself (ease of completion, time to be spent, sensitivity of the questions asked, length of the questionnaire);
- invitations to a follow-up interview (face-to-face or by telephone);
- encouragement to participate by a friendly third party;
- understanding the nature of the sample population in depth, so that effective targeting strategies can be used.

The advantages of the questionnaire over interviews, for instance, are: it tends to be more reliable; because it is anonymous, it may encourage greater honesty (though, of course, dishonesty and falsification might not be able to be discovered in a questionnaire, and this is a particular issue in Internet questionnaires, where even the factual details about a respondent may be false). For example, an online respondent can create a different persona and make up responses (Shulman *et al*., 2011; Ramírez and Palu-ay, 2015). Further, a questionnaire is often more economical than the interview in terms of time and money, for example, it can be mailed or conducted online.

Its disadvantages, on the other hand, are: there is often too low a percentage of returns; the interviewer is unable to answer questions concerning both the purpose of the interview and any misunderstandings experienced by the interviewee, for it sometimes happens in the case of the latter that the same questions have different meanings for different people; if only closed items are used, the questionnaire may lack coverage or authenticity; if only open items are used, respondents may be unwilling to write their answers for one reason or another; questionnaires present problems to people of limited literacy; and an interview can be conducted at an appropriate speed whereas questionnaires are often filled in hurriedly. There is a need, therefore, to pilot questionnaires and refine their contents, wording, length, etc. as appropriate for the sample being targeted.

One central issue in considering the reliability and validity of questionnaire surveys is that of sampling. An unrepresentative, skewed sample, one that is too small or too large, can easily distort the data, and indeed, in the case of very small samples, prohibit statistical analysis. We address sampling in Chapter 12.

14.14 Validity and reliability in observations

There are questions about two types of validity in observation-based research. Comments about the subjective and idiosyncratic nature of the participant observation study are about its external validity. How do we know that the results of this one piece of research are applicable to other situations? Fears that observers' judgements will be affected by their close involvement in the group relate to the internal validity of the method. How do we know that the results of this one piece of research represent the real thing? In Chapter 12 on sampling, we refer to a number of techniques (quota sampling, snowball sampling, purposive sampling) that researchers employ as a way of checking on the representativeness of the events that they observe and of cross-checking their interpretations of the meanings of those events.

In addition to external validity, participant observation should have rigorous internal validity checks. There are several threats to validity and reliability here, for example:

- the researcher, in exploring the present, may be unaware of important antecedent events;

- informants may be unrepresentative of the sample in the study;
- the presence of the observer might bring about different behaviours (reactivity);
- the researcher might 'go native', becoming too attached to the group to see it sufficiently dispassionately.

To address this, Denzin (1989) suggests triangulation of data sources and methodologies. Chapter 26 discusses the principal ways of overcoming problems of reliability and validity in observational research in naturalistic inquiry. In essence it is suggested that 'trustworthiness' (Lincoln and Guba, 1985) replaces more conventional views of reliability and validity, and that this is devolved on issues of *credibility*, *confirmability*, *transferability* and *dependability*.

If observational research is more structured in its nature, yielding quantitative data, then the conventions of intra- and inter-rater reliability apply. Here steps are taken to ensure that observers enter data into the appropriate categories consistently (i.e. intra- and inter-rater reliability) and accurately. Further, to ensure validity, a pilot should have been conducted to ensure that the observational categories themselves are appropriate, exhaustive, discrete, unambiguous and effectively operationalize the purposes of the research.

14.15 Validity and reliability in tests

The researcher will have to judge the place and significance of test data, not forgetting the problem of the Hawthorne effect operating negatively or positively on students who undertake the tests. There is a range of issues which might affect the reliability of the test – for example, the time of day, the time of the school year, the temperature in the test room, the perceived importance of the test, the degree of formality of the test situation, 'examination nerves', the amount of guessing of answers by the students, how the test is administered and marked, the degree of closure or openness of test items. Hence the researcher who is considering using testing for acquiring research data must ensure that it is appropriate, valid and reliable (Linn, 1993; Borsboom *et al*., 2004).

Wolf (1994) suggests four main factors that might affect reliability: the range of the group that is being tested; the group's level of proficiency; the length of the measure (the longer the test, the greater the chance of errors); and the way in which reliability is calculated. (Fitz-Gibbon (1997, p. 36) argues that, *ceteris paribus*, longer tests are more reliable than shorter tests.) Additionally, there are several ways in which reliability might be compromised in tests. Feldt and Brennan (1993) suggest four types of threat to reliability:

- individuals (e.g. their motivation, concentration, forgetfulness, health, carelessness, guessing, their related skills, e.g. reading ability, their usedness to solving the type of problem set, the effects of practice);
- situational factors (e.g. the psychological and physical conditions for the test – the context);
- test marker factors (e.g. idiosyncrasy and subjectivity);
- instrument variables (e.g. poor domain sampling, errors in sampling tasks, the realism of the tasks and relatedness to the experience of the testees, poor question items, the assumption or extent of unidimensionality in item response theory, length of the test, mechanical errors, scoring errors, computer errors).

Sources of unreliability

There are several threats to reliability in tests and examinations, particularly tests of performance and achievement, for example (Cunningham, 1998; Airasian, 2001; Cohen *et al*., 2010; Creswell, 2012).

For example, with respect to *examiners* and *markers* these concern:

- errors in marking (e.g. attributing, adding and transfer of marks);
- inter-rater reliability (different markers giving different marks for the same or similar pieces of work);
- inconsistency in the marker (e.g. being harsh in the early stages of the marking and lenient in the later stages of the marking of many scripts);
- variations in the award of grades for work that is close to grade boundaries (some markers placing the score in a higher or lower category than other markers);
- the Halo effect, wherein a student who is judged to do well or badly in one assessment is given undeserved favourable or unfavourable assessment respectively in other areas.

With reference to the *students* and *teachers* themselves, there are several sources of unreliability:

- Motivation and interest in the task has a considerable effect on performance. Clearly, students need to be motivated if they are going to make a serious attempt at any test that they are required to

undertake, where motivation is intrinsic (doing something for its own sake) or extrinsic (doing something for an external reason, e.g. obtaining a certificate or employment or entry into higher education). The results of a test completed in a desultory fashion by resentful pupils are hardly likely to supply the researcher with reliable information about the students' capabilities (Wiggins, 1998). Motivation to participate in test-taking sessions is strongest when students have been helped to see its purpose, and where the examiner maintains a warm, purposeful attitude towards them during the testing session (Airasian, 2001).

- The relationship (positive to negative) between the assessor and the testee exerts an influence on the assessment. This takes on increasing significance in teacher assessment, where the students know the teachers personally and professionally – and vice versa – and where the assessment situation involves face-to-face contact between the teacher and the student. Both test-takers and test-givers mutually influence one another during examinations, oral assessments and the like (Harlen, 1994). During a face-to-face test, students respond to such characteristics of the assessor as the person's sex, age and personality.
- The conditions – physical, emotional, social – exert an influence on the assessment, particularly if they are unfamiliar. Wherever possible, students should take tests in familiar settings, preferably in their own classrooms under normal school conditions. Distractions in the form of extraneous noise, walking about the room by the examiner, and intrusions into the room, all have significant impact upon the scores of the test-takers, particularly when they are younger pupils (Gipps, 1994). An important factor in reducing students' anxiety and tension during an examination is the extent to which they are quite clear about what exactly they are required to do. Simple instructions, clearly and calmly given by the examiner, can significantly lower the general level of tension in the test-room. Teachers who intend to conduct testing sessions may find it beneficial in this respect to rehearse the instructions they wish to give to pupils before the actual testing session. Ideally, test instructions should be simple, direct and as brief as possible.
- The Hawthorne effect, wherein, in this context, simply informing a student that this is an assessment situation will be enough to disturb her performance – for better or worse (either case not being a fair reflection of her usual abilities).
- Distractions (including superfluous information).
- Students respond to the tester in terms of their perceptions of what he/she expects of them (Haladyna, 1997; Tombari and Borich, 1999; Stiggins, 2001).
- The time of the day, week or month will exert an influence on performance. Some students are fresher in the morning and more capable of concentration (Stiggins, 2001).
- Students are not always clear on what they think is being asked in the question; they may know the right answer but not infer that this is what is required in the question.
- The students may vary from one question to another – a student may have performed better with a different set of questions which tested the same matters. Black (1998) argues that two questions which, to the expert, may seem to be asking the same thing but in different ways, to the students might well be seen as completely different questions.
- Students (and teachers) practice test-like materials, which, even though scores are raised, might make them better at taking tests, but the results might not indicate increased performance.
- A student may be able to perform a specific skill in a test but not be able to select or perform it in the wider context of learning.
- Cultural, ethnic and gender background affect how meaningful an assessment task or activity is to students, and meaningfulness affects their performance.
- Students' personalities may make a difference to their test performance.
- Students' learning strategies and styles may make a difference to their test performance.
- Marking practices are not always reliable, markers maybe being too generous, marking by effort and ability rather than performance.
- The context in which the task is presented affects performance: some students can perform the task in everyday life but not under test conditions.

With regard to the *test items* themselves, there may be problems (e.g. test bias), for example:

- The task itself may be multi-dimensional, for example, testing 'reading' may require several components and constructs. Students can execute a mathematics operation in the mathematics class but they cannot perform the same operation in, for example, a physics class; students will disregard English grammar in a science class but observe it in an English class. This raises the issue of the number of contexts in which the behaviour must be

demonstrated before a criterion is deemed to have been achieved (Cohen *et al*., 2010). The question of transferability of knowledge and skills is also raised in this connection. The context of the task affects the student's performance.

- The validity of the items may be in question.
- Clarity of the test items (Creswell, 2012): the avoidance of ambiguity.
- The language of the assessment and the assessor exerts an influence on the testee, for example, if the assessment is carried out in the testee's second language or in a 'middle-class' code (Haladyna, 1997).
- The readability level of the task can exert an influence on the test, for example, a difficulty in reading might distract from the purpose of a test which is of the use of a mathematical algorithm.
- The size and complexity of numbers or operations in a test (e.g. of mathematics) might distract the testee who actually understands the operations and concepts.
- The number and type of operations and stages to a task – a student might know how to perform each element, but when they are presented in combination the size of the task can be overwhelming.
- The form and presentation of questions affect the results, giving variability in students' performances.
- A single error early on in a complex sequence may confound the later stages of the sequence (within a question or across a set of questions), even though the student might have been able to perform the later stages of the sequence, thereby preventing the student from gaining credit for all she or he can, in fact, do.
- Questions might favour boys more than girls or vice versa.
- Essay questions favour boys if they concern impersonal topics and girls if they concern personal and interpersonal topics (Haladyna, 1997; Wedeen *et al.*, 2002).
- Boys may perform better than girls on multiple-choice questions and girls perform better than boys on essay-type questions (perhaps because boys are more willing than girls to guess in multiple-choice items), and girls may perform better in written work than boys.
- Questions and assessment may be culture-bound: what is comprehensible in one culture may be incomprehensible in another.
- The test may be so long, in order to ensure coverage, that boredom and loss of concentration may impair reliability.

With regard to the *operational procedures* of the test, there may be variability in:

- the conditions operating at the time of the test (e.g. noise, distractions, ambient, temperature, time of day/week);
- the test administration, with unstandardized procedure in the timing, duration, teacher intervention, instructions given, distribution and collection of materials/test papers, monitoring etc.

Hence specific contextual factors can exert a significant influence on learning and this has to be recognized in conducting assessments, to render an assessment as unthreatening and natural as possible.

Harlen (1994, pp. 140–2) suggests that inconsistency and unreliability in teacher- and school-based assessment may derive from differences in: (a) interpreting the assessment purposes, tasks and contents, by teachers or assessors; (b) the actual task set, or the contexts and circumstances surrounding the tasks (e.g. time and place); (c) how much help is given to the test-takers during the test; (d) the degree of specificity in the marking criteria; (e) the application of the marking criteria and the grading or marking system that accompanies it; (f) how much additional information about the student or situation is being referred to in the assessment.

Harlen advocates the use of a range of moderation strategies, both before and after the tests, including:

- statistical reference/scaling tests;
- inspection of samples (by post or by visit);
- group moderation of grades;
- post hoc adjustment of marks;
- accreditation of institutions;
- visits of verifiers;
- agreement panels;
- defining marking criteria;
- exemplification;
- group moderation meetings.

Whilst moderation procedures are essentially post hoc adjustments to scores, agreement trials and practice marking can be undertaken *before* the administration of a test, which is particularly important if there are large numbers of scripts or several markers.

The issue here is that results as well as instruments should be reliable. Reliability is also addressed by:

- calculating coefficients of reliability, split-half techniques, the Kuder-Richardson formula, parallel/equivalent forms of a test, test/re-test methods, the alpha coefficient;
- calculating and controlling the standard error of measurement;

- increasing the sample size (to maximize the range and spread of scores in a norm-referenced test), though criterion-referenced tests recognize that scores may bunch around the high level (in mastery learning, for example), i.e. the range of scores might be limited, thereby lowering the correlation coefficients that can be calculated;
- increasing the number of observations made and items included in the test (in order to increase the range of scores);
- ensuring effective domain sampling of items in tests based on item response theory (a particular issue in Computer adaptive testing, introduced below (Thissen, 1990));
- ensuring effective levels of item discriminability and item difficulty.

Reliability not only has to be achieved but has to be seen to be achieved, particularly in 'high-stakes' testing (where a lot hangs on the results of the test, e.g. entrance to higher education or employment). Hence the procedures for ensuring reliability must be transparent. The difficulty here is that the more one moves towards reliability as defined above, the more the test will become objective, the more students will be measured as though they are standardized objects, and the more the test will become decontextualized.

An alternative form of reliability which is premised on a more constructivist psychology emphasizes the significance of context, the importance of subjectivity and the need to engage and involve the testee more fully than a simple test. This rehearses the tension between positivism, post-positivism and more interpretive approaches outlined in the first chapter of this book. Objective tests, as described in the present chapter, lean strongly towards the positivist/post-positivist paradigm, whilst more phenomenological and interpretive paradigms of social science research will emphasize the importance of settings, of individual perceptions, of attitudes, in short, of 'authentic' testing (e.g. by using non-contrived, non-artificial forms of test data, e.g. portfolios, documents, course work, tasks that are stronger in realism and more 'hands on'). Though this latter adopts a view which is closer to assessment rather than narrowly 'testing', nevertheless the two overlap, both can yield marks, grades and awards, both can be formative as well as summative, both can be criterion-referenced.

With regard to validity, it is important to note here that an effective test will ensure adequate:

- content validity (e.g. adequate and representative coverage of programme and test objectives in the test items, a key feature of domain sampling); content validity is achieved by ensuring that the content of the test fairly samples the class or fields of the situations or subject matter in question. Content validity is achieved by making professional judgements about the relevance and sampling of the contents of the test to a particular domain. It is concerned with coverage and representativeness rather than with patterns of response or scores. It is a matter of judgement rather than measurement (Kerlinger, 1986). Content validity will need to ensure several features of a test (Wolf, 1994): (a) test coverage (the extent to which the test covers the relevant field); (b) test relevance (the extent to which the test items are taught through, or are relevant to, a particular programme); (c) programme coverage (the extent to which the programme covers the overall field in question);
- criterion-related validity (where a high correlation coefficient exists between the scores on the test and the scores on other accepted tests of the same performance); criterion-related validity is achieved by comparing the scores on the test with one or more variables (criteria) from other measures or tests that are considered to measure the same factor. Wolf (1994) argues that a major problem facing test devisers addressing criterion-related validity is the selection of the suitable criterion measure. He cites the example of the difficulty of selecting a suitable criterion of academic achievement in a test of academic aptitude. The criterion must be: (a) relevant (and agreed to be relevant); (b) free from bias (i.e. where external factors that might contaminate the criterion are removed); (c) reliable – precise and accurate; (d) capable of being measured or achieved;
- construct validity (e.g. the clear relatedness of a test item to its proposed construct/unobservable quality or trait, demonstrated by both empirical data and logical analysis and debate, i.e. the extent to which particular constructs or concepts can account for performance on the test); construct validity is achieved by ensuring that performance on the test is fairly explained by particular appropriate constructs or concepts. As with content validity, it is not based on test scores, but is more a matter of whether the test items are indicators of the underlying, latent construct in question. In this respect construct validity also subsumes content and criterion-related validity. Construct validity is threatened by (a) under-representation of the construct, i.e. the test is too narrow and neglects significant facets of a construct, and (b) the inclusion of irrelevancies – excess variance;

- concurrent validity (where the results of the test concur with results on other tests or instruments that are testing/assessing the same construct/performance – similar to predictive validity but without the time dimension. Concurrent validity can occur simultaneously with another instrument rather than after some time has elapsed);
- face validity (that, superficially, the test appears – at face value – to test what it is designed to test);
- jury validity (an important element in construct validity, where it is important to agree on the conceptions and operationalization of an unobservable construct);
- predictive validity (where results on a test accurately predict subsequent performance – akin to criterion-related validity);
- consequential validity (where the inferences that can be made from a test are sound);
- systemic validity (Fredericksen and Collins, 1989) (where programme activities both enhance test performance and enhance performance of the construct that is being addressed in the objective). Cunningham (1998) gives an example of systemic validity where, if the test and the objective of vocabulary performance leads to testees increasing their vocabulary, then systemic validity has been addressed.

To ensure test validity, then, the test must demonstrate fitness for purpose as well as addressing the several types of validity outlined above. The most difficult for researchers to address, perhaps, is construct validity, as it argues for agreement on the definition and operationalization of an unseen, half-guessed-at construct or phenomenon. The community of scholars has a role to play here. We also refer readers here to Chapter 27 on testing.

14.16 Validity and reliability in life histories

Three central issues underpin the quality of data generated by life history methodology. They concern representativeness, validity and reliability. Plummer (1983) draws attention to a frequent criticism of life history research, namely that its cases are atypical rather than representative. To avoid this charge, he urges researchers to clarify and make explicit the life history in question's relationship to a wider population (Plummer, 1983) by way of appraising the subject on a continuum of representativeness and non-representativeness.

Reliability in life history research hinges on identifying sources of bias and applying techniques to reduce them. Bias arises from the informant, the researcher and the interactional encounter itself. Box 14.1, adapted

BOX 14.1 PRINCIPAL SOURCES OF BIAS IN LIFE HISTORY RESEARCH

Source: Informant
Is misinformation (unintended) given?
Has there been evasion?
Is there evidence of direct lying and deception?
Is a 'front' being presented?
What may the informant 'take for granted' and hence not reveal?
How far is the informant 'pleasing you'?
How much has been forgotten?
How much may be self-deception?

Source: Researcher
Attitudes of researcher: age, gender, class, race, religion, politics etc.
Demeanour of researcher: dress, speech, body language etc.
Personality of researcher: anxiety, need for approval, hostility, warmth etc.
Scientific role of researcher: theory held (etc.), researcher expectancy.

Source: The interaction
The encounter needs to be examined. Is bias coming from:
The physical setting – 'social space'?
The prior interaction?
Non-verbal communication?
Vocal behaviour?

Source: Adapted from Plummer (1983, table 5.2, p. 103)

from Plummer (1983), provides a checklist of some aspects of bias arising from these principal sources.

Several validity checks are available to researchers here. Plummer identifies the following:

1 The subject of the life history may present an autocritique of it, having read the entire product.
2 A comparison may be made with similar written sources by way of identifying points of major divergence or similarity.
3 A comparison may be made with official records by way of imposing accuracy checks on the life history.
4 A comparison may be made by interviewing other informants.

Essentially, the validity of any life history lies in its ability to represent the informant's subjective reality, that is to say, his or her definition of the situation.

14.17 Validity and reliability in case studies

Case studies can use quantitative, qualitative and mixed methods research, and we have indicated earlier in this chapter the canons of validity and reliability for these. Yin (2009) focuses on three main types of validity in case studies: construct, internal and external. Construct validity, he avers, can be addressed by using: (a) multiple sources of evidence (which can lead to convergent lines of enquiry) (pp. 41–2); (b) a chain of evidence (from case study questions to the protocols for the case study – those protocols which link case study questions to the topic in hand, to the evidentiary base, to the conclusions and reporting) (p. 123); and (c) key informants to review drafts of the case study report (p. 41).

Pattern matching can also be used for establishing construct validity (Yin, 2009, p. 41). Here a predicted pattern (a theoretical pattern) in the data is matched to an observed operational pattern and any plausible alternative theories are removed. Pattern matching here can correlate or compare the extent to which what actually occurred reflects the theoretical predictions or explanations (Trochim, 2006).

Internal validity, Yin (2009, p. 41) suggests, can be addressed by: (a) pattern matching; (b) building explanations and considering rival, alternative explanations, and using logic models (where the dependent variable at one stage becomes the independent variable in the next stage of the causal research in a time sequence and in which predicted and observed events are compared (pp. 149ff.)).

Case studies, given their context-specificity and emphasis on subjectivity, may have limited or no external validity; that is, they may not be generalizable. However, external validity, Yin observes, can be addressed by careful use of theory in the single-case studies, such that replication can be conducted (2009, p. 41). He suggests that 'analytic generalizability' (p. 43) may be possible, i.e. where a research strives to generalize from a particular set of findings to some broader or more enduring theory (p. 43). In this he notes the importance of replication studies (p. 44).

External validity here also has to consider the likelihood of transferability of the case study from one context to another, and whether those contexts and the causal connections (Cartwright and Hardie, 2012) between elements in those contexts differ.

Reliability, Yin suggests, benefits from a case study database (2009, p. 41) as this can provide the evidentiary source for checking, together with respondent validation. Yin underlines the importance of keeping careful documentary evidence here (p. 45) and of documenting all aspects and stages of the research so that they can be checked (i.e. transparency).

In essence, the points that Yin makes for addressing validity and reliability in case study research can apply to other types of educational research, and they act as a useful conclusion to this chapter.

Companion Website

The companion website to the book provides additional materials and PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Part 3
Methodologies for educational research

It is important to distinguish between design, methodology and instrumentation. Too often methods of data collection are confused with methodology, and methodology is confused with design. Part 2 provided an introduction to design issues and this part examines different methodologies of research, different styles, kinds of, and approaches to, research, separating them from methods – instruments for data collection. We identify key styles of educational research in this section: a bundle of approaches that come under the umbrella of naturalistic/qualitative/ethnographic types of research; historical and documentary research (entirely rewritten by Jane Martin); different kinds of survey, with an entirely new chapter on Internet surveys; case studies; different kinds of experiment, an extended review of randomized controlled trials and coverage of *ex post facto* research; a chapter on meta-analysis, research syntheses and systematic reviews (entirely rewritten by Harsh Suri), which takes account of the increased prominence given to these in the research community; action research; and an entirely rewritten and updated chapter on virtual worlds, social network software and netography in educational research (written by Stewart Martin). These chapters include more extended analysis of key issues and features of the different research styles that researchers can address in planning and implementing their research.

Although we recognize that these are by no means exhaustive, we suggest that they cover the major styles of research methodology. These take in quantitative as well as qualitative research, mixed methods, the emerging field of virtual worlds, social networking and netography, together with small-scale and large-scale approaches. Selecting research approaches is not a matter simply of preference, arbitrary or automatic decision making, but, like other aspects of research, is a deliberative process in which the key is the application of the notion of *fitness for purpose*. We do not advocate slavish adherence to a single methodology in research; indeed combining methodologies may be appropriate for the research in hand. The intention here is to shed light on the different styles of research, locating them in the paradigms of research introduced in Part 1.

The companion website to the book provides additional materials and PowerPoint slides for the chapters in this part, which can be found online at: www.routledge.com/cw/cohen.

Qualitative, naturalistic and ethnographic research

CHAPTER 15

The title of this chapter indicates that a wide range of types and kinds of qualitative research are addressed here. The chapter addresses several key issues in planning and conducting qualitative research:

- foundations of qualitative, naturalistic and ethnographic inquiry (theoretical bases of these kinds of research)
- naturalistic research
- ethnographic research
- critical ethnography
- autoethnography
- virtual ethnography
- phenomenological research
- planning qualitative, naturalistic and ethnographic research
- reflexivity
- doing qualitative research
- some challenges in qualitative, ethnographic and naturalistic approaches

There is no single blueprint for naturalistic, qualitative or ethnographic research, because there is no single picture of the world. Rather, there are many worlds and many ways of investigating them. In this chapter we set out a range of key issues in understanding these worlds.

'Qualitative research' is a loosely defined term that includes a vast range of kinds of research, has a wide range of meanings and covers a heterogeneity of fields (Preissle, 2006; Hammersley, 2013, p. 9), so much so that Hammersley (2013) suggests that, given this range, the term may no longer be a 'genuine or useful category' (p. 99). He quotes Bryman's (2008) view that qualitative research connotes the use of words rather than numbers (p. 366), and Sandelowski's (2001) view that it focuses on the attitudes towards understanding, experiences and interpretations by humans of the social world, and how to enquire about all of these (p. 893) (though, as Hammersley (2013, p. 2) notes, these are not exclusive to qualitative research). Hammersley defines qualitative research as:

> a form of social inquiry that tends to adopt a flexible and data-driven research design, to use relatively unstructured data, to emphasize the essential role of subjectivity in the research process, to study a number of naturally occurring cases in detail, and to use verbal rather than statistical forms of approach.
>
> (Hammersley, 2013, p. 12)

There are several purposes of qualitative research, for example, description, explanation, reporting, creation of key concepts, theory generation and testing. It is important to stress, at the outset, that, though there are many similarities and overlaps between naturalistic/ethnographic and qualitative methods, there are also differences between them. The former connotes long-term residence with an individual, group or specific community (cf. Swain, 2006, p. 206), whilst the latter, often being concerned with the nature of the data and the kinds of research question to be answered, is an approach that need not require naturalistic approaches or principles. That said, there are sufficient areas of commonality to render it appropriate to consider them in the same chapter, and we tease out differences between them where relevant. The intention of this chapter is to provide guidance for qualitative researchers who are conducting either long-term ethnographic research or small-scale, short-term qualitative research.

There are many varieties of qualitative research, indeed Preissle (2006, p. 686) remarks that qualitative researchers cannot agree on its purposes, boundaries, disciplinary fields or, indeed, its terminology (interpretive, naturalistic, qualitative, ethnographic, phenomenological, anthropological, symbolic interactionist, critical theoretical, case study, grounded theory etc.). However, she does indicate that qualitative research is characterized by a 'loosely defined' group of designs that elicit verbal, aural, observational, tactile, gustatory and olfactory information from a range of sources including audio, film, documents and pictures, that it draws strongly on direct experience and meanings, and that

these may vary according to the style of qualitative research undertaken.

Qualitative research provides an in-depth, intricate and detailed understanding of meanings, actions, non-observable as well as observable phenomena, attitudes, intentions and behaviours, and these are well served by naturalistic enquiry (Gonzales *et al*., 2008, p. 3). It gives voices to participants and it probes issues that lie beneath the surface of presenting behaviours and actions.

Qualitative research can be used in systematic reviews (Dixon-Woods *et al*., 2001; see also Chapter 21 of the present volume), to:

- identify and refine questions, fields, foci and topics of the review, i.e. to act as a precursor to a full review;
- provide data in their own right for a research synthesis;
- indicate and identify the outcomes that are of interest, and for whom;
- complement and augment data from quantitative reviews;
- fill gaps in quantitative reviews;
- explain the findings from quantitative reviews and data;
- provide alternative perspectives on topics;
- contribute to the drawing of conclusions from the review;
- be part of a multi-methods research synthesis;
- suggest how to turn evidence into practice.

Whilst the lack of controls in much qualitative research renders it perhaps unattractive for research syntheses, this is possibly unjustified, as it suggests that qualitative research has to abide by the rules of the game of quantitative approaches. Qualitative methods have their own tenets, and these complement very well those of numerical research. As with quantitative studies, qualitative studies have to be weighted, downgraded, upgraded or excluded according to the quality of the evidence and sampling that they contain. They also have to overcome the problem that, by stripping out the context in order to obtain themes and key concepts, they destroy the heart of qualitative research – context (Dixon-Woods *et al*., 2001, p. 131).

15.1 Foundations of qualitative, naturalistic and ethnographic inquiry

The social and educational world is a messy place, full of contradictions, richness, complexity, connectedness, conjunctions and disjunctions. It is multilayered and not easily susceptible to the atomization or aggregation processes inherent in much numerical research. It has to be studied in total rather than in fragments if a true understanding is to be reached. Chapter 1 indicated that several approaches to educational research are contained in the paradigm of qualitative, naturalistic and ethnographic research. The characteristics of that paradigm (Boas, 1943; Blumer, 1969; Lincoln and Guba, 1985; Woods, 1992; LeCompte and Preissle, 1993; Ary *et al*., 2002; Flick, 2009; Larsson, 2009; Hammersley, 2013, 2014; Pring, 2015; Wellington, 2015) can be set out ontologically (what is it we are trying to understand?), epistemologically (how can we know about something?) and methodologically (how can we research something?).

Ontology of qualitative research

- Qualitative research regards people as anticipatory, meaning-making beings who actively construct their own meanings of situations and make sense of their world and act in it through such interpretations (the constructivist/constructionist premise). People are deliberate, intentional and creative in their actions, and meaning arises out of social situations, interactions and negotiations, and is handled through the interpretive processes of the humans involved.
- Meanings used by participants to interpret situations are culture- and context-bound, and there are multiple realities, not single truths in interpreting a situation. History and biography intersect – we create our own futures but not necessarily in situations of our own choosing.
- Realities are multiple, constructed and holistic, capable of sustaining multiple interpretations, including those of all parties involved. People, situations, events and objects are unique and have meaning conferred upon them rather than possessing their own intrinsic meaning. Knower and known are interactive, inseparable.

Epistemology of qualitative research

- Behaviour and, thereby, data are socially situated, context-related, context-dependent and context-rich. To understand a situation researchers need to understand the context both specifically and holistically – the whole picture – because situations affect behaviour and perspectives and vice versa. One task of the researcher is to understand, describe and explain the multiple and differing interpretations of situations, their distinctiveness, causes and consequences.
- All factors, rather than a limited number of variables, have to be taken into account in understanding

a phenomenon. Research looks at relationships between elements in a whole system. As all entities are in a state of mutual simultaneous shaping, it is difficult, if not impossible, or inappropriate to distinguish causes from effects. The attribution of meaning is continuous and evolving over time.

- Social reality, experiences and social phenomena are capable of multiple, sometimes contradictory interpretations and are available to us through social interaction. Researchers focus on subjective accounts, views and interpretations of a phenomenon by the participants (including the researcher): their 'definition of the situation', which is typically reported verbally rather than numerically. Social research examines situations through the eyes of the participants; the task of ethnographies, as Malinowski (1922, p. 25) observed, is to grasp the point of view of the native [*sic*], his [*sic*] view of the world and in relation to his [*sic*] life.

Methodology of qualitative research

- Research must include 'thick descriptions' (Geertz, 1973) of the contextualized behaviour; for descriptions to be 'thick' requires inclusion not only of detailed observational data and data on meanings, participants' interpretations of situations and unobserved factors. Observational data are important, acquired from the natural, undisturbed setting, with participants speaking in their own terms and behaving 'naturally'. To understand and research a situation often requires long-term immersion in the system, not least as researchers do not know in advance what they will see or what they will look for.
- Social research should be conducted in natural, uncontrived, real-world settings with as little intrusiveness as possible by the researcher. Here data are collected systematically, analysed inductively and abductively, with constructs and findings deriving and inferred from the data during the research. Human phenomena seem to require even more conditional stipulations than do other kinds of phenomena, and meanings and understandings replace proof. Only time- and context-bound working hypotheses and idiographic statements are possible, and researchers generate rather than test hypotheses. Theory generation is derivative – grounded (Glaser and Strauss, 1967) – the data suggest the theory rather than vice versa.
- The *processes* of research and behaviour are as important as the outcomes. Research is value-bound and is influenced by the researcher's values as expressed in the choice of the focus of the research, its framing and bounding, method of working and data collection, analysing and reporting findings. Research is influenced by the choice of the paradigm that guides the investigation into the problem, and the choice of the substantive theory utilized to guide the collection and analysis of data and in the interpretation of findings. Research is influenced by the values that inhere in the context, which may be congruent or dissonant within and between the parties involved.
- Researchers are the instruments of the research (Eisner, 1991), blurring the distinction between the researcher and other participants and between subjective and objective facts, as 'objective facts' are mediated through subjective interpretations.
- Generalizability is interpreted as generalizability to identifiable, specific settings and subjects rather than universally. The context-specificity of the phenomenon being research often precludes generalization. Larsson (2009) suggests that generalization can be addressed through maximizing variation, context similarity and recognition of patterns (p. 28).

Hammersley (2013, pp. 29–34) notes the 'critical' tradition in qualitative research, in which situations are observed and interpreted through wide-angle lenses that include a focus on the multiple, intersecting, wider factors that bear on a situation, utilizing ideology critique with an interest in emancipation from oppression, exploitation, inequality, power and powerlessness, and un-freedoms, i.e. research with an overtly political intent to expose the deforming interests (ideologies) at work in a situation and to bring about a more just society.

Lincoln and Guba (1985, pp. 39–43), Ary *et al*. (2002, pp. 451–7) and Polkinghorne (2007) tease out implications of these axioms:

- studies must be set in their natural settings as context is heavily implicated in meaning;
- humans are the research instrument;
- utilization of tacit knowledge is inescapable;
- qualitative methods sit more comfortably than quantitative methods with the notion of the human-as-instrument;
- purposive sampling enables the full scope of issues to be explored;
- data analysis is inductive rather than a priori and deductive;
- theory emerges rather than being pre-ordinate. A priori theory is replaced by grounded theory;
- research designs emerge over time (and as the sampling changes over time);

- the outcomes of the research are negotiated;
- the natural mode of reporting is the case study;
- nomothetic interpretation is replaced by idiographic interpretation;
- applications are tentative and pragmatic;
- the focus of the study determines its boundaries;
- trustworthiness, credibility, theoretical adequacy, corroboration, interpretive adequacy, dependability and confirmability replace more conventional views of reliability and validity. Here a statement or claim for knowledge is not 'intrinsically valid'; rather, validity is a matter of 'intersubjective judgement' as determined by the community of participants (widely defined) and the force of the argument and evidence (Polkinghorne, 2007, pp. 474–5).

Whilst these points above suggest considerations in addressing quality in qualitative research (Hammersley, 2007), researchers will need to note that it is invidious to produce simplistic, single, permanent or universal lists of criteria for quality in qualitative research (Guba and Lincoln, 2005), as they may all too easily be a poor fit to the range of types and methodologies of qualitative research. Tracy (2010, p. 840), whilst being mindful of the dangers in this enterprise (p. 838), sets out and defends 'eight "big tent" criteria for excellent qualitative research':

1. *A worthy topic* (one which is timely, relevant, significant and interesting, pointing out surprises that challenge common-sense assumptions). Pelias (2015) notes that the researcher has to ask whose interests are being served by the research.
2. *'Rich rigor'*, with attention to the theoretical constructs used (matching the complexity of the phenomenon with the complexity of theoretical constructs), contexts, sampling, sufficient data to support the claims made and the levels of analysis applied, data collection and analysis, time in the field and transparency of data and analysis.
3. *Sincerity*: addressing self-reflexivity (discussed below) and introspection, honesty, vulnerability, authenticity and transparency concerning the research process, from entry to the field to exit from it, together with data analysis.
4. *Credibility*: 'trustworthiness, verisimilitude and plausibility of the research findings' (Tracy, 2010, p. 842), addressed by thick description, triangulation, multivocality, autoethnographies, member reflections, crystallization, demonstration of how the findings and conclusions were reached, persuasiveness of the claims in light of the warrants, concrete details and disclosure of tacit knowledge. In this respect Tracy (2010) notes (p. 844) that triangulation and crystallization may sit together uncomfortably, as triangulation suggests a single correct conclusion (accuracy) whilst crystallization (looking through a crystal from many different viewpoints to see many refracted images) yields different findings.
5. *Resonance*: readers find points of resonance with themselves (empathy, identification and reverberation) and are affected by the research through evocative, engaging, vivid and carefully worded representations, transferable findings to their own situation and 'naturalistic generalizations' (applicability to their own situation in improving practice).
6. *Significant contribution*: moving forward the field conceptually, theoretically, methodologically, practically, heuristically, morally and practically, which includes catalytic validity (see Chapter 14).
7. *Ethical*: attention to procedural ethics (see the discussion of ethics later in this chapter), situational (see Chapter 7), cultural, relational (awareness of the researcher's influence on other participants) and the ethics of leaving the research field.
8. *Meaningful coherence*: achievement of the study's purposes, fitness for purposes in methods and procedures used, linkages between literature, research questions, methods, findings and interpretations.

Lincoln and Guba (1985, pp. 226–47) set out ten elements in research design for qualitative studies:

1. Determining a focus for the inquiry;
2. Determining the fit of paradigm to focus;
3. Determining the 'fit' of the inquiry paradigm to the substantive theory selected to guide the inquiry;
4. Determining where and from whom data will be collected;
5. Determining successive phases of the inquiry;
6. Determining instrumentation;
7. Planning data collection and recording modes;
8. Planning data-analysis procedures;
9. Planning the logistics:
    a. prior logistical considerations for the project as a whole
    b. the logistics of field excursions prior to going into the field
    c. the logistics of field excursions while in the field
    d. the logistics of activities following field excursions
    e. the logistics of closure and termination;
10. Planning for trustworthiness.

These elements can be set out into a sequential, staged approach to planning naturalistic research (e.g. Schatzman and Strauss, 1973; Delamont, 1992). Spradley (1979) sets out the stages of: (i) selecting a problem; (ii) collecting cultural data; (iii) analysing cultural data; (iv) formulating ethnographic hypotheses; (v) writing the ethnography. We offer a fuller, twelve-stage model later in this chapter.

Like other styles of research, naturalistic and qualitative methods can formulate research questions which should be clear and unambiguous but open to change as the research develops. Strauss (1987) terms these 'generative questions': they stimulate the line of investigation, suggest initial hypotheses and areas for data collection, yet they do not foreclose the possibility of modification as the research develops. A balance must be struck between having research questions that are so broad that they do not steer the research in any particular direction, and so narrow that they block new avenues of enquiry (Flick, 2004b, p. 150).

Miles and Huberman (1994) identify two types of qualitative research design: loose and tight. Loose research designs have broadly defined concepts and areas of study, and, indeed, are open to changes of methodology. These are suitable, they suggest, when researchers are experienced and when the research is investigating new fields or developing new constructs, akin to the flexibility and openness of theoretical sampling (see Chapter 37). By contrast, a tight research design has narrowly restricted research questions and predetermined procedures, with limited flexibility. These, the authors suggest, are useful when researchers are inexperienced, when the research is intended to look at particular specified issues, constructs, groups or individuals, or when the research brief is explicit.

Even though, in qualitative research, issues and theories emerge from the data, this does not preclude the value of having research questions. Flick (1998, p. 51) suggests three types of research questions in qualitative research, namely, those concerned with: (a) describing states, their causes and how these states are sustained; (b) describing processes of change and consequences of those states; (c) suitability for supporting or not supporting hypotheses and assumptions or for generating new hypotheses and assumptions (the 'generative questions' referred to above).

Should one have a hypothesis in qualitative research?

We mentioned in Chapter 1 that positivist approaches typically test pre-formulated hypotheses and that a distinguishing feature of naturalistic and qualitative approaches is its reluctance to enter the hypothetico-deductive paradigm (e.g. Meinefeld, 2004, p. 153), not least because there is a recognition that the researcher influences the research and because the research is much more open and emergent in qualitative approaches. Indeed, Meinefeld, citing classic studies like Whyte's (1955) *Street Corner Society*, suggests that it is impossible to predetermine hypotheses, whether one wishes to or not, as prior knowledge cannot be presumed. Glaser and Strauss (1967) suggest that researchers should deliberately free themselves from all prior knowledge, even suggesting that it is impossible to read up in advance, as it is not clear what reading will turn out to be relevant – the data speak for themselves. Theory is the end point of the research, not its starting point.

One has to be mindful that the researcher's own background interest, knowledge and biography precede the research and that though initial hypotheses may not be foregrounded in qualitative research, nevertheless the initial establishment of the research presupposes a particular area of interest, i.e. the research and data for focus are not theory-free; knowledge is not theory-free. Indeed Glaser and Strauss (1967) acknowledge that they brought their own prior knowledge to their research on dying.

The resolution of this apparent contradiction – the call to reject an initial hypothesis in qualitative research, yet a recognition that all research commences with some prior knowledge or theory that gives rise to the research, however embryonic – lies in several fields. These include: an openness to data (Meinefeld, 2004, pp. 156–7); a preparedness to modify one's initial presuppositions and position; a declaration of the extent to which the researcher's prior knowledge may be influencing the research (i.e. reflexivity); a recognition of the tentative nature of one's hypothesis; a willingness to use the research to generate a hypothesis; and an acknowledgement that having a hypothesis may be just as much a part of qualitative research as it is of quantitative research.

An alternative to research hypotheses in qualitative research is a set of research questions, and we consider these below. For qualitative research, Miles and Huberman (1994, p. 74) also suggest the replacement of 'hypotheses' with 'propositions', as this indicates that the qualitative research is not necessarily concerned with testing a predetermined hypothesis as such but, nevertheless, is concerned to be able to generate and test a theory (e.g. grounded theory).

15.2 Naturalistic research

Main *kinds* of naturalistic enquiry are (Arsenault and Anderson, 1998, p. 121; Flick, 2004a, 2004b, 2009):

- *case study* (an investigation into a specific instance or phenomenon in its real-life context);
- *comparative studies* (where several cases are compared on the basis of key areas of interest);
- *retrospective studies* (which focus on biographies of participants or which ask participants to look back on events and issues);
- *snapshots* (analyses of particular situations, events or phenomena at a single point in time);
- *longitudinal* studies (which investigate issues or people over time);
- *ethnography* (a portrayal and explanation of social groups and situations in their real-life contexts);
- *grounded theory* (developing theories to explain phenomena, the theories emerging from the data rather than being prefigured or predetermined);
- *biography* (individual or collective);
- *phenomenology* (seeing things as they are really like and establishing the meanings of things through illumination and explanation rather than through taxonomic approaches or abstractions, and developing theories through the dialogic relationships of researcher to researched).

The main *methods* for data collection in naturalistic enquiry are (Hammersley and Atkinson, 1983):

- participant observation
- interviews and conversations
- documents and field notes
- accounts
- notes and memos.

Ary *et al*. (2002) add to these grounded theory and historical research.

Lofland (1971) suggests that naturalistic methods are intended to address three major questions:

- What are the characteristics of a social phenomenon?
- What are the causes of the social phenomenon?
- What are the consequences of the social phenomenon?

These include: (a) the environment; (b) people and their relationships; (c) behaviour, actions and activities; (d) verbal behaviour; (e) psychological stances; (f) histories; and (g) physical objects (Baker, 1994, pp. 241–4).

There are several key differences between the naturalistic approach and that of the positivists to whom we made reference in Chapter 1. LeCompte and Preissle (1993, pp. 39–44) suggest that ethnographic approaches are concerned with description rather than prediction, induction rather than deduction, generation rather than verification of theory, construction rather than enumeration, and subjectivities rather than objective knowledge. With regard to the latter, they distinguish between *emic* approaches (as in the term 'phonemic', where the concern is to catch the subjective meanings placed on situations by participants) and *etic* approaches (as in the term 'phonetic', where the intention is to identify and understand the objective or researcher's meaning and constructions of a situation) (p. 45).

Woods (1992), however, argues that some differences between quantitative and qualitative research are exaggerated, that the epistemological contrast between the two is overstated, as qualitative techniques can be used for both generating and testing theories.

15.3 Ethnographic research

As the 'interview society' is losing ground to the 'observation society' (Gobo, 2011), ethnography, being largely observation-based, is coming into prominence. LeCompte and Preissle (1993) suggest that ethnographic research seeks to create as vivid and analytical a reconstruction as possible of the culture or groups being studied (p. 235). An ethnography is a descriptive, analytical and explanatory study of the culture (and its components), values, beliefs and practices of one or more groups (e.g. Creswell, 2012, p. 462; Bhatti, 2012; Denscombe, 2014). It can study a small group (a few people: micro-ethnography) (p. 463) or a larger group/society/community, and, in autoethnography, an individual in a social setting. Though it typically uses qualitative data, it does not preclude the use of relevant quantitative data (Hamersley, 2006).

LeCompte and Preissle (1993) and Denscombe (2014) indicate several key elements of ethnographic approaches:

- the world view of the participants is investigated and represented – their 'definition of the situation' (Thomas, 1923);
- data are elicited and gathered;
- researchers spend considerable amounts of time in the field – immersion – to research the everyday as well as the non-normal aspects of the culture, group, etc. (though Hammersley (2006) notes that, in comparison to earlier times, much fieldwork includes shorter rather than longer stays in the field, and this may risk loss of important historical contextual information and the danger of assuming that the data

collected are a fair representation of the entire situation);
- meanings are accorded to phenomena by both the researcher and the participants; the process of research, therefore, is hermeneutic, uncovering meanings;
- the constructs of the participants are used to structure the investigation;
- empirical data are gathered in their naturalistic setting (unlike laboratories or in controlled settings as in other forms of research where variables are manipulated);
- observational techniques are used extensively (both participant and non-participant) to acquire data on real-life settings;
- the research is holistic, that is, it seeks a description and interpretation of 'total phenomena';
- there is a move from description and data to inference, explanation, suggestions of causation, and theory generation;
- methods are 'multimodal' and the ethnographer is a 'methodological omnivore' (LeCompte and Preissle, 1993, p. 232).

Hitchcock and Hughes (1989, pp. 52–3) suggest that ethnographies involve:

- the production of descriptive cultural knowledge of a group;
- the description of activities in relation to a particular cultural context from the point of view of the members of that group themselves;
- the production of a list of features constitutive of membership in a group or culture;
- the description and analysis of patterns of social interaction;
- the provision as far as possible of 'insider accounts';
- the development of theory.

Bryman (2008) notes that ethnographic researchers immerse themselves in the group or society which they are studying in order to collect field data which may comprise descriptive notes and analytical comments about the culture of the members of the society or group which they are studying, including the views and definitions of the situation of the members themselves, which are then written up in way that is amenable and accessible to the target audience or readership. An ethnography moves beyond description to data analysis, to theory generation and, if appropriate, to hypothesis generation, to explain what is happening and observed in a situation, group, culture or society and why, what are its key dynamics, in short to understand why the group, culture or society is acting as it does and what can be learned from this.

In educational research, Walford (2009) notes that ethnographies can use multiple data types to focus in depth on cultural formations and maintenance: how the culture works (p. 273). Knowledge about these is obtained through sustained, long-term immersion and involvement in the group, giving importance to the 'accounts of participants' perspectives and understandings' (p. 272), all of which lead to the formation of hypotheses and theory testing which can provide the basis for theoretical generalization and, indeed, subsequent data collection (p. 272). Like Hammersley (2006), Walford does not rule out quantitative data. Ethnography, Walford avers (p. 275), is story-telling, with the researcher centrally involved in the generation and telling of the story (p. 275).

For Denscombe (2014, p. 90), the attractions of ethnographies are that they use detailed and direct observational data; they focus on holism in the research; bring a fresh eye to the obvious, ordinary, taken-for-granted and everyday behaviour; take seriously the participants' views; have strong ecological validity; and are self-aware (see section below, 'Reflexivity'). On the other hand, he notes that ethnographies have to balance objective descriptions of events and cultures with the researcher's own interpretation of these, and they have to avoid the risk of creating isolated 'pictures' of situations which lack an overall structure. Ethnographers and ethnographies must not sacrifice analysis to telling a story. Ethnographies are difficult – if not impossible – to replicate or to check, and they raise difficult ethical issues more prominently than other approaches (discussed below), and researchers may experience difficulties in gaining access to the research setting (p. 91).

Dobbert and Kurth-Schai (1992) urge not only that ethnographic approaches become more systematic but that they study and address regularities in social behaviour and social structure (pp. 94–5). The task of ethnographers (p. 150) is to balance a commitment to catching the diversity, variability, creativity, individuality, uniqueness and spontaneity of social interactions (e.g. by 'thick descriptions'; Geertz, 1973) with a commitment to the task of social science to seek regularities, order and patterns within such diversity. As Durkheim (1982) noted, there are 'social facts'.

Following this line, it is possible to suggest that ethnographic research can address issues of generalizability – a tenet of positivist research – interpreted as 'comparability' and 'translatability' (LeCompte and Preissle, 1993, p. 47). For comparability, the characteristics of the group that is being studied need to be made

explicit so that readers can compare them with other similar or dissimilar groups. For translatability, the analytic categories used in the research as well as the characteristics of the groups are made explicit so that meaningful comparisons can be made to other groups and disciplines.

Spindler and Spindler (1992, pp. 72–4) put forward several hallmarks of effective ethnographies:

- Observations have contextual relevance, both in the immediate setting in which behaviour is observed and in further contexts beyond.
- Hypotheses emerge *in situ* as the study develops in the observed setting.
- Observation is prolonged and often repetitive. Events and series of events are observed more than once to establish reliability in the observational data.
- Inferences from observation and various forms of ethnographic inquiry are used to address insiders' views of reality.
- A major part of the ethnographic task is to elicit socio-cultural knowledge from participants, rendering social behaviour comprehensible.
- Instruments, schedules, codes, agenda for interviews, questionnaires, etc. should be generated *in situ*, and should derive from observation and ethnographic inquiry.
- A transcultural, comparative perspective is usually present, although often it is an unstated assumption, and cultural variation (over space and time) is natural.
- Some socio-cultural knowledge that affects behaviour and communication under study is tacit/implicit, and may not be known even to participants or known ambiguously to others. It follows that one task for an ethnographer is to make explicit to readers what is tacit/implicit to informants.
- The ethnographic interviewer should not frame or predetermine responses by the kinds of questions that are asked, because the informants themselves have the emic, native cultural knowledge.
- In order to collect as much live data as possible, any technical device may be used.
- The ethnographer's presence should be declared and his or her personal, social and interactional position in the situation should be described.

Ethnographic researchers will need to consider whether to employ interviewing at all, as it is a non-natural situation, or, if it is to be used, what form it will take – away from the interviewer as 'miner' (Kvale, 1996) – seeking nuggets of information (see Chapter 25) – and moving towards the interviewer as 'traveller' in a collaborative journey along the road of knowledge creation for both interviewer and interviewee, i.e. as part of a mutually empowering relationship (e.g. Edwards and Holland, 2013, p. 32).

With 'mutual shaping and interaction' between the researcher and participants taking place (Lincoln and Guba, 1985, p. 155), the researcher becomes, as it were, the 'human instrument' in the research (p. 187), building on her tacit knowledge and her propositional knowledge, using methods that sit comfortably with human inquiry, for example, observations, interviews, documentary analysis and 'unobtrusive' methods (p. 187). The advantage of the 'human instrument' is her adaptability, responsiveness, knowledge, ability to handle sensitive matters, ability to see the whole picture and ability to clarify, summarize, explore, analyse and examine atypical or idiosyncratic responses (pp. 193–4). Here Hammersley (1992b) comments on the risk of researcher bias (see section below on 'Reflexivity').

Denscombe (2014) notes that ethnographies can include life histories, and they need to provide thick descriptions and use both idiographic and nomothetic approaches, the former to produce a detailed picture of the unique situation/culture/group and the latter to produce theories that can apply beyond the situation in question.

A key concern for ethnographers is how far out to go in order to understand a situation (macro issues affecting, contextualizing, locating or contributing to the situation in hand) or how far in to go in focusing on a situation (micro ethnography). In other words, if ethnography celebrates holism, what is the whole and how are data about the whole to be gathered (Hammersley, 2006, pp. 6–7)?

15.4 Critical ethnography

One branch of ethnography that resonates with the critical paradigm outlined in Chapter 3 is critical ethnography – 'critical theory in action' (Madison, 2005, p. 13), which, as Thomas (1993, p. vii) suggests, adopts a 'subversive worldview' to conventional traditions of research. Marshall and Rossman (2016) note that critical ethnography has a wide embrace, taking in different kinds of critical theory, queer theory, critical race theory, autoethnography, feminist theories, critical discourse analysis, participatory action research, cultural studies, post-colonial theories and Internet studies.

Whereas conventional ethnography is concerned with what is, critical ethnography concerns itself with what could or should be (Thomas, 1993, p. 4). Here

qualitative, anthropological, participant, observer-based research has its theoretical basis in critical theory (Quantz, 1992, p. 448; Carspecken, 1996; Creswell, 2012). As outlined in Chapter 3, this paradigm is concerned with the exposure of oppression and inequality in society with a view to emancipating individuals and groups towards collective empowerment. In this respect, research is an inherently political enterprise; it is ethnography with a political intent (cf. Thomas, 1993, p. 4). Madison (2005, p. 5) indicates that critical ethnography has an explicit agenda and an 'ethical responsibility' to promote freedom, social justice, equity and well-being. This, he avers, inevitably involves disturbing accepted meanings and disrupting the status quo and purported neutrality of research, together with exposing taken-for-granted, 'domesticated' (Thomas, 1993, p. 7) assumptions that perpetuate the power of the already powerful at the expense of the powerless and the dominated.

Critical ethnography takes power, control, empowerment, privilege, repression, hegemony, victimization, marginalization and social exploitation as problematic and to be changed rather than simply to be interrogated and discovered (Thomas, 1993, p. 6; Creswell, 2012, p. 467). Like ethnography, it catches ethnographic data, but, beyond this, exposes the data to the ideology critique (see Chapter 3).

Like Habermas's *emancipatory interest* (see Chapter 3 of this volume), research is not simply a scientific, technical exercise, nor is it simply a hermeneutic matter of understanding and interpreting a situation; it does not reject these, but it requires the researcher to move beyond them to engage change (Thomas, 1993, p. 19) as a political act, and it must play its part as activism against hegemonic oppression. Here researchers have to consider their own 'positionality' in this enterprise (Madison, 2005, p. 7), i.e. how their research will help to break domination and inequality. Researchers and their research are neither neutral nor innocent. Both subjectivity and objectivity have to be interrogated for their political stances and effects (p. 8) in relation to those being researched (the 'Others') (p. 9); the research has to make a positive difference to the worlds of the 'Others' (the participants). This moves the ethnographer beyond simply being reflexive to being an activist.

This is contentious: on the one hand it suggests that the researcher is an ideologue (rather than, say, a cool theorist); on the other hand, the claim made is that, like it or not, research is a political act, and that this has been hidden in much research.

Carspecken (1996, pp. 4ff.) suggests several key premises of critical ethnography:

- research and thinking are mediated by power relations;
- these power relations are socially and historically located;
- facts and values are inseparable;
- relationships between objects and concepts are fluid and mediated by the social relations of production;
- language is central to perception;
- certain groups in society exert more power than others;
- inequality and oppression are inherent in capitalist relations of production and consumption;
- ideological domination is strongest when oppressed groups see their situation as inevitable, natural or necessary;
- forms of oppression mediate each other and must be considered together (e.g. race, gender, class).

Quantz (1992, pp. 473–4) argues that research is inescapably value-laden in that it serves some interests, and that in critical ethnography researchers must expose these interests and move participants towards emancipation and freedom. The focus and process of research, at heart political, concern issues of power, domination, voice and empowerment (cf. Lather, 1991). In critical ethnography the cultures, groups and individuals being studied are located in contexts of power and interests. These contexts must be exposed, their legitimacy interrogated and the value base of the research itself exposed. Reflexivity is high in critical ethnography. What separates critical ethnography from other forms of ethnography is that in the former, questions of legitimacy, power, values in society and domination and oppression are foregrounded.

How does the critical ethnographer proceed? This is not an easy task, as critical ethnography focuses on, and challenges, taken-for-granted assumptions and meanings, and these may be difficult to expose simply because they are so taken-for-granted, i.e. embedded in our daily lifeworlds and behaviour. In this sense a critical ethnography is untidy, the study emerges rather than being planned in advance; areas of focus emerge as meanings are revealed and challenged from the position of ideology critique (Thomas, 1993, p. 35). It starts with unsettling issues in society and explores them further (Thomas gives the examples of prisons, the social construction of deviance, racism, prejudice and repressive legislation).

Carspecken and Apple (1992, pp. 512–14) and Carspecken (1996, pp. 41–2) identify five stages in critical ethnography (Figure 15.1).

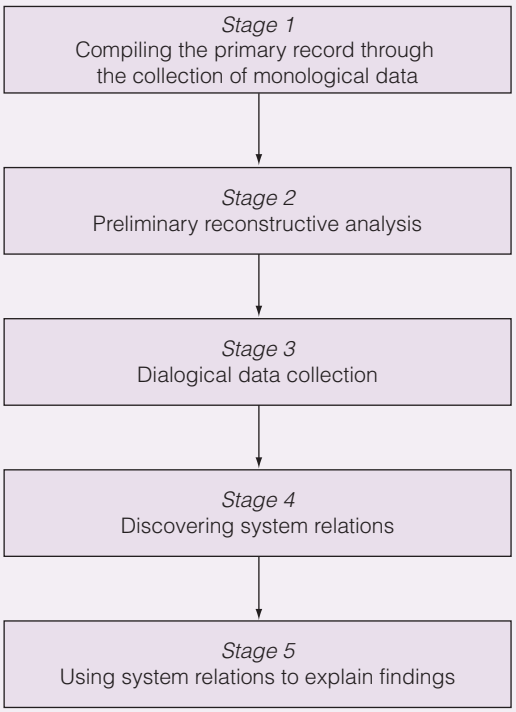

FIGURE 15.1 Five stages in critical ethnography

Stage 1: Compiling the primary record through the collection of monological data

At this stage the researcher is comparatively passive and unobtrusive: a participant observer. The task here is to acquire *objective* data and it is 'monological' in the sense that it concerns only the researcher writing her own notes to herself. Lincoln and Guba (1985) suggest that validity checks at this stage will include:

1. using multiple devices for recording together with multiple observers;
2. using a flexible observation schedule in order to minimize biases;
3. remaining in the situation for a long time in order to overcome the Hawthorne effect;
4. using low-inference terminology and descriptions;
5. using peer-debriefing;
6. using respondent validation.

Echoing Habermas's (1979, 1982, 1984) work on speech-act validity claims, validity here includes truth (the veracity of the utterance), legitimacy (rightness and appropriateness of the speaker), comprehensibility (that the utterance is comprehensible) and sincerity (of the speaker's intentions). Carspecken (1996, pp. 104–5) takes this further in suggesting several categories of reference in objective validity: (i) that the act is comprehensible, socially legitimate and appropriate; (ii) that the actor has a particular identity and particular intentions or feelings when the action takes place; (iii) that objective, contextual factors are acknowledged.

Stage 2: Preliminary reconstructive analysis

Reconstructive analysis attempts to uncover the taken-for-granted components of meaning or abstractions that participants have of a situation. Such analysis is intended to identify the value systems, norms and key concepts that are guiding and underpinning situations. Carspecken (1996, p. 42) suggests that the researcher go back over the primary record from stage one to examine patterns of interaction, power relations, roles, sequences of events, and meanings accorded to situations. He asserts that what distinguishes this stage as 'reconstructive' is that cultural themes and social and system factors that are not usually articulated by the participants themselves are, in fact, reconstructed and articulated, turning the undiscursive into discourse. Moving to higher-level abstractions, this stage can utilize high-level coding (see the discussion of coding below).

In critical ethnography, Carspecken (p. 141) recommends several ways to ensure validity at this stage:

1. use interviews and group discussions with the subjects themselves;
2. conduct member checks on the reconstruction in order to equalize power relations;
3. use peer debriefing (a peer is asked to review the data to suggest if the researcher is being too selective, e.g. of individuals, of data, of inference) to check biases or absences in reconstructions;
4. employ prolonged engagement to heighten the researcher's capacity to assume the insider's perspective;
5. use 'strip analysis' – checking themes and segments of extracted data with the primary data, for consistency;
6. use negative case analysis.

Stage 3: Dialogical data collection

Here data are generated by, and discussed with, the participants (Carspecken and Apple, 1992). The authors argue that this is non-naturalistic in that the participants are being asked to reflect on their own situations, circumstances and lives and to begin to theorize about

their lives. This is a crucial stage because it enables the participants to have a voice, to democratize the research. It may be that this stage produces new data which challenge the preceding two stages.

In introducing greater subjectivity by participants into the research at this stage, Carspecken (1996, pp. 164–5) proffers several validity checks, for example: (a) consistency checks on interviews that have been recorded; (b) repeated interviews with participants; (c) matching observation with what participants say is happening or has happened; (d) avoiding leading questions at interview, reinforced by having peer debriefers check on this; (e) respondent validation; (f) asking participants to use their own terms in describing naturalistic contexts, and encouraging them to explain these terms.

Stage 4: Discovering system relations

This stage relates the group being studied to other factors that impinge on that group, for example: local community groups, local sites that produce cultural products. At this stage Carspecken (1996, p. 202) notes that validity checks will include: (i) maintaining the validity requirements of the earlier stages; (ii) seeking a match between the researcher's analysis and the commentaries that are provided by the participants and other researchers; (iii) using peer debriefers and respondent validation.

Stage 5: Using system relations to explain findings

This stage seeks to examine and explain the findings in light of macro-social theories (Carspecken, 1996, p. 202). In part, this is a matching exercise to fit the research findings within a social theory.

In critical ethnography, therefore, the move is from describing a situation to understanding it, to questioning it and to changing it. This parallels the stages of ideology critique set out in Chapter 3:

Stage 1: a description of the existing situation – a hermeneutic exercise;
Stage 2: a penetration of the reasons that brought the situation to the form that it takes;
Stage 3: an agenda for altering the situation;
Stage 4: an evaluation of the achievement of the new situation.

Critical ethnographies can also be conducted online (Evans, 2010), and we turn to this later in the present chapter.

15.5 Autoethnography

Autoethnography, a derivative of ethnography, is a process, method and product that 'seeks to describe and systematically analyze (*graphy*) personal experience (*auto*) in order to understand cultural experience (*ethno*)' (Ellis *et al*., 2011, p. 1; cf. Reed-Danahay, 1997) and to 'extend sociological understanding' (Wall, 2008, p. 39) by looking at oneself in a wider context. Autoethnographies are 'highly personalized accounts that draw upon the experience of the author/researcher for the purposes of extending sociological understanding' (Sparkes, 2000, p. 21). For examples of this, see Reed-Danahay (1997), Ellis (2004) and Chang (2008).

An autoethnography places the self – the researcher – at the centre of research about himself/herself in a social context; it is self-focused (Ngunjiri *et al*., 2010), though it can engage collaborative as well as individual study (Denshire, 2014). It examines the relationship of the researcher to others through the eyes of the researcher and connects the personal, autobiographic to the social and cultural (Ellis, 2004, p. xix).

Autoethnography often has a deliberate political, social, critical theoretical and emancipatory or transformative agenda (Belbase *et al*., 2008; Bettez, 2015; see Chapter 3 and the comments above on critical ethnography) and it focuses on 'things that matter a great deal to the autoethnographer' (Delamont, 2009, p. 57). It problematizes and interrogates the socially constructed self and the situatedness and relationship of self to others (Starr, 2010, p. 3). For educationists, it has been likened to a form of critical pedagogy in its commitment to transformative and emancipatory processes and the social construction of knowledge (Starr, 2010, p. 4).

Autoethnography concerns studying and writing about our personal and socio-cultural selves, identities and the human condition (Dyson, 2007; Nicol, 2013; Marshall and Rossman, 2016, p. 24), on the assumption that the individual mirrors a social group (Walford, 2009, p. 276). Autoethnography differs from autobiography in that in the latter the focus is only on the self, whilst in the former the focus is on the self in context, typically a socio-cultural context. Denshire (2014) notes that autoethnography moves beyond autobiography 'whenever writers critique the depersonalizing tendencies that can come into play in social and cultural spaces that have asymmetrical relations of power' (p. 833). Autoethnography here concerns how one is 'othered' (Hamilton *et al*., 2008, p. 22) and how one's 'positionality' (discussed later in this chapter) affects the researcher and what is researched (Starr, 2010).

Here emphasis is placed on the writing of the research in a personal, authentic, vivid, engaging and

evocative style, 'writing from the heart' (Denzin, 2006, p. 422) and celebrating the researcher's 'voice' (Wall, 2006, p. 3). As Ellis and Bochner (2006) note, autoethnography catches passion, feelings, struggles, i.e. to evoke the empathy, emotions and sympathy of the reader, indeed for the reader to take action (p. 433), with ideas grounded in the personal experiences of their author, and written in a way that promotes empathy between readers and the 'other' in research.

By contrast, Anderson (2006) and Atkinson (2006) argue for an 'analytic' rather than 'evocative' stance to doing and writing autoethnography, and Anderson (2006) sets out five features of analytic autoethnography: complete member research status (the researcher is a member of the social world being studied); analytic reflexivity (an awareness of, and introspection about, the reciprocal influence of settings, data and researcher) (p. 382); narrative visibility of the researcher's self; dialogue with informants beyond the self; and commitment to theoretical analysis.

Autoethnography recognizes the unavoidable influence of the researcher on the research process, and raises reflexivity (discussed below), subjectivity, emotionality, personal characteristics of the researcher and autobiography to new prominence in the research (cf. Wall, 2006, 2008; Nicol, 2013). It focuses on, and reflects on, the views, 'confessional tales' (Van Maanen, 1988) and analyses of the author on the personal experiences of self and others included in his or her experiences. The author is the participant, looking at himself/herself in socio-cultural locations and terms. In implicating others (often family members, friends and social contacts) in that personal ethnography, ethical issues are raised concerning the confidentiality, anonymity, privacy, safety and protection, non-identifiability and non-traceability of those others and their communities, and relations (sometimes intimate) between the researcher and his/her circle of contacts, social circles and workplace groups. Not only are the 'others' vulnerable, but so is the researcher, the subject of the autoethnography, as self-disclosure about sensitive personal issues can be damaging (Ngunjiri *et al*., 2010).

The consequences of the written autoethnography for the author and others included have to be considered (e.g. Wall, 2006, 2008). This may lead to the need for respondent validation (raising issues of what happens if the respondent wishes to veto data) (Bettez, 2015), or for the removal of identifying features, or changing identifying features (e.g. gender, race, location, appearance) (Ellis *et al*., 2011). The researcher also has to consider the danger of selective memory on his/her part, for example, we may recall but unconsciously distort vivid experiences, raising issues of the credibility and trustworthiness of the report, and these are ethical matters in themselves (cf. Wall, 2006, 2008; Bochner, 2007; Walford, 2009).

Further, in seeking an expressive, evocative style of writing with the intent of reconstructing the authenticity of a lived experience and persuading, touching or moving the reader, there is the danger of subordination of the facts of the case to the emotional response; whether this is legitimate is a moot point – it may be acceptable or out of court. Anderson (2006), for example, as mentioned above, argues for a more analytical than evocative approach to writing autoethnography, whilst Denshire (2014) argues that autoethnography is an essential part of a 'fictive tradition' (p. 836).

In terms of method, autoethnography combines autobiography with ethnography (Ellis *et al*., 2011, p. 2), as the researcher reviews personal experience reflexively, usually retrospectively, and from this analyses and distils key issues about that autobiography from an ethnographic stance, i.e. what the personal experiences say to the reader about culture, values, relations and society in relation to the topic of research interest. This may include writing about moments of existential crisis, turning points ('epiphanies') and life-changing moments.

Autoethnography uses the common tools of ethnography, such as field notes, documents, self-observation and observation of others, interviews, dialogues and conversations (though see the comments later in this chapter about interviews), thick descriptions, reflexivity, grounded theory, long-term attachment and observations of events, times, locations, personal accoutrements such as clothing and artefacts, relationships, power and social life.

An autoethnography is often written in the first person and uses emotional terms, in contrast to much standard academic writing which deliberately adopts a third-person, passive voice and neutral, objective tone. It is often written as a story or narrative and as a personal experience (Marshall and Rossman, 2016, p. 24), with an aesthetic sense as well as a factual basis (Ellis *et al*., 2011). Such storied texts may focus on inequality, oppression, exploitation, subordination, lack of understanding or acceptance (e.g. issues of gender, sexuality, race), injustice, marginalization, stigmatization and 'dominant discourses' (Ellis and Bochner, 2000; Wall, 2008). Less politically or critically, autoethnography may concern issues or experiences that are important to the researchers (e.g. Dyson, 2007; Nicol, 2013). Writing an autoethnography can be therapeutic and cathartic as well as constituting a method of enquiry (Richardson, 2000; Roth, 2009).

Autoethnography is not without its critics (Anderson, 2006; Delamont, 2007, 2009; Ellis *et al*., 2011). For example, it is accused of being an indulgence of the writer, conflating autobiography with research, lacking analytical and theoretical rigour, failing to generate or to test hypotheses or theories, bringing emotions into what should be neutral work, and making reflexivity a thing in itself rather than a tool of ethnography (e.g. Atkinson, 1997; Sparkes, 2000; Wall, 2006). It might be good for the writer, privileging the self (Hamilton *et al*., 2008, p. 17), but of little use to others.

Delamont (2007) argues trenchantly that 'autoethnography is essentially lazy, literally lazy and also intellectually lazy' (p. 1), that it cannot fight familiarity, that it violates ethical standards of privacy and permissions for identifying individuals in published research, that it sacrifices analytical outcomes to reporting of experience, that it focuses on the 'wrong side of the power divide' (p. 5), that it abrogates the duty of the social scientist to go out and gather data rather than 'sit in our offices obsessing about ourselves' (p. 5), that we are not sufficiently interesting to warrant attention by others, and that it is antithetical to two tenets of social science, which are to study the social world and to move the discipline forward. In short, as she writes (Delamont, 2009), it is an 'intellectual *cul de sac*' (p. 51).

Critics contend that it lacks genuine fieldwork and is the apotheosis of navel-gazing, narcissism and self-absorption (e.g. Atkinson, 2006; Madison, 2006; Delamont, 2007, 2009; Ellis *et al*., 2011), i.e. it is more about the 'auto' than the 'ethnography' (Atkinson, 2006, p. 402; Roth, 2009, p. 5). It stands accused of an absence of social context, social action and interaction, of not being sufficiently social to qualify as social science, and of operating in a social vacuum (Atkinson, 1997, p. 339). Delamont (2009), noting that ethnographic research is demanding and hard, derides autoethnography as 'an abrogation of the honourable trade of the scholar' (p. 61).

Such criticisms have been roundly refuted, arguing that differences of views of research should be celebrated rather than proscribed (e.g. Ellis and Bochner, 2000; Bochner, 2001; Denzin, 2006; Wall, 2006, 2008; Starr, 2010; Ellis *et al*., 2011; Denshire, 2014).

15.6 Virtual ethnography

As the Internet is a means of searching a repository of knowledge, a means of communication and a venue for connecting people – real or virtual (Marshall and Rossman, 2016, p. 30) – so the cyberworld has, itself, become a source of ethnographic research. Online communication is a routine and integral part of people's everyday lives, and, given this, its part in ethnographic research is unsurprising. Researchers can enter the Internet and study what is happening in and through it with respect to cultures and communities; the Internet is 'a place where cultural and social phenomena happen' (Webster and da Silva, 2013, p. 123) and where ethnographic interviews can be conducted online (Hanna, 2012).

The Internet is a 'socially constructed space' (Marshall and Rossman, 2016, p. 30), albeit a virtual space (Hine, 2000, 2004), peopled by interacting participants with real and virtual lives, their own cultures, online communities, groups, rites of passage, negotiated roles, group membership and behaviours, and these can be researched as one would conduct an ethnography. The virtual, online environment is the site for the research (Evans, 2010), requiring different, computer-based tools for conducting the research. The computer screen is the on-screen location of the research, and the majority of the data is likely to be text-based, though this does not preclude other data types which are increasingly available on the Internet, for example, Skype, Blackboard Collaborate (Webster and da Silva, 2013).

'Virtual ethnography' (Hine, 2004), netnography (Kozinets, 2010), netography and 'webnography' (Evans, 2010) can be conducted though social networking media, email, online interviews, message boards and messaging, bulletin boards, blogs, chat rooms, forums, discussion boards (see Chapters 23 and 25). The researcher, as in traditional ethnography, is still a participant observer or non-participant observer (Evans, 2010), permanently or intermittently immersed in and observing the virtual environment and what is happening in it, keeping systematic field notes (Hine, 2000).

Because virtual ethnography works with virtual people and alter egos (e.g. avatars), the researcher is often deprived of assurances of honesty and of several features of face-to-face ethnography conducted in the physical presence of the ethnographer and the 'real' participants in their real, physical, 'natural habitat' (Hallett and Barber, 2014, p. 306) (e.g. knowledge of gender, race, age, social status) (Hammersley, 2006, p. 8); it works *as if* participants are real – which they may or may not be – and the 'natural habitat' is now the 'online habitat' (Hallett and Barber, 2014, p. 308).

Netographies overcome problems of time, location and space; they enable the anonymity, privacy and security of the real people to be respected, though this renders problematic the issues of identity and authenticity of the world being investigated. In short, the virtual world is a projection, true or false, of the face-to-face world; it may be no more or less real because of

this (Boellstorff, 2015). The ethnographer proceeds *as if* the Internet world is the real thing, working with the data provided on the Internet, with few, if any, checks on the correctness or authenticity of the actual people behind the avatars. As with other forms of online research, virtual ethnographies raise ethical issues of confidentiality, privacy, anonymity, disclosure, protection from harm to self and others, and informed consent (see also Chapter 8).

For educationists, virtual ethnography can focus on 'real people' in their virtual communities (Hallett and Barber, 2014, p. 310), and on the data which they provide online rather than focusing on virtual people or avatars. This questions how far these are real, full-blooded ethnographies or simply partial and selective data posted online about specific topics of communal or shared interest by interested parties, i.e. extended discussions or sharing of opinions. Indeed Evans (2010) question whether a virtual ethnography is, in fact, more like an extended online survey than an ethnography defined as a 'faithful reproduction of a particular cultural setting' (p. 7).

In conducting a virtual ethnography, Evans (2010) suggests that researchers identify relevant 'proactive communities' (p. 9), raising issues of access, gatekeepers and ethical issues of privacy, anonymity, informed consent, covert or overt research, and permissions. Then researchers can identify key informants and key participants, negotiating access to people and groups and addressing the same ethical issues, with informed consent including both the process and product of the ethnography, and the audience and dissemination of the ethnography. Kulavuz-Onal and Vásquez (2013) remind researchers that they may need to register as a member of an online community in order to gain access and may need to be an active participant in some events whilst being able to be less active in others (p. 229). After this, the researcher can make further contact in order to commence the research, engaging in interaction with the participants (if participant observation is selected) or being a non-participant observer (though Kozinets (2010) advocates participant observation). The researcher gathers ongoing systematically collected and systematically reviewed data and field notes (Kulavuz-Onal and Vásquez, 2013); indeed, online, digital data (including online interviews, see Chapter 25) may lend themselves to software for data analysis. Kulavuz-Onal and Vásquez (2013) comment that fieldwork practices in ethnographies of online communities need to be 'reconceptualised' (p. 237) because they differ from practices in 'in-person ethnographic fieldwork', being software based and computer mediated.

Then the researcher will need to write the ethnography and the report, and seek respondent validation and member checks. This sequence echoes Kozinets's (2010) comments that the methods of traditional ethnographers – gaining entry to the field and community, collecting data, careful analysis and interpretation of data, and reporting, all couched within ethical principles – apply to netographers.

Whilst online research catches some of the social space and topical issues in the community of participants, whether this is sufficient to be called a true, fully fledged, genuine ethnography in the traditional sense of catching the all-round, overall, holistic picture of participants and their socio-cultural settings, is an open question. They are communities united by, or formed by, a common interest rather than having any other connections.

Whilst traditional ethnography sees participants in many settings, presenting many faces and aspects of self to many parties, and whilst participants may present different faces in virtual ethnographies, whether this happens sufficiently in a virtual ethnography for it to be counted as a full-blooded ethnography (rather than, for example, differing views on a topic or different stories from participants) is another open question.

Webster and da Silva (2013) and Hallett and Barber (2014) suggest that, in reality, to conduct a full ethnography could require researchers to study the same participants both online and offline, as the online world is as much part of their 'real' daily lives as the offline, face-to-face, physical interactions. It is a false dualism to separate the online and offline worlds of participants.

15.7 Phenomenological research

Phenomenological research is based on the view that our knowledge of the world is rooted in our (immediate) experiences, and the task of the researcher is to describe, understand, interpret and explain these experiences (Hammersley, 2013, p. 27; Denscombe, 2014, pp. 94–5). This type of research aims to describe, explain and interpret a phenomenon, situation or experience by identifying the meaning of these as understood by the participants, often at an individual as well as a group level (Marshall and Rossman, 2016, pp. 16–17).

As there are many participants involved, each of whom has his/her own authentic meaning and interpretation, there will be multiple realities and accounts; the researcher has to put to one side any prior concepts or suppositions (pp. 27–8) and seek to understand how everyday events and 'commonsense knowledge' (p. 28) are as they are, how they are perceived and

sustained by the participants, and what are the attitudes of participants towards them. In this enterprise, emphasis is placed on the fully described subjective experiences, perceptions, interpretations, attitudes, beliefs, values, feelings and meanings of agentic individuals (Denscombe, 2014, p. 94). In full depiction of lived experiences through the eyes of participants, in come rich description and fidelity to the original experience and out go categorization, abstraction, over-interpretation, quantification and even theorization (pp. 95–6).

Ary *et al*. (2002, p. 447) note that, whilst this is common to much qualitative research, the distinctive feature of phenomenological research is its focus on the subjective experiences of the participants, which are at the heart of the research; what they mean for the participants rather than, for example, the objective 'status of experiences' (p. 447). Not only is there an individual construction of reality, but a social construction of reality (Berger and Luckman, 1967), i.e. there is a shared rather than a solipsistic understanding of the 'real', with shared and multiple realities.

To understand the meanings that participants give to the experiences typically requires in-depth, open-ended and often unstructured interviews with the participants (Marshall and Rossman, 2016, p. 18), which seek to grasp the essence of the meaning(s) of a situation as given by each participant, with detailed descriptions figuring highly here and a recognition that complexity rather than unity or simplicity may be the hallmarks of the meanings given. The researcher has to strive to set aside any of his/her own values, beliefs, taken-for-granted conceptual frameworks, predispositions and everyday background and to see the experience for what it is in the eyes of the participants, freed from such researcher preconceptions, in other words to act as a 'stranger' (Denscombe, 2014, p. 99).

Denscombe writes that phenomenology is suited to small-scale research, descriptive detail of authentic experiences and sympathy to humanistic research which focuses on 'lived experiences'. On the other hand, he notes that, in its pursuit of rich, individualized descriptions, phenomenological research may lack the scientific tenets of 'objectivity, analysis and measurement' (p. 103), may not move beyond description (e.g. to analysis and explanation), may not be generalizable and may focus on trivial everyday events to the neglect of bigger issues (p. 103).

15.8 Planning qualitative, naturalistic and ethnographic research

In many ways the planning issues in qualitative research are not exclusive; they apply to other forms of research, for example: identifying the problem and research purposes; deciding the focus of the study; identifying the research questions; selecting the research design and instrumentation; addressing validity and reliability; ethical issues; approaching data analysis and interpretation. These are common to all research. More specifically, Wolcott (1992, p. 19) suggests that naturalistic researchers should address the stages of watching, asking and reviewing, or, as he puts it, experiencing, enquiring and examining. It is possible to formulate stages in planning naturalistic research (Hitchcock and Hughes, 1989, pp. 57–71; Bogdan and Biklen, 1992; LeCompte and Preissle, 1993). These are presented in Figure 15.2 and are subsequently dealt with in the later pages of this chapter.

One has to be cautious here: Figure 15.2 suggests a linearity in the sequence; in fact, the process is often more complex that this, with a backwards-and-forwards movement between the several stages over the course of the planning and conduct of the research. The process is iterative and recursive, as different elements come into focus and interact with each other in different ways at different times. Indeed Flick (2009, p. 133) suggests a circularity or mutually informing nature of elements of a qualitative research design. In this instance the stages of Figure 15.2 might be better presented as interactive elements as in Figure 15.3.

Further, in some smaller-scale qualitative research not all of these stages may apply, as the researcher may not always be staying for a long time in the field but might only be gathering qualitative data on a 'one-shot' basis (e.g. a qualitative survey, qualitative interviews). However, for several kinds of naturalistic and ethnographic study in which the researcher intends to remain in the field for some time, the several stages set out here, and commented upon in the following pages, may apply.

These stages are shot through with a range of issues that affect the research, for example:

- personal issues (the disciplinary sympathies of the researcher, researcher subjectivities and characteristics, personal motives and goals of the researcher). Hitchcock and Hughes (1989, p. 56) indicate that there are serious strains in conducting fieldwork because the researcher's own emotions, attitudes, beliefs, values, characteristics enter the research; indeed, the more this

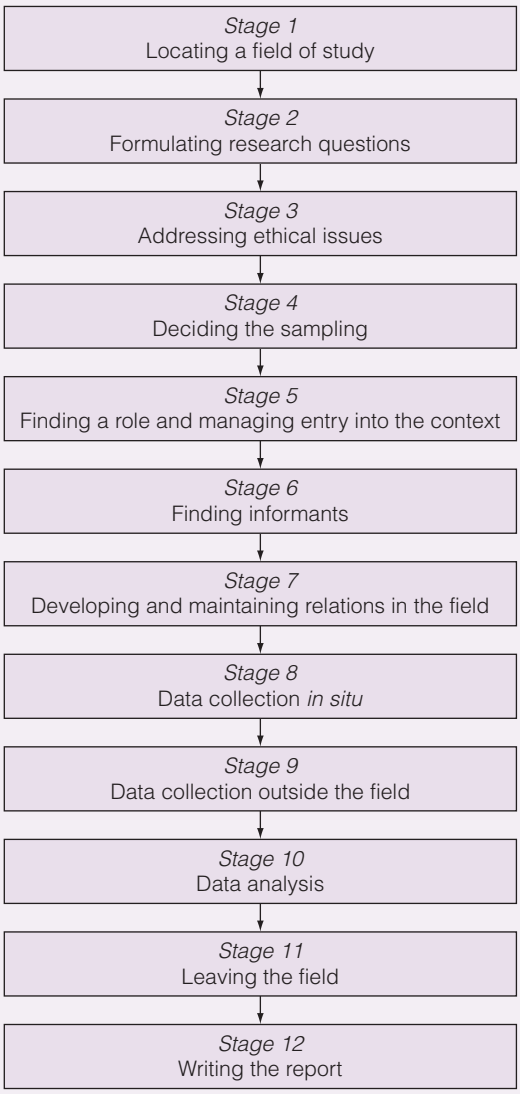

FIGURE 15.2 Stages in the planning of naturalistic, qualitative and ethnographic research

happens the less will be the likelihood of gaining the participants' perspectives and meanings;

- the kinds of participation that the researcher will undertake;
- issues of advocacy (where the researcher may be expected to identify with the same emotions, concerns and crises as the members of the group being studied and wishes to advance their cause, often a feature that arises at the beginning and the end of the research when the researcher is considered to be a legitimate spokesperson for the group);
- role relationships;
- boundary maintenance in the research;
- the maintenance of the balance between distance and involvement;
- ethical issues;
- reflexivity.

15.9 Reflexivity

Reflexivity is a central component of, and a 'crucial strategy' in, qualitative research (Berger, 2015). Researchers have a central role in the creation of knowledge in qualitative enquiry, hence they need to look at themselves and their 'positionality' (discussed later) as part of the research process. Reflexivity recognizes that researchers are inescapably part of the social world that they are researching (Hammersley and Atkinson, 1983, p. 14; Atkinson, 2006, p. 402), and, indeed, that this social world is one already interpreted by the actors, undermining the notion of objective reality. Researchers are in the world and of the world that they research. They bring their own biographies and values to the research situation and participants behave in particular ways in their presence. As Denscombe (2014, p. 88) notes, the researcher does not commence the research 'with a clean sheet', but uses conceptual tools which derive from several sources, including culture and values. What we focus on, what we see, how we understand, describe, interpret and explain are shaped by ourselves and what we bring to the situation. We cannot stand outside these.

Qualitative inquiry is not a neutral activity, and researchers are not neutral; they have their own values, biases and world views, and these are lenses through which they look at and interpret the already-interpreted world of participants (cf. Preissle, 2006, p. 691). Researcher bias is a key issue in qualitative research (as it is with quantitative research) (Hammersley, 1992a).

Researchers, then, have to self-appraise their role in the research process and product (Berger, 2015, p. 220). Pillow (2010) and Bettez (2015) note that reflexive researchers bring their own personal characteristics, experiences, knowledge, backgrounds, values, beliefs, theories, age, gender, sexuality, politics, theories, race, ethnicity, conceptual frameworks and prejudices to the research and that these are often mediated through, and are in conjunction with, issues of power and status. They influence every stage of the research and affect the rapport and conduct of the research. They can affect the formulation of the research topic and questions, access to the field, relationships with participants, data collection, analysis and interpretation, insider and

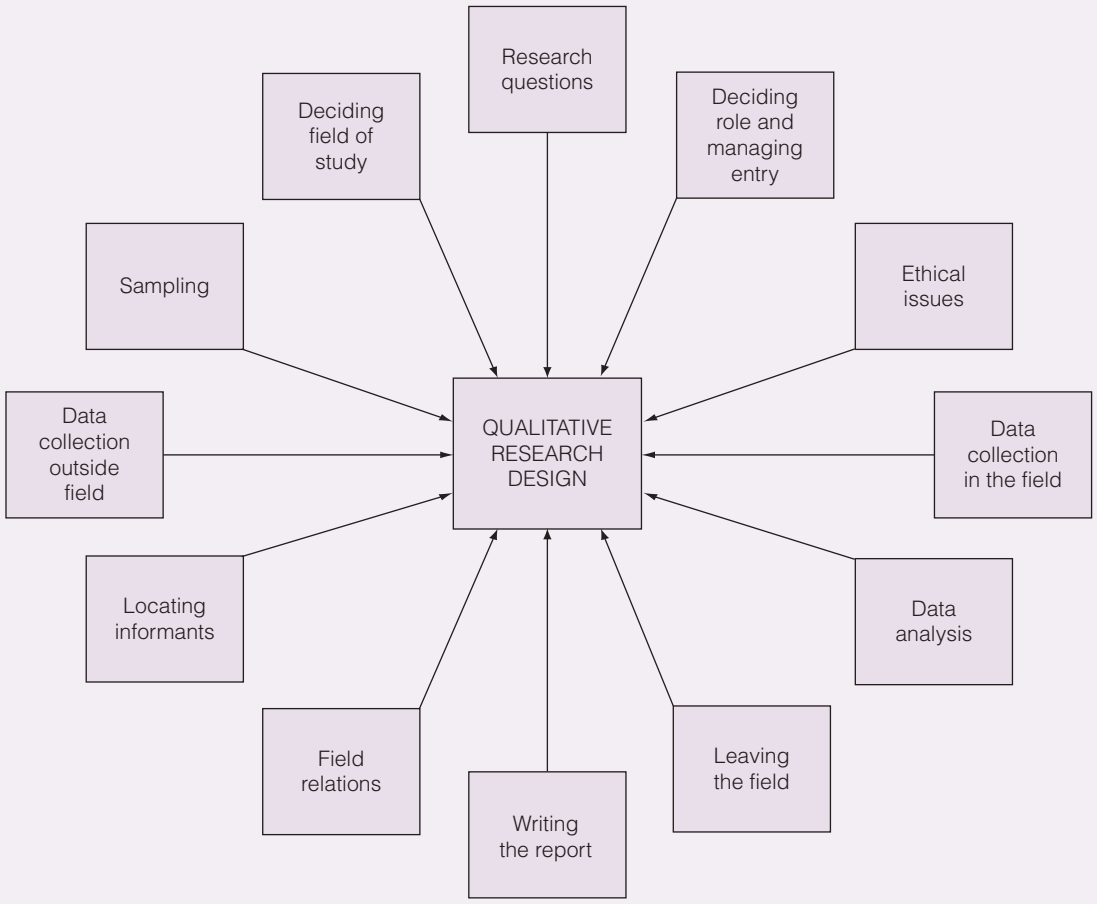

FIGURE 15.3 Elements of a qualitative research design

outsider research, and so on. In short, the researcher may project something or a lot about themselves onto the research (Berger, 2015).

Reflexivity suggests that researchers should consciously and deliberately acknowledge, interrogate and disclose their own selves in the research, seeking to understand their part in, and influence on, the research. Rather than trying to eliminate researcher effects (which is impossible, as researchers are part of the world that they are investigating), researchers should hold themselves up to the light, echoing Cooley's (1902) notion of the 'looking glass self', and researchers should go beyond private reflection on how their own biographies and backgrounds have influenced the research and disclose this publicly as part of the necessary transparency of the research.

Highly reflexive researchers will be acutely aware of the ways in which their selectivity, perception, background, values and inductive processes, frames and paradigms shape the research. They are research instruments. McCormick and James (1988, p. 191) argue that combating reactivity through reflexivity requires researchers to monitor closely and continually their own interactions with participants, their own reactions, roles and biases, and any other matters that might affect the research. This is addressed more fully in Chapter 14 on validity, encompassing issues of triangulation and respondent validity.

15.10 Doing qualitative research

An effective qualitative study has several features (Creswell, 1998, pp. 20–2), and these can be addressed in evaluating qualitative research:

- it uses rigorous procedures and multiple methods for data collection;

- the study is framed within the assumptions and nature of qualitative research;
- enquiry is a major feature, and can follow one or more different traditions (e.g. biography, ethnography, phenomenology, case study, grounded theory);
- the project commences with a focus on an issue, a group, a problem rather than having a hypothesis or the supposition of a causal relationship of variables; relationships may emerge later, but that is open;
- criteria for verification are set out, together with rigour in writing the report;
- verisimilitude is required, such that readers can imagine being in the situation;
- data are analysed at different levels; they are multilayered;
- the writing engages the reader and is replete with unexpected insights, whilst maintaining believability and accuracy.

Maxwell (2005, p. 21) argues that qualitative research should have both *practical* goals (e.g. that can be accomplished, that deliver a specific outcome and meet a need) and *intellectual* goals (e.g. to understand or explain something). His practical goals (p. 24) are: (a) to generate 'results and theories' that are credible and comprehensible to participants and other readers; (b) to conduct formative evaluation in order to improve practice; and (c) to engage in 'collaborative and action research' with different parties. His intellectual goals (pp. 22–3) are: (a) to understand the meanings attributed to events and situations by participants; (b) to understand particular contexts in which participants are located; (c) to identify unanticipated events, situations and phenomena and to generate grounded theories that incorporate these; (d) to understand processes that contribute to situations, events and actions; and (e) to develop causal explanations of phenomena.

He suggests that, whilst quantitative research is interested in discovering the variance and regularity in the effects of one or more particular independent variables on an outcome, qualitative research is interested in the causal processes at work in understanding how one or more interventions or factors lead to an outcome, the mechanisms of their causal linkages. Quantitative research can tell us correlations, how much, whether and 'what', whilst qualitative research can tell us the 'how' and 'why' – the processes involved in understanding and explaining how things occur.

Maxwell also argues that qualitative research should be based on a suitable theoretical basis or paradigm. Quoting Becker (1986), he argues that if a researcher bases his or her research in an inappropriate theory or paradigm it is akin to a worker wearing the wrong clothes: it inhibits comfort and the ability to work properly. Maxwell notes that theoretical premises may not always be clear at the outset of the research; they may emerge, change, be added to etc. over time as the qualitative research progresses (see Chapters 1 and 4 on paradigms and theories). Theory, Maxwell avers (p. 43), can provide a supporting set of principles, world view or sense-making referent, and it can be used as a 'spotlight', illuminating something very specific in a particular event or phenomenon. He advocates a cautious approach to the use of theory (p. 46), steering between, on the one hand, having it unnecessarily constrain and narrow a field of investigation and being accepted too readily and uncritically, and, on the other hand, not using it enough to ground rigorous research. Theories in qualitative research should be those of the researcher and the participants. He suggests that theory can provide the conceptual and justificatory basis for the qualitative research being undertaken, and it can also inform the methods and data sources for the study (p. 55).

Against this background, we set out a twelve-stage process for doing qualitative research.

Stage 1: locating a field of study

Bogdan and Biklen (1992, p. 2) suggest that research questions in qualitative research are not framed by simply operationalizing variables as in the positivist paradigm. Rather, they are formulated *in situ* and in response to situations observed, i.e. topics are investigated in all their complexity in the naturalistic context.

In some qualitative studies, the selection of the research field will be informed by the research purposes, the need for the research, what gave rise to the research, the problem to be addressed and the research questions and sub-questions. In other qualitative studies these elements may only emerge after the researcher has been immersed for some time in the research site itself.

Stage 2: formulating research questions

Research questions are an integral and driving feature of qualitative research. They must be able to be answered concretely, specifically and with evidence (see Chapter 10). They must be achievable and finite (cf. Maxwell, 2005, pp. 65–78) and are often characterized by being closed rather than open questions. Whereas research purposes can be open and less finite, motivated by a concern for 'understanding', research questions, by contrast, though they are informed by research purposes, are practical and able to be accomplished (Maxwell, 2005, pp. 68–9).

Hence, instead of asking a non-directly answerable question such as 'how should we improve online

learning for biology students?', we can ask a specific, focused, bounded and answerable question such as 'how has the introduction of an online teacher–student chat room improved Form 5 students' interest in learning biology?'. Here the word 'should' (as an open question) has been replaced with 'has', the general terminology of 'online learning' has been replaced with 'an online teacher–student chat room' and the open-endedness of the first question has been replaced with the closed nature of the second (cf. Maxwell, 2005, p. 21).

Whereas in quantitative research, a typical research question asks 'what' and 'how much' (e.g. 'how much do male secondary students prefer female teachers of mathematics, and what is the relative weighting of the factors that account for their preferences?'), a qualitative research question often asks more probing, process-driven research questions (e.g. 'how do secondary school students in school X decide their preferences for male or female teachers of mathematics?').

Maxwell (2005, p. 75) suggests that qualitative research questions are suitable for answering questions about: (a) the *meanings* attributed by participants to situations, events, behaviours and activities; (b) the influence of *context* (e.g. physical, social, temporal, interpersonal) on participants' views, actions and behaviours; and (c) the *processes* by which actions, behaviours, situations and outcomes emerge.

Whilst in quantitative research, the research questions (or hypotheses to be tested) typically drive the research and are determined at the outset, in qualitative research a more iterative process occurs (Light *et al*., 1990, p. 19). Here the researcher may have an initial set of research purposes, or even questions, but these may change over the course of the research, as the researcher finds out more about the research setting, participants, context and phenomena under investigation, i.e. deciding research questions is not a once-and-for-all affair. This is not to say that qualitative research is an unprincipled, aimless activity; rather it is to say that, whilst the researcher may have clear purposes, she is sensitive to the emergent situation in which she finds herself, and this steers the research questions. Research questions are the consequence, not the driver, of the situation and the interactions that take place within it. It is important for the qualitative researcher to ask the right questions rather than to ask about what turn out to be irrelevancies to the participants. As Tukey (1962, p. 13) remarked, it is better to have approximate, inexact or imprecise answers to the right question than to have precise answers to the wrong question. The qualitative researcher has to be sensitized to the emergent key features of a situation before firming up the research questions.

Stage 3: addressing ethical issues

Deyle *et al*. (1992, p. 623) and Hammersley and Traianou (2012) identify several critical ethical issues that need to be addressed in the research: how does one present oneself in the field? As whom does one present oneself? How ethically defensible is it to pretend to be somebody that you are not in order to gain knowledge that you would otherwise not be able to acquire or to obtain and preserve access to places which otherwise you would be unable to secure or sustain.

The issues here are several. First, there is the matter of *informed consent* (to participate and for disclosure), whether and how to gain participant assent (see also LeCompte and Preissle, 1993, p. 66). Hammersley and Traianou (2012) comment that the researcher must respect the autonomy of the participants and this means gaining informed consent and, where appropriate, regarding participants as equals in the research project (they also note that researchers studying certain groups, e.g. paedophiles, rapists, elite power groups (p. 82) may not wish to regard them as equals). They note that consideration has to be given to who gives consent, and on behalf of whom, and for what, and what 'fully informed' means (see Chapter 7 of the present volume).

Gaining consent also uncovers another consideration, namely *covert* or *overt* research. On the one hand there is a powerful argument for informed consent. However, the more participants know about the research the less naturally they might behave (Hammersley and Traianou, 2012, p. 108), and naturalism is a key criterion of the naturalistic paradigm.

Mitchell (1993) catches the dilemma for researchers in deciding whether to undertake overt or covert research. The issue of informed consent, he argues, can lead to the selection of particular forms of research – those where researchers can control the phenomena under investigation – thereby excluding other kinds of research where subjects behave in less controllable, predictable, prescribed ways, indeed where subjects may come in and out of the research over time.

Mitchell argues that in the real social world access to important areas of research is prohibited if informed consent has to be sought, for example, in researching those on the margins of society or the disadvantaged. It is to the participants' own advantage that secrecy is maintained as, if it is not, important work may not be done and 'weightier secrets' (1993, p. 54) may be kept that are of legitimate public concern. Mitchell makes a powerful case for secrecy, arguing that informed consent may excuse social scientists from the risk of confronting powerful, privileged and cohesive groups

who wish to protect themselves from public scrutiny. Secrecy and informed consent are moot points.

Patrick (1973) indicates this point sharply when, as an ethnographer of a Glasgow gang, he was witness to a murder; the dilemma was clear – to report the matter (and thereby to act legally but 'blow his cover', consequently endangering his own life) or to stay as a covert researcher, thereby breaking the law. As Ary *et al*. (2002) remark, researchers may obtain knowledge of unforeseen illicit activities, or even be part of those, and this raises ethical dilemmas for them (p. 437). The researcher, then, has to consider her loyalties and responsibilities (LeCompte and Preissle, 1993, p. 106), for example, what is the public's right to know and what is the individual's right to privacy? Researchers must decide 'whose side are we on' (Becker, 1967).

In addition to the issue of overt or covert research, LeCompte and Preissle (1993) indicate that the problems of *risk* to, and *vulnerability* of, subjects must be addressed; steps must be taken to prevent risk or harm to participants (non-maleficence – the principle of *primum non nocere*) (cf. Hammersley and Traianou, 2012; see Chapter 7 of this volume). Bogdan and Biklen (1992, p. 54) extend this to include issues of embarrassment as well as harm to those taking part (e.g. harm from physical or psychological pain, material damage, damage to a project in which people are involved, damage to reputation or status) (Hammersley and Traianou, 2012, p. 62). Bettez (2015) asks what to do with information from one participant that could be emotionally painful for another.

The question of vulnerability is present when participants in the research have their freedom to choose limited, for example, by dint of their age, health, social constraints, by dint of their lifestyle, social acceptability, experience of being victims (e.g. of abuse, of violent crime) (Bogdan and Biklen, 1992, p. 107). As the authors comment, participants rarely initiate research, so it is the responsibility of the researcher to protect them.

Ethical issues concern both those being researched and the researcher. As we mention in Chapter 13, research can also take its toll on the researcher, not only in terms of the sensitivity or nature of the topic but in terms of the process of undertaking the enquiry itself, which may be stressful, emotional and disturbing (Dickson-Swift *et al*., 2008, 2009; Blix and Wettergren, 2015; Emerald and Carpenter, 2015). Emerald and Carpenter (2015) note that researchers often downplay the emotional and personal risk of the research, in which they may feel vulnerable and exposed (p. 744). They must be aware of, and reflexive about, the emotional signals they may be obtaining about themselves in undertaking the research, and Blix and Wettergren (2015) note that this can particularly feature when gaining and maintaining access to the field and in building trust. Whilst the emotions of the researcher may, indeed, become part of the research data, this does not obviate the ethical concern of ensuring that the research does not harm the researcher. Emotional self-management is an issue (cf. Hochschild (2012) on 'emotion work').

A standard protection for participants is often the guarantee of *confidentiality* and *privacy*, withholding participants' real names and other identifying characteristics. The authors contrast this with anonymity, where identity is withheld because it is genuinely unknown (p. 106). Issues of identifiability and traceability are raised, and participants might be able to identify themselves in the research report, though others may not be able to identify them. A related factor here is the *ownership* of the data and the results, the control of the release of data (and to whom, and when) and what rights respondents have to veto the research results.

Positionality addresses relationships; it is an ethical matter. Relationships between researcher and the researched are rarely symmetrical in terms of power; it is often the case that those with more power, information and resources research those with less (Hammersley and Traianou, 2012, p. 12). Bettez (2015) notes that research knowledge, how it is produced, understood, evaluated and used, is affected by, or refracted through, 'positionalities' – how we see ourselves and others – which are influenced by cultural values, beliefs, ascribed and achieved social position, status, gender, race, sexuality, insider and outsider status etc. She argues for 'communion' in qualitative research: meaningful connection between all participants (including the researcher) in a spirit of mutual and shared equality, inclusion, respect, humanity and dignity.

Bogdan and Biklen (1992, p. 54) add to this discussion the need to respect participants as subjects, not simply as research objects to be used and then discarded. It is important for researchers to consider the parties, bodies, practices that might be interested in, or affected by, the research and the implications of the answers to these questions for the conduct, reporting and dissemination of the inquiry (Mason, 2002, p. 41). This extends to exiting the research (Ary *et al*., 2002), as the researcher may have built up strong relationships with the participants over the course of the research, and indeed is likely to have built up friendships which cannot be severed simply because the research has finished. The researcher performs a balancing act, as such friendships may develop *during* the research, and this

raises issues of mutual trust in reporting the results. The issue also concerns reciprocity and respect: how do the participants benefit from the research?

We address ethics in Chapters 7 and 8 and we advise readers to refer to these.

Stage 4: deciding the sampling

In an ideal world the researcher would be able to study a group in its entirety: a population. This was the case in Goffman's (1968) work on 'total institutions', for example, hospitals, prisons and police forces (see also Chapter 35). It was also the practice of anthropologists who were able to explore specific isolated communities or tribes. That is rarely possible nowadays because such groups are no longer isolated or insular. Hence the researcher is faced with the issue of sampling, that is, deciding which people it will be possible to select to represent the wider group (however defined). The researcher has to decide the groups for which the research questions are appropriate, the contexts which are important for the research, the time periods needed and the possible issues and artefacts of interest to the investigator. This takes the discussion beyond conventional notions of sampling.

In several forms of research, sampling is fixed at the start of the study, though there may be attrition of the sample through 'mortality' (e.g. people leaving the study), and this is problematic. Ethnographic research regards this as natural rather than irksome. People come into and go from the study. This impacts on the decision whether to have a synchronic investigation at a single point in time, or a diachronic study where events and behaviour are monitored over time to allow for change, development and evolving situations. In ethnographic inquiry sampling is recursive and ad hoc rather than fixed at the outset; it changes and develops over time. Let us consider how this might happen.

LeCompte and Preissle (1993, pp. 82–3) point out that ethnographic methods rule out statistical sampling, for a variety of reasons:

- the characteristics of the wider population are unknown;
- there are no straightforward boundary markers (categories or strata) in the group;
- generalizability, a goal of statistical methods, is not necessarily a goal of ethnography;
- characteristics of a sample may not be evenly distributed across the sample;
- only one or two subsets of a characteristic of a total sample may be important;
- researchers may not have access to the whole population;
- some members of a subset may not be drawn from the population from which the sampling is intended to be drawn.

Hence other types of sampling are required. A criterion-based selection requires the researcher to specify in advance a set of attributes, factors, characteristics or criteria that the study must address. The task is to ensure that these appear in the sample selected (the equivalent of a stratified sample). There are other forms of sampling (see Chapter 12) that are useful in ethnographic research (Patton, 1980; Guba and Lincoln, 1989; Bogdan and Biklen, 1992, p. 70; LeCompte and Preissle, 1993, pp. 69–83; Ezzy, 2002), such as:

- convenience sampling (opportunistic sampling, selecting from whomever happens to be available);
- critical-case sampling (e.g. people who display the issue or set of characteristics in their entirety or in a way that is highly significant for their behaviour). This is done in order to permit maximum applicability to others: if the information holds true for critical cases (e.g. cases where all of the factors sought are present), then it is likely to hold true for others;
- extreme-/deviant-case sampling (the norm of a characteristic is identified, then the extremes of that characteristic are located and, finally, the bearers of that extreme characteristic are selected). This is done in order to gain information about unusual cases that may be particularly troublesome or enlightening;
- typical-case sampling (where a profile of attributes or characteristics that are possessed by an 'average', typical person or case is identified, and the sample is selected from these conventional people or cases). This is done in order to avoid rejecting information on the grounds that it has been gained from special or deviant cases;
- unique-case sampling, where cases that are rare, unique or unusual on one or more criteria are identified, and sampling takes places within these. Here whatever other characteristics or attributes a person might share with others, a particular attribute or characteristic sets that person apart;
- reputational-case sampling, a variant of extreme-case and unique-case sampling, where a researcher chooses a sample on the recommendation of experts in the field;
- snowball sampling: using the first interviewee to suggest or recommend other interviewees, and so on;
- maximum variation sampling. This is done in order to document the range of unique changes that have emerged, often in response to the different conditions to which participants have had to adapt.

It is useful if the aim of the research is to investigate the variations, range and patterns in a particular phenomenon or phenomena;
- intensity sampling: according to the intensity with which the features of interest are displayed or occur;
- sampling politically important or sensitive cases. This can be done to draw attention to the case;
- convenience sampling. This saves time and money and spares the researcher the effort of finding less amenable participants.

One can add to this list, from Miles and Huberman (1994, p. 28):

- homogeneous sampling (which focuses on groups with similar characteristics);
- theoretical sampling (in grounded theory, discussed below, where participants are selected for their ability to contribute to the developing/emergent theory);
- confirming and disconfirming cases (akin to extreme- and deviant-case sampling), in order to look for exceptions to the rule, which may lead to the modification of the rule;
- random purposeful sampling (when the potential sample is too large, a smaller sub-sample can be used which still maintains some generalizability);
- stratified purposeful sampling (to identify subgroups and strata);
- criterion sampling (all those who meet some stated criteria for membership of the group or class under study);
- opportunistic sampling (to take advantage of unanticipated events, leads, ideas, issues).

Miles and Huberman make the point that these strategies can be used in combination as well as in isolation, and that using them in combination contributes to triangulation.

Patton (1980, p. 181) and Miles and Huberman (1994, pp. 27–9) also note the dangers of convenience sampling, arguing that, being 'neither purposeful nor strategic' (Patton, 1980, p. 88), it cannot demonstrate representativeness even to the wider group being studied, let alone to a wider population.

Maxwell (2005, pp. 89–90) indicates four possible purposes of 'purposeful selection':

- to achieve representativeness of the activities, behaviours, events, settings and individuals involved;
- to catch the breadth and heterogeneity of the population under investigation (i.e. the range of the possible variation: the 'maximum variation' sampling discussed above);
- to examine critical cases or extreme cases that provide a 'crucial test' of theories or that can illuminate a situation in ways which representative cases may not be able to do;
- to identify reasons for similarities and differences between individuals or settings (comparative research).

He notes that methods of data collection and sampling are not a logical corollary of, nor an analytically necessary consequence of, the research questions (p. 91). Research questions and data collection are two conceptually separate activities, though, as we have mentioned earlier in this book, the researcher needs to ensure that they are mutually informing, in order to demonstrate cohesion and fitness for purpose. Methods and sampling cannot simply be cranked out, mechanistically, from research questions; rather the methods of data collection and the research questions are strongly influenced by the setting, the participants, the relationships and the research design as they unfold over time.

Lincoln and Guba (1985, pp. 201–2) suggest an important difference between 'conventional' and naturalistic research designs. In the former the intention is to focus on similarities and to be able to make generalizations, whereas in the latter the objective is informational, to provide such a wealth of detail that the uniqueness and individuality of each case can be represented. To the charge that naturalistic inquiry, thereby, cannot yield generalizations because of sampling flaws, the writers argue that this may be necessarily though trivially true, i.e. unimportant.

Patton (1980, p. 184) suggests that 'there are no rules for sample size in qualitative inquiry', with the size of the sample depending on what one wishes to know, the purposes of the research, what will be useful and credible and what can be done within the resources available, for example, time, money, people, support – important considerations for the novice researcher.

In much qualitative research, it may not be possible, or, indeed, desirable, to know in advance whom to sample or whom to include. One of the features of qualitative research is its emergent nature. Hence the researcher may only know which people to approach or include as the research progresses and unfolds (Flick, 2009, p. 125). In this case the nature of sampling is determined by the emergent issues in the study; this is 'theoretical sampling' (Glaser and Strauss, 1967, p. 45): once data have been collected, the researcher decides where to go next, in light of the analysis of the data, in order to gather more data in order to develop his or her theory (Flick, 2009, p. 118).

Ezzy (2002, p. 74) underlines the importance of 'theoretical sampling' in his comment that, unlike other forms of research, qualitative inquiries may not always commence with the full knowledge of whom to sample, but the sample is determined on an ongoing, emergent basis. Theoretical sampling starts with data and then, having reviewed these, the researcher decides where to go next to collect data for the emerging theory (Glaser and Strauss, 1967, p. 45).

In theoretical sampling, individuals and groups are selected for their potential – or hoped-for – ability to offer new insights into the emerging theory, i.e. they are chosen on the basis of their significant contribution to theory generation and development. As the theory develops, so the researcher decides whom to approach to request their participation. Theoretical sampling does not claim to know the population characteristics or to represent known populations in advance, and sample size is not defined in advance; sampling is only concluded when theoretical saturation (discussed below) is reached. We discuss this more fully in Chapter 37.

In the educational field one could imagine theoretical sampling in the following example: interviewing teachers about their morale might give rise to a theory that teacher morale is negatively affected by disruptive student behaviour in schools. This might suggest the need to sample teachers working with many disruptive students in difficult schools, as 'critical-case sampling'. However, the study finds that some of the teachers working in these circumstances have high morale, not least because they have come to expect disruptive behaviour from students with so many problems and so are not surprised or threatened by it, and because the staff in these schools provide tremendous support for each other in difficult circumstances – they all know what it is like to have to work with challenging students.

So the study decides to focus on teachers working in schools with far fewer disruptive students. The researcher discovers that it is these teachers who experience far lower morale, and she hypothesizes that this is because this latter group of teachers has higher expectations of student behaviour, such that having only one or two students who do not conform to these expectations deflates staff morale significantly, and because disruptive behaviour is regarded in these schools as teacher weakness, and there is little or no mutual support. Her theory, then, is refined, to suggest that teacher morale is affected more by teacher expectations than by disruptive behaviour, so she adopts a 'maximum variation sampling' of teachers in a range of schools, to investigate how expectations and morale are related to disruptive behaviour. In this case the sampling emerges as the research proceeds and the theory emerges; this is theoretical sampling, the 'royal way for qualitative studies' (Flick, 2004b, p. 151). Schatzman and Strauss (1973, pp. 38ff.) suggest that theoretical sampling may change sampling according to time, place, individuals and events.

The above procedure accords with Glaser's and Strauss's (1967) view that sampling involves continuously gathering data until practical factors (boundaries) put an end to data collection, or until no amendments have to be made to the theory in light of further data – their stage of 'theoretical saturation' – where the theory fits the data even when new data are gathered. Theoretical saturation is described by Glaser and Strauss (1967, p. 61) as being reached when, even when further data are used, the properties of the category in question are not developed any further. That said, the researcher has to be cautious to avoid premature cessation of data collection; it would be too easy to close off research with limited data, when, in fact, further sampling and data collection might lead to a reformulation of the theory.

An extension of theoretical sampling is 'analytic induction', a process advanced by Znaniecki (1934). Here the researcher starts with a theory (that may have emerged from the data as in grounded theory) and then deliberately proceeds to look for deviant or discrepant cases, to provide a robust defence of the theory. This accords with Popper's notion of a rigorous scientific theory having to stand up to falsifiability tests. In analytic induction, the researcher deliberately seeks data which potentially could falsify the theory, thereby giving strength to the final theory.

We are suggesting here that, in qualitative research, sampling cannot always be decided in advance on a 'once-and-for-all' basis. It may change through the stages of data collection, analysis and reporting. Data collection, analysis, interpretation and reporting and sampling do not necessarily proceed in a linear fashion; the process is recursive and iterative. Sampling is not decided a priori – in advance – but may be decided, amended, added to, increased and extended as the research progresses. Indeed, whilst sampling often refers to *people*, in qualitative research it also refers to *events*, *places*, *times*, *behaviours*, *activities*, *settings* and *processes* (cf. Miles and Huberman, 1984, p. 36).

Many researchers will conduct short-term, small-scale qualitative research (e.g. qualitative interviews) rather than extended or large-scale ethnographic research. A fundamental question for the researcher is to decide how long to stay in a situation. Too short, and

she may miss an important outcome; too long, and key features may become a blur.

For example, let us imagine a situation of two teachers in the same school. Teacher A introduces collaborative group work to a class, in order to improve their motivation for, say, learning a foreign language. She gives them a pre-test on motivation, and finds that it is low; she conducts the intervention and then, at the end of two months, gives them another test of motivation, and finds no change. She concludes that the intervention has failed. However, months later, after the intervention has finished, the students tell her that, in fact, their overall motivation to learn that foreign language had improved, but it took time for them to realize it after the intervention. Teacher B tries the same intervention, but decides to administer the post-test one year after the intervention has ended; she finds no change to motivation levels of the students, but had she conducted the post-test sooner, she would have found a difference. Timing and sampling of timing are important.

Stage 5: finding a role and managing entry into the context

This involves matters of access and permission, establishing a reason for being there, developing a role and a persona, identifying the 'gatekeepers' who facilitate entry and access to the group being investigated (see LeCompte and Preissle, 1993, pp. 100, 111). This is complex, as the researcher will be both a member of the group and yet studying that group, so it is a delicate matter to negotiate a role that will enable the investigator to be both participant and observer. The most important elements in securing access are the willingness of researchers to be flexible and their sensitivity to nuances of behaviour and response in the participants (p. 112).

De Laine (2000, p. 41) remarks that an ability to get on with people in the situation in question, and a willingness to join in with, and share experiences in, the activities in question, are important criteria for gaining and maintaining access and entry into the field. Barley and Bath (2014) note that this is a particular challenge when conducting research with young children, and they suggest that a period of 'familiarisation' is important before the research 'officially' commences, particularly as so much advice is given to children about 'stranger-danger' (p. 184). Such familiarization can help the researcher to understand the norms, rules and rituals of the field location, developing early mutual relationships of trust, establishing positionality (discussed earlier), unobtrusively collecting data, 'mapping the setting' (p. 185) and preparing for informed consent or assent.

Wolff (2004, pp. 195–6) suggests that there are two fundamental questions to be addressed in considering access and entry into the field:

1. How can the researcher succeed in making contact and securing cooperation from informants?
2. How can the researcher position herself/himself in the field so as to secure the necessary time, space, social relations to be able to carry out the research?

Flick (1998, p. 57), summarizing Wolff's work, identifies several issues concerning entering institutions for conducting research:

1. Research is always an intrusion and intervention into a social system, and, so, disrupts the system to be studied, such that the system reacts, often defensively.
2. There is a 'mutual opacity' between the social system under study and the research project, which is not reduced by information exchange between the system under study and the researcher; rather this increases the complexity of the situation and, hence, 'immune reactions'.
3. Rather than striving for mutual understanding at the point of entry, it is more advisable to recognize agreement as a process.
4. Whilst it is necessary to agree storage rights for data, this may contribute to increasing the complexity of the agreement to be reached.
5. The field under study only becomes clear when one has entered it.
6. The research project usually has nothing to offer the social system; hence no great promises for benefit or services can be made by the researcher, yet there may be no real reason why the social system should reject the researcher.

As Flick (1998, p. 57) remarks, the research will disturb the system and disrupt routines without being able to offer any real benefit for the institution.

The issue of managing relations is critical for the qualitative researcher. We discuss issues of access, gatekeepers and informants in Chapter 12. The researcher is seen as coming 'without history' (Wolff, 2004, p. 198), a 'professional stranger' (Flick, 1998, p. 59), one who has to be accepted, become familiar and yet remain distant from those being studied. Indeed Flick (p. 60) suggests four roles of the researcher: stranger, visitor, insider and initiate. The first two essentially maintain the outsider role, whilst the latter two attempt to reach into the institution from an insider's perspective. These latter two become difficult to

manage if one is dealing with sensitive issues (see Chapter 13). This typology resonates with the four roles typically cited for observers:

OUTSIDER ←				→ INSIDER
Detached as observer	Observer	Observer as participant	Participant	Complete participant

Swain (2006), discussing ethnography, suggests that researchers may have to switch roles, from being completely passive observers to being completely active participants, as the situation demands, i.e. to draw on the complete continuum of observations and roles. Participant observation is not without its debates. Mills and Morton (2013, pp. 52–3) note that, whilst some researchers advocate participant observation as enabling the researcher to get inside the workings of the institution and its members, others are more hesitant about whether a researcher should be a participant, as this might threaten the objectivity of the researcher and, anyway, being a participant takes valuable time away from the research work of the researcher.

Role negotiation, balance and trust are significant and difficult. For example, if one were to research a school, what role should one adopt: a teacher, a researcher, an inspector, a friend, a manager, a provider of a particular service (e.g. extra-curricular activities), a counsellor, a social worker, a resource provider, a librarian, a cleaner, a server in the school shop or canteen, and so on? One has to try to select a role that will provide access to as wide a range of people as possible, preserve neutrality (not being seen as on anybody's side) and enable confidences to be secured.

Role conflict, role strain and role ambiguity are to be expected in qualitative research. For example, De Laine (2000, p. 29) comments on the potential conflicts between the researcher qua researcher, therapist and friend; she indicates that diverse roles are rarely possible to plan in advance, and are an inevitable part of fieldwork, giving rise to ethical and moral problems for the researcher, and, in turn, require ongoing negotiation and resolution.

Roles change over time. Walford (2001, p. 62) reports a staged process wherein the researcher's role moved through five phases: newcomer, provisional acceptance, categorical acceptance, personal acceptance and imminent migrant. He also reports (p. 71) that it is almost to be expected that managing different roles not only throws the researcher into questioning his/her ability to handle the situation, but brings considerable emotional and psychological stress, anxiety and feelings of inadequacy. This is thrown into sharp relief when researchers have to conceal information, take on different roles in order to gain access, retain neutrality, compromise personal beliefs and values, and handle situations where they are seeking information from others but not divulging information about themselves. Walford suggests that researchers may have little opportunity to negotiate roles and manoeuvre roles, as they are restricted by the expectations of those being researched.

A related issue is the timing of the point of entry, so that researchers can commence the research at an appropriate time (e.g. before the start of a programme, at the start of a programme, during a programme, at the end of a programme, after the end of a programme).

Further, the ethnographer seeks acceptance into the group, which engages matters of dress, demeanour, persona, age, colour, religion, ethnicity, empathy and identification with the group, language, accent, argot and jargon, willingness to become involved and to take on the group's values and behaviour etc. (see Patrick's (1973) study of a Glasgow gang). The researcher, then, must be sensitive to the significance of 'impression management' (Hammersley and Atkinson, 1983, pp. 78ff.). In covert research these factors take on added significance, as one slip could 'blow one's cover' (Patrick, 1973).

Lofland (1971) suggests that the field researcher should attempt to adopt the role of the 'acceptable incompetent', balancing intrusion with knowing when to remain apart. Such balancing is an ongoing process. Hammersley and Atkinson (1983, pp. 97–9) suggest that researchers also have to handle the management of 'marginality': they are in the organization but not of it. They comment that 'the ethnographer must be intellectually poised between "familiarity" and "strangeness", while socially he or she is poised between "stranger" and "friend"', and that this management of several roles, not least the management of marginality, can engender 'a continual sense of insecurity' (p. 100).

Gaining access and entry is a process that unfolds over time rather than a once-and-for-all matter (Walford, 2001, p. 31), as setbacks, delays and modifications can occur and have to be expected in gaining entry to qualitative research sites.

Stage 6: finding informants

This involves identifying those people who have the knowledge about the group, issue or institution being studied. This places the researcher in a difficult position, for she has to be able to evaluate key informants, to decide:

- whose accounts are more important than others;
- which informants are competent to pass comments;

- which are reliable;
- what the statuses of the informants are;
- how representative are the key informants (of the range of people, of issues, of situations, of views, of status, of roles, of the group);
- how to see the informants in different settings;
- how knowledgeable informants actually are – do they have intimate and expert understanding of the situation;
- how central to the organization or situation the informant is (e.g. marginal or central);
- how to meet and select informants;
- how critical the informants are as gatekeepers to other informants, opening up or restricting entry to people;
- the relationship between the informant and others in the group or situation being studied.

Selecting informants and engaging with them is challenging; LeCompte and Preissle (1993, p. 95), for example, suggest that the first informants that an ethnographer meets might be self-selected people who are marginal to the group, who have a low status and who, therefore, might be seeking to enhance their own prestige by being involved with the research. Lincoln and Guba (1985, p. 252) argue that the researcher must be careful to use informants rather than informers, the latter possibly having 'an axe to grind'. Researchers who are working with gatekeepers, they argue, will be engaged in a constant process of bargaining and negotiation.

A 'good' informant, Morse (1994, p. 228) declares, is one who has the necessary knowledge, information and experience of the issue being researched, is capable of reflecting on that knowledge and experience, has time to be involved in the project, is willing to be involved in the project and, indeed, can provide access to other informants. An informant who fulfils all of these criteria he termed a 'primary informant'. Morse also cautions that not all these features may be present in the informants, but that they may still be useful for the research, though the researcher would have to decide how much time to spend with these 'secondary' informants (those who meet some but not all of the selection criteria).

Stage 7: developing and maintaining relations in the field

This involves addressing interpersonal and practical issues, for example:

- building participants' confidence in the researcher;
- developing rapport, trust, sensitivity and discretion;
- handling people and issues with which the researcher disagrees or finds objectionable or repulsive;
- being attentive and empathizing;
- being discreet;
- deciding how long to stay. Spindler and Spindler (1992, p. 65) suggest that ethnographic validity is attained by having the researcher *in situ* long enough to see things happening repeatedly rather than just once, that is to say, observing regularities.

LeCompte and Preissle (1993, p. 89) suggest that fieldwork, particularly because it is conducted face-to-face, raises challenges and questions that are less significant in research that is conducted at a distance, for example: (a) how to communicate meaningfully with participants; (b) how they and the researcher might be affected by the emotions evoked in one another, and how to handle these; (c) differences and similarities between the researcher and the participants (e.g. personal characteristics, power, resources), and how these might affect relationships between parties and the course of the research; (d) the researcher's responsibilities to the participants (qua researcher and member of their community), even if the period of residence in the community is short; (e) how to balance responsibilities to the community with responsibilities to other interested parties.

Rapport

Critically important in this area is the maintenance of trust and rapport (De Laine, 2000, p. 41), showing interest, assuring confidentiality (where appropriate) and avoiding being judgemental. De Laine adds to these (p. 97) the ability to tolerate ambiguity, to keep self-doubt in check, to withstand insecurity and to be flexible and accommodating. Such features cannot be encapsulated in formal agreements, but they are the lifeblood of effective qualitative enquiry. They are process matters.

Qualitative research recognizes that relationships emerge over time, they are not a one-off affair or in which access is negotiated and achieved on a once-and-for-all basis; rather, relationships, trust, intimacy, reciprocity, intrusion, consideration and access have to be constantly negotiated, renegotiated and agreed as time, relationships and events move on, as in real life (De Laine, 2000, pp. 83–5). In this context Maxwell (2005, p. 83) suggests that 'rapport' is problematic in discussing relationships, as it is not a unitary concept concerning its *amount* or *degree* (indeed one may have too much or too little of it) (Seidman, 1998, pp. 80–2), but its nature and kind changes over time, as people and events evolve.

Rapport and relationships influence data collection, sampling and research design (Maxwell, 2005, p. 83). Indeed, in longitudinal qualitative research, Thomson and Holland (2003, p. 235) report that maintaining and sustaining positive relationships over time can contribute significantly to lower attrition rates of participants and researchers (and attrition is a problem in longitudinal research as people move out of the area, leave as they grow older, lose contact, become too busy and so on; p. 241). Similarly, Gordon and Lahelma (2003, p. 246), researching the transition of participants from being secondary school students into becoming adults, comment that maintaining rapport is a critical factor in longitudinal ethnographic research. Rapport, they aver (p. 248), is signified in attention to non-verbal communication as well as in the sensitive handling of verbal communication.

Rapport is not easy to maintain: for example, Bettez (2015) records the dilemma when maintaining rapport with one participant might negatively affect rapport with another or with readers, and another situation where a participant in a powerful, oppressive position may not want to be reported as such, or where a family may not wish to be portrayed in a particular way as it would affect their standing in the community, i.e. where the researchers and the participants do not agree about the reporting.

Rapport is often overlaid with power relations. For example, Swain (2006, p. 205) comments that, as an adult conducting an ethnography with junior school children, he felt obliged, at times, to take the 'adult', controlling position in the research, and that he could not act as a young child, indeed that the children would find it odd if he did (p. 207). He was not a child – he was older, taller, had a deeper voice and dressed differently, but he gave the children freedom to respond to his questions as they wished. That said, he commented that he tried to adopt a role that made it clear to the children that he was not a teacher.

The issue here is that the data-collection process is itself socially situated; it is neither a clean, antiseptic activity nor always a straightforward negotiation.

Stage 8: data collection *in situ*

The qualitative researcher can use a variety of techniques for gathering information. There is no single prescription for which data-collection instruments to use; rather the issue here is of 'fitness for purpose' because, as mentioned earlier, the ethnographer is a methodological omnivore. Some qualitative research can be highly structured, with the structure being determined in advance of the research (pre-ordinate research), for example in order to enable comparisons to be made – similarities and differences (e.g. Miles's and Huberman's (1984) cross-site analysis of several schools).

Less structured approaches to qualitative research enable specific, unique and idiographic accounts to be given, in which the research is highly sensitive to the specific situation, the specific participants, the relationships between the researcher and the participants (Maxwell, 2005, p. 82), and the emergent, most suitable ways of conducting the data analysis.

For data collection the researcher can use field notes, participant observation, journal notes, interviews, diaries, life histories, artefacts, documents, video recordings, audio recordings etc. Several of these are discussed elsewhere in this book. Lincoln and Guba (1985, p. 199) distinguish between 'obtrusive' methods (e.g. interviews, observation, non-verbal language) and 'unobtrusive' methods (e.g. documents and records), on the basis of whether another human typically is present at the point of data collection.

Field notes can be written both *in situ* and away from the situation. They contain the results of observations, analysis, researchers' comments and self-memos (cf. Mills and Morton, 2013, chapter 4). The nature of observation in ethnographic research is discussed fully in Chapter 26 of the present volume. Accompanying observation techniques are interviews, documentary analysis and life histories (discussed in Chapters 25 and 16). A popularly used interview technique employed in qualitative research is the semi-structured interview, where an interview schedule (list of items, questions, prompts and probes) is prepared that is sufficiently open-ended to enable the contents to be re-ordered, digressions and expansions made, new avenues to be included and further probing to be undertaken. Carspecken (1996, pp. 159–60) describes how such interviews can range from the interrogator giving bland encouragements, 'non-leading' leads, active listening and low-inference paraphrasing to medium- and high-inference paraphrasing. In interviews, the researcher might wish to further explore some matters arising from observations. In naturalistic research, validity in interviews include honesty, depth of response, richness of response and commitment of the interviewee (Oppenheim, 1992).

Lincoln and Guba (1985, pp. 268–70) propose several purposes for interviewing, including: *present constructions* of events, feelings, persons, organizations, activities, motivations, concerns, claims, etc.; *reconstructions* of past experiences; *projections* into the future; *verifying, amending and extending data*. Silverman (1993, pp. 92–3) adds that interviews in qualitative research are useful for: (a) gathering facts;

(b) accessing beliefs about facts; (c) identifying feelings and motives; (d) commenting on the standards of actions (what could be done about situations); (e) exploring present or previous behaviour; (f) eliciting reasons and explanations.

Lincoln and Guba (1985) emphasize that the planning of the conduct of the interview is important, including the background preparation, the opening of the interview, its pacing and timing, keeping the conversation going and eliciting knowledge, and rounding off and ending the interview. It is important for careful consideration to be given to the several stages of the interview. For example, at the planning stage, attention will need to be given to the number of interviews per interviewer, duration, timing, frequency, setting/location, number of people in a single interview situation (e.g. individual or group interviews) and respondent styles (LeCompte and Preissle, 1993, p. 177). At the implementation stage the conduct of the interview will be important, for example, responding to interviewees, prompting, probing, supporting, empathizing, clarifying, crystallizing, exemplifying, summarizing, avoiding censure, accepting. At the analysis stage there are several considerations, for example: the ease and clarity of communication of meaning; the interest levels of the participants; the clarity of the question and the response; the precision (and communication of this) of the interviewer; how the interviewer handles questionable responses (e.g. fabrications, untruths, claims made).

The qualitative interview tends to move away from a pre-structured, standardized format and towards an open-ended or semi-structured format (see Chapter 25), which enables respondents to project their own ways of defining the world. It permits flexibility rather than fixity of sequence of discussions, allowing participants to raise and pursue issues and matters that might not have been included in a pre-devised schedule (Denzin, 1970; Silverman, 1993).

The use of interviews is not automatic for qualitative research. Some participants may find it alien to their culture; they may feel uncomfortable with interviews, or indeed with any such formal verbal communication (Maxwell, 2005, p. 93). The qualitative researcher has to find a culturally appropriate and culturally sensitive way of gathering data. Maxwell (echoing Whyte, 1993, p. 303, discussed in Chapters 12 and 13) cites sensitive research (heroin users) which indicates that it is unwise or inappropriate to ask too many questions, and that conducting formal interviews is an alienating activity, better replaced by informal conversations and field notes.

In addition to interviews, Lincoln and Guba (1985) discuss data collection from non-human sources, including:

- documents and records (e.g. archival records, private records). These have the attraction of being always available, often at low cost, and being factual. On the other hand, they may be unrepresentative or selective, they may lack objectivity, may be of unknown validity and may possibly be deliberately deceptive (see Finnegan, 1996; see also Chapter 16);
- unobtrusive informational residues. These include artefacts, physical traces and a variety of other records. Whilst they frequently have face validity, and whilst they may be simple and direct, gained by non-interventional means (hence reducing the problems of reactivity), they may also be very heavily inferential, difficult to interpret and may contain elements whose relevance is questionable.

Qualitative data collection is not hidebound to a few named strategies; it is marked by eclecticism and fitness for purpose. It is not to say that 'anything goes' but that 'use what is appropriate' is sound advice. Mason (2002, pp. 33–4) advocates integrating methods, for several reasons:

- to explore different elements or parts of a phenomenon, ensuring that the researcher knows how they interrelate;
- to answer different research questions;
- to answer the same research question but in different ways and from different perspectives;
- to give greater or lesser depth and breadth to analysis;
- to triangulate – corroborate – by seeking different data about the same phenomenon.

She argues that integration can take many forms, and she suggests that researchers should consider whether the data are to complement each other, to be combined, grouped and aggregated, and to contribute to an overall picture. She also argues that it is important for the data to complement each other *ontologically*, to be ontologically consistent (p. 35). Added to this, integration must be in an *epistemological* sense, i.e. where the data emanate from the same, or at least complementary, epistemologies, and whether they are based on 'similar, complementary or comparable assumptions' (p. 36) about what researchers can legitimately constitute as evidential knowledge. Finally, she argues that integration must occur at the level of *explanation*. By this she means that the data from different sources and methods

must be able to be combined into a coherent, convincing and relevant explanation and argument (p. 36).

Data collection also relates to sampling. For example, in qualitative or ethnographic interviews, though the researcher may wish to include a range of participants, in fact some of those participants may be shy, inarticulate, marginalized, dominated, introverted, overwhelmed or fearful in the presence of others or of being censured, or uninterested in participating (Swain, 2006, p. 202). In these circumstances the researcher may have to use alternative methods of gathering data, such as observation. Miller and Dingwall (1997) point out that an interview may be very unsettling for some participants, being too formal or unnatural; it is not the same as a conversation, and some participants may not 'open up' in a non-conversational situation. We discuss interviews and interviewing in Chapter 25.

Stage 9: data collection outside the field

In order to make comparisons and to suggest explanations for phenomena, researchers might find it useful to go beyond the confines of the groups in which they occur. That this is a thorny issue is indicated in the following example. Two students are arguing violently and physically in a school. At one level it is simply a fight between two people. However, this is a common occurrence between these two students as they are neighbours outside school and they don't enjoy positive, amicable relations as their families are frequently feuding. The two households have been placed next door to each other by the local authority because it has taken a decision to keep together families who are very poor at paying for local housing rent (i.e. a 'sink' estate). The local authority has taken this decision because of a government policy to keep together disadvantaged groups so that targeted action and interventions can be more effective, thus meeting the needs of whole communities as well as individuals.

The issue here is: how far out of (or indeed inside) a micro-situation does the researcher need to go to understand that micro-situation (Morrison, 2009, p. 7), for example, the individual, familial, neighbourhood, local government or national government level?

Stage 10: data analysis

Though we devote six chapters specifically to qualitative data analysis later in this book (Part 5), there are some preliminary remarks that we make here. Data analysis involves organizing, accounting for and explaining the data; in short, making sense of data in terms of participants' definitions of the situation, noting patterns, themes, categories and regularities. Typically in qualitative research, data analysis commences during the data-collection process. There are several reasons for this, discussed below.

At a practical level, qualitative research rapidly amasses huge amounts of data, and early analysis reduces the problem of data overload by selecting significant features for future focus. Miles and Huberman (1984) suggest that careful data display is an important element of data reduction and selection. 'Progressive focussing', according to Parlett and Hamilton (1976), starts with the researcher taking a wide-angle lens to gather data, and then, by sifting, sorting, reviewing and reflecting on them, the salient features of the situation emerge. These are then used as the agenda for subsequent focusing. The process is like funnelling from the wide to the narrow.

Maxwell (2005, p. 95) argues for data analysis not only to be built into the design of qualitative research, but to start as soon as each stage or round of data collection happens, or as soon as any data have been collected, i.e. without waiting for the next stage, round or piece of data to have taken place. He cites the analogy of the fox having to keep close to the hare: keeping the collection and the analysis close together ensures that the researchers can keep close to changes and their effects. He suggests that data analysis commences with careful reading and re-reading of the data, then constructing memos, categorizations (e.g. coding into organizational, substantive – descriptive – and theoretical categories (e.g. related to prior theory, 'etic' categories, grounded theory)) and thematic analysis, and 'connecting strategies' such as narrative analysis (p. 96) and vignettes, discourse analysis and profiles (p. 98) that set the data in context and indicate relationships between different parts of the data such that the integrity – the wholeness – of the original context is preserved (p. 98), rather than the fracturing and regrouping of the data that can occur in a coding exercise.

Analytical memos, including striking observations and comments, enable researchers to make connections between observations, analysis and literature (Mills and Morton, 2013, p. 122). They act as a record, a reminder, a focus, a conjecture, a tentative explanation and a suggestion for future steps to take in the research.

At a theoretical level, a major feature of qualitative research is that analysis commences early on in the data-collection process so that theory generation can happen (LeCompte and Preissle, 1993, p. 238). LeCompte and Preissle (1993, pp. 237–53) advise researchers to: (a) set out the main outlines of the phenomena that are under investigation; then (b) assemble chunks or groups of data, putting them together to make a coherent whole (e.g. through writing summaries of what has been found); then (c) painstakingly take

apart their field notes, matching, contrasting, aggregating, comparing and ordering notes made. The intention is to move from description to explanation and theory generation.

Thomson and Holland (2003, p. 236) suggest that, in longitudinal qualitative research, data analysis should be both cross-sectional (in order to discover the discourses and themes at work in the construction of identities and interpretations at a particular point in time) and longitudinal (in order to chart the development of narrative(s) over time). However, they also recognize that cross-sectional approaches and longitudinal approaches may sit together uncomfortably, as the former chops up and reassembles text from different participants in order to present themes at one moment in time, whilst the latter seeks individual narratives that require the continuity that only emerges over time and within individuals (p. 239).

Longitudinal research that uses ethnographic techniques (e.g. life histories) can also be used to chart transitions in participants, for example, from primary to secondary school, from secondary school to university, from school to work, from childhood to adulthood etc. Gordon and Lahelma (2003) comment that in such research, the reflexivity of the participants can increase over time, and that sensitivity and rapport (discussed earlier) are key elements for success. Indeed the authors go further, to argue that as the research develops over time, so does the obligation to demonstrate reciprocity in the relationships between researcher(s) and participants, so that, just as the participants give information, so the researcher has an ethical obligation to ensure that the research offers something positive, in return, to the participants. This need not necessarily mean a material incentive or reward; it could mean an opportunity for the participants to reflect on their own situation, to learn more about themselves and to support their development (p. 249). In this case reflexivity is not confined to the researcher, but extends to the participants as well (p. 252).

We discuss cross-sectional and longitudinal studies (surveys) in Chapter 17.

Thomson and Holland (2003) indicate the frustration and intimidation that early analysis in longitudinal research can cause for researchers, as there is never complete closure on data analysis, as 'the next round of data' can challenge earlier interpretations made by researchers. Indeed they question when the right time is to commence writing up or make interpretations.

In addition to the challenge of continual openness to interpretation as qualitative research unfolds is the related issue of whose views/voices one includes in the data analysis, given that, in the interests of practicality, it may not be possible to include everyone's voice, even though the canons of validity in qualitative research might call for multiple voices to be heard. Eisenhart (2001, p. 19) points out that researchers all too easily can privilege some voices at the expense of others and that the express, beneficent intention of protecting some participants can have the effect of silencing them. How will the researcher present different, even conflicting voices, accounts or interpretations? What are the politics surrounding inclusion and exclusion of voices? We return to this issue in Part 5 on qualitative data analysis.

For clarity, the process of data analysis can be portrayed in a sequence of seven steps which are set out here and addressed in subsequent pages (Figure 15.4).

Step 1: establish units of analysis of the data, indicating how these units are similar to and different from each other

The criterion here is that each unit of analysis (category – conceptual, actual, classification element, cluster, issue) should be as discrete as possible whilst retaining fidelity to the integrity of the whole, i.e. that each unit must be a fair rather than a distorted representation of the context and other data. The creation of units of analysis can be done by ascribing *codes* to the data (Miles and Huberman, 1984). This is akin to the process of 'unitizing' (Lincoln and Guba, 1985, p. 203).

Step 2: create a 'domain analysis'

A domain analysis involves grouping together items and units into related clusters, themes and patterns, a domain being a category which contains several other categories.

Step 3: establish relationships and linkages between the domains

This process ensures that the data, their richness and 'context-groundedness' are retained. Linkages can be found by identifying confirming cases, by seeking 'underlying associations' (LeCompte and Preissle, 1993, p. 246) and connections between data subsets. This helps to establish core themes, i.e. those themes which seem to underpin or to have reference made to them most frequently or most significantly in the data, or which explain a lot (Gonzales *et al*., 2008, pp. 5–6).

Step 4: make speculative inferences

This stage moves the research from description to inference. It requires the researcher, on the basis of the evidence, to posit some explanations for the situation, some key elements and possibly even their causes. It is

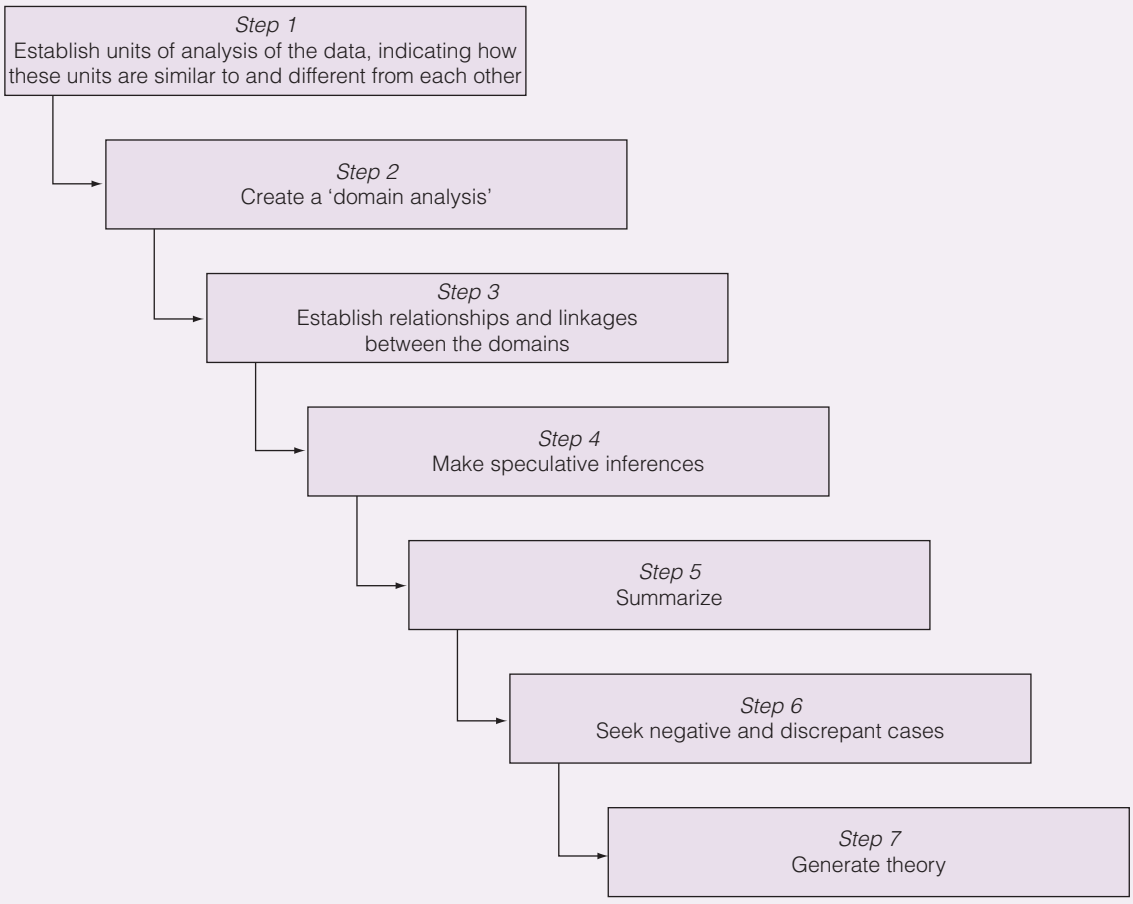

FIGURE 15.4 Seven steps in qualitative data analysis

the process of hypothesis generation or the setting of working hypotheses that feeds into theory generation.

Step 5: summarize

Here the researcher writes a preliminary summary of the main features, key issues and key concepts, constructs and ideas encountered so far in the research. We address summarizing in more detail in Chapter 33.

Step 6: seek negative and discrepant cases

In theory generation it is important to seek not only confirming cases but to weigh the significance of disconfirming cases. LeCompte and Preissle (1993, p. 270) suggest that because interpretations of the data are grounded in the data themselves, results that fail to support an original hypothesis are neither discarded nor discredited; rather, it is the hypotheses themselves that must be modified to accommodate these data. LeCompte and Preissle (1993, pp. 250–1) define a negative case as an exemplar which disconfirms or refutes the working hypothesis, rule or explanation so far. The theory that is being developed becomes more robust if it addresses and can embrace or explain negative cases, for it sets the boundaries to the theory, modifies the theory and sets parameters to the applicability of the theory.

Discrepant cases are not so much exceptions to the rule (as in negative cases) as variants of the rule (LeCompte and Preissle, 1993, p. 251). The discrepant case leads to the modification or elaboration of the construct, rule or emerging hypothesis. Discrepant case analysis requires the researcher to seek out cases for which the rule, construct or explanation cannot account or with which they will not fit, i.e. they are neither exceptions nor contradictions, they are simply different!

Step 7: generate theory

Here the theory derives from the data; it is grounded in the data and emerges from it (see Chapter 37). As Lincoln and Guba (1985, p. 205) argue, grounded theory must fit the situation that is being researched. Grounded theory is an iterative process, moving backwards and forwards between data and theory until the theory fits the data. This breaks the linearity of much conventional research (Flick, 1998, pp. 41, 43) in which hypotheses are formulated, sampling is decided, data are collected and then analysed and hypotheses are supported or not supported. In grounded theory, a circular and recursive process is adopted, wherein modifications are made to the theory in light of data, more data are sought to investigate emergent issues (theoretical sampling), and hypotheses and theories emerge from the data.

Lincoln and Guba (1985, pp. 354–5) urge the researcher to be mindful of several issues in analysing and interpreting the data, including: (a) data overload; (b) the problem of acting on first impressions only; (c) the availability of people and information (e.g. how representative these are and how to know if missing people and data might be important); (d) the dangers of seeking only confirming rather than disconfirming instances; (e) the reliability and consistency of the data and confidence that can be placed in the results.

Maxwell (2005, p. 108) draws attention to some important issues of validity for the qualitative data analyst, including researcher bias and reactivity. The former concerns the projection of the researcher's own values and judgements onto the situation, whilst the latter concerns the effect of the research(er) on the participants, giving rise to unreliable behaviours or changes to the natural setting (a particular problem, for example, in interviewing or observing children). Maxwell sets out a useful checklist of ways in which attention can be given to validity in qualitative research:

- *intensive, long-term involvement*, enabling the researcher to probe beneath immediate behaviours, for reducing reactivity and for revealing causal processes;
- *'rich' data*, sufficient to provide a sufficiently, revealing, varied and full picture of the phenomenon, participants and settings;
- *respondent validation*, to solicit feedback from participants on the interpretations made of, and conclusions from, the data;
- *intervention*, where the researcher intervenes formally or informally, in a small or a large way, in the natural setting in order to contribute positively to a situation (whether this is legitimate is a moot point, as it disturbs the natural setting, even though its intention might be in the interests of serving the ethical issue of 'beneficence'; see Chapter 7);
- *searching for discrepant evidence and negative cases*, in order to constitute a strong test of the theory or conclusions drawn;
- *triangulation*, in order to give reliability to the findings and data (see Chapter 14);
- *quasi-statistics*, where quasi-quantitative statements are interrogated, for example, claims that a finding is rare, extreme, unusual, typical, frequent, dominant, prevalent and so on;
- *comparison*, between groups, sub-groups, sites and settings, events and activities, times, contexts, behaviours and actions etc., to look for consistency or inconsistency, similarity or difference across these.

Swain (2006, p. 202) comments that, in writing up an ethnography or qualitative research, the researcher must exercise discipline, in that a faithful account has to be written, yet, for manageability, the level of detail on the context, emerging situation and events has to be reduced. Indeed he argues that less than 1 per cent of the collected data may feature in the final report, and that, even if all the data that were collected were included, these would constitute less than 1 per cent of everything that took place or that was experienced by the researcher. Fidelity to the detail may stand in a relation of tension to the final, necessarily selective, use of data, and care has to be given to issues of reliability and validity in such a situation.

These are significant issues in addressing reliability, trustworthiness and validity in the research (see Chapter 14). Further, the essence of this approach, that theory emerges from and is grounded in data, is not without its critics. For example, Silverman (1993, p. 47) suggests that it fails to acknowledge the implicit theories which guide research in its early stages (i.e. data are not theory-neutral but theory saturated) and that the theory might be strong on providing categorizations without necessarily explanatory potential. These caveats should feed into the process of reflexivity in qualitative research.

Maxwell (2005, pp. 115–16) also indicates that the process of data analysis, and the conclusions drawn from the data, should address generalizability, i.e. to whom the results are generalizable. Internal generalizability will indicate that the results and conclusions are generalizable to the group in question, whilst external generalizability will indicate that the results and conclusions are generalizable to the wider population beyond the group under study. He suggests that, whilst

the former may be applicable to qualitative research, the latter often may not. However, he also indicates that this by no means rules out the external generalizability of qualitative studies, as respondents themselves might have commented on the generalizability of their situation, or the researcher or readers might see similarities to other, comparable situations, constraints or dynamics, or the research might be corroborated by, or corroborate, other studies. He indicates, however, that external generalizability is not a strong feature, indeed a concern, of qualitative research.

Stage 11: leaving the field

The issue here is how to conclude the research, how to terminate the roles adopted, how (and whether) to bring to an end the relationships that have built up over the course of the research, and how to disengage from the field in ways that bring as little disruption to the group or situation as possible (LeCompte and Preissle, 1993, p. 101). De Laine (2000, p. 142) remarks that some participants may want to maintain contact after the research is over, and not to do this might create, for them, a sense of disappointment, exploitation or even betrayal.

The researcher has to consider the after-effects of leaving and take care to ensure that nobody comes to harm or is worse off from the research, even if it is impossible to ensure that they have benefited from it.

Stage 12: writing the report

Often the main vehicle for writing naturalistic research is the case study (see Chapter 19), whose 'trustworthiness' (Lincoln and Guba, 1985, p. 189) is defined in terms of credibility, transferability, dependability and confirmability (see Chapter 14). Case studies are useful in that they can provide the thick descriptions that typify ethnographic research, and can catch and portray to the reader what it is like to be involved in the situation (p. 214). As Lincoln and Guba comment (p. 359), the case study is the ideal instrument for 'emic' inquiry. They provide several guidelines for writing case studies (pp. 65–6):

- the writing should strive to be informal and to capture informality;
- as far as possible, the writing should report facts except in those sections where interpretation, evaluation and inference are made explicit;
- in drafting the report it is more advisable to opt for over-inclusion rather than under-inclusion;
- the ethical conventions of report writing must be honoured, for example, anonymity, non-traceability;
- the writer should make clear the data that give rise to the report, so the readers have a means of checking back for reliability and validity and inferences;
- a fixed completion date should be specified.

Spradley (1979) suggests a sequence of nine practical steps in writing an ethnography:

1. Select the audience.
2. Select the thesis.
3. Make a list of topics and create an outline of the ethnography.
4. Write a rough draft of each section of the ethnography.
5. Revise the outline and create subheadings.
6. Edit the draft.
7. Write an introduction and a conclusion.
8. Re-read the data and report to identify examples.
9. Write the final version.

Clearly there are several other aspects of case study reporting that need to be addressed. These are set out in Chapter 19.

The writing of a qualitative report can also consider the issue of the generalizability of the research. Whilst much qualitative research strives to embrace the uniqueness and individual idiographic features of the phenomenon and/or participants, rendering generalization irrelevant (though the study would still need to ensure that it contributes something that is worthwhile and significant for the research community), this need not preclude attention to generalization where applicable in qualitative research. Indeed one can question the value or contribution of idiographic research that does not have any generalizable function or utility (Wolcott, 1994, p. 113).

Generalization takes many forms; it is not a unitary or singular concept, and it connotes far more than the familiar terms 'transferability' (Denzin and Lincoln, 1994) or 'external validity' (Cook and Campbell, 1979). Larsson (2009, p. 27) comments that defining generalization as that which is derived by strict sampling from a defined population is often irrelevant in qualitative research. He also suggests that those single studies that seek to undermine 'universal' truths similarly do not need to aspire to be generalizable, as the single instance of falsification ('negative cases'; p. 30) may be sufficient to bring down the theory (though the case would need to be made that the 'truths' claimed to be universal in the first place as social actions may not be susceptible to universal laws of behaviour). However, he suggests three kinds of reasoning on which generalization in qualitative research might be useful:

1 Enhancing the potential for generalization by maximizing the range of a sample's characteristics in exploring a particular issue (e.g. in theoretical sampling) or phenomenon, i.e. to ensure that as many different cases or categories of an issue as possible are included in the research. Here uncommon cases have as equal a weight as the typical cases, and the variation that exists within the study should be expected to exist in the wider population, context or situation to which one wishes to generalize (p. 31). This, in turn, may require a larger sample than may be normal in qualitative research, in order to have as broad a variation and range of characteristics as possible included, and this may not be possible in some qualitative research, for example, case studies. It also assumes that the researcher will know what the maximum variation will look like, so that he or she knows when it is reached, and this, too, may not be realistic (p. 32).
2 Generalization by ensuring the similarity of contexts between that of the qualitative research and the wider contexts to which it is wished to be applied (akin to the 'transferability' criterion of Guba and Lincoln (1994)). Here Strauss and Corbin (1990, p. 267) argue that generalizability might also be replaced by 'explanatory power' in the context of the research and the wider contexts. This view of generalizability assumes that the characteristics of the wider contexts are known, and this may not be for the researcher to judge, but, rather, for the outsider readers, audiences or users of the research to make such judgements (cf. Wolcott, 1994, p. 113). Hence, Larsson (2009, p. 32) argues, the task of the researcher is to provide sufficient details and 'thick descriptions' for the audiences to come to an informed judgement about generalizability here. A problem is raised in this kind of generalizability, in deciding when and on what – and how many – criteria the contexts of the research and the wider contexts are similar and when sufficient similarity of contexts has been reached for the research to be generalizable to those wider contexts (p. 33), as the same people or kinds of people may act differently in different – or even the same – contexts.
3 Generalization by recognizing similar patterns between the research and other contexts (Larsson, 2009, pp. 33–5) in terms of, for example: theoretical constructions; themes; concepts; behaviours; assumptions made; processes; interpretations of actions, events or descriptions. Here the issue of interpretation is raised, as interpretations of one context may be very different from the interpretations made of another – however similar – context. Whether a pattern is indeed a pattern, or whether a construction is an acceptable construction, is a matter of debate and interpretation. Researchers have to be sure that the patterns between both research and the wider context are, indeed, tenable. Interpretation is an inescapable feature of qualitative research, and it is this precise matter that renders difficult the applicability of research from one context to another, because it is not the context but the *interpretation* of the context that has to be similar to that to which it is being applied. Further, one is faced with the added problem of identifying whose interpretation should stand (not only the issue of 'emic' and 'etic' research, but also whose 'etic' and 'emic' interpretations, given that there will be multiple variants of each type).

Larsson (2009, p. 36) is arguing powerfully that responsibility for generalization from qualitative research resides with the audience rather than the researcher. However, to suggest this may be to invite the view that the researcher has no special expertise to offer here; if so, then how is the research justified? Perhaps the solution to this is to regard the research, as with other kinds of research, as raising working hypotheses rather than conclusions, i.e. as 'work in progress' rather than unassailable truths.

Whilst it appears that writing comes late in the stage of the research, in fact it should be a continuous, ongoing activity, from the start to the finish of the research. Indeed Mills and Morton (2013) place the ongoing writing of an ethnography as a key, central feature of doing ethnographic work. Writing on an ongoing basis clarifies thoughts, observations, steps to take, reflections, analysis and so on. We strongly advise ethnographers to start writing from day one of their research.

15.11 Some challenges in qualitative, ethnographic and naturalistic approaches

There are several challenges in qualitative, ethnographic and natural approaches. These might affect the reliability and validity of the research, and include:

1 *The definition of the situation*: participants are asked for their definition of the situation, yet they have no monopoly on wisdom. They may be 'falsely conscious' (unaware of the 'real' situation), deliberately distorting or falsifying information, or being highly selective. Issues of reliability and validity here are addressed in Chapter 14 (see the discussions of triangulation).

2 *Reactivity* – the Hawthorne effect – the presence of the researcher, or the fact that it is 'research' can alter the situation as participants may wish to avoid, impress, direct, deny or influence the research(er). Again, this is discussed in Chapter 14. Reactivity can be addressed by careful negotiation in the field, remaining in the field for a considerable time and ensuring a careful presentation of the researcher's self.

3 The *halo effect* – where existing or given information about the situation or participants might be used in judging subsequent data or people, or may bring about a particular reading of a subsequent situation (the research equivalent of the self-fulfilling prophecy). This is an issue of reliability, and can be addressed by having a wide, triangulated database and the assistance of an external observer. The *halo effect* commonly refers to the researcher's belief in the goodness of participants (the participants have haloes around their heads!), such that the more negative aspects of their behaviour or personality are neglected or overlooked. By contrast, the *horns effect* refers to the researcher's belief in the badness of the participants (the participants have devil's horns on their heads!), such that the more positive aspects of their behaviour or personality are neglected or overlooked.

4 The *implicit conservatism* of the interpretive methodology. The kind of research described in this chapter, with the possible exception of critical ethnography, accepts the perspective of the participants and corroborates the status quo. It is focused on the past and the present rather than on the future.

5 There is the difficulty of focusing on the *familiar*, as participants (and, maybe, researchers too) may be so close to the situation that they neglect certain, often tacit, aspects of it. The task, therefore, is to make the familiar strange. Delamont (1981) suggests that this can be done by:

   - studying unusual examples of the same issue (e.g. atypical classrooms, timetabling or organizations of schools);
   - studying examples in other cultures;
   - studying other situations that might have a bearing on the situation in hand (e.g. if studying schools it might be useful to look at other similar-but-different organizations, for instance hospitals or prisons);
   - taking a significant issue and focusing on it deliberately, for example, gendered behaviour.

6 The *open-endedness and diversity* of the situations studied. The drive towards focusing on specific contexts and situations might overemphasize differences between contexts and situations rather than their gross similarity and routine features. Researchers should be as aware of regularities as of differences.

7 The *neglect of wider social contexts and constraints*. Studying situations that emphasize how highly context-bound they are might neglect broader currents and contexts – micro-level research risks putting boundaries that exclude important macro-level factors. Wider macro-contexts cannot be ruled out of individual situations.

8 The issue of *generalizability*. If situations are unique and non-generalizable, as many naturalistic principles would suggest, how is the issue of generalizability to be addressed? To which contexts will the findings apply, and what is the role and nature of replication studies (and are they necessary)?

9 How to write up *multiple realities* and explanations? How will a representative view be reached? What if the researcher sees things that are not seen by the participants?

10 Who *owns* the data and the report, and who has control over the release of the data?

Naturalistic and ethnographic research raises important, if challenging, questions for research in education.

To interview or not to interview?

Should the qualitative researcher, seeking to research a natural setting in as undisturbed a way as possible, intervene by interviewing, as interviewing is a non-natural activity, a disturbance of the natural setting? On the one hand, open-ended interviewing can find out participants' views on a situation, event, experience or phenomenon: it provides 'witness information' (Hammersley, 2013, p. 68) and involves participants in the situation. On the other hand, an interview is a contrived activity that is not part of the normal run of events for the participants but, rather, is a non-normal activity initiated by the researcher and his/her agenda, i.e. framing and shaping the situation through the researcher's eyes and asking for second-hand information in the sense of asking participants to comment on others' views in addition to their own. As we mention in Chapter 25, interviews are speech acts in their own right, not simply vehicles for collecting proxy data (cf. Atkinson and Delamont, 2006, p. 752).

Further, participants and interviews may not be genuine. Participants may withhold information (deliberately or not), distort the truth, promote their own agenda (e.g. 'position' themselves) and overlook the non-verbal interactions involved in interviews and their

transcription, to the extent that a 'radical critique' of interviews would reject them out of hand (Hammersley, 2013, pp. 69–72), for example, for being unreliable and invalid.

Hammersley (2006) also notes that the 'radical critique' of interviews raises questions of how far what is said in an interview really represents what is happening outside the interview (p. 9). Interviews, he contends, are their own context, and they shape what is said or not said (p. 9). Further, Atkinson and Delamont (2006) argue that short-stay, 'quick-fix' activities like interviews risk betraying the complexity of the social situation that qualitative research seeks to portray and understand, which can only be achieved by sustained research in the field.

Despite these challenges, this chapter has argued that qualitative research in its many forms is a very valuable approach to educational enquiry.

Useful websites for those commencing qualitative research are:

http://nsuworks.nova.edu/tqr (which gives the websites of several hundred other sites providing materials on qualitative research);
www.ukdataservice.ac.uk (the UK's Data Service, which includes qualitative data);
www.data-archive.ac.uk (the UK Data Archive);
http://gsociology.icaap.org/methods/qual.htm (a source for accessing other websites for online materials and support).

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Historical and documentary research

CHAPTER 16

Jane Martin

16.1 Introduction

The focus of this chapter is on research using historical and documentary evidence. Its aim is to convey the value of historical study, to consider the resources that may be available for the researcher and how relevant sources should be handled. The chapter goes beyond command of institutionalized, archival sources to consider the sheer diversity of sources and the ways these are affected by ideas of progress and loss. Debate and discussion will include: recent empirical trends and methodological arguments concerning the diverse material from which history is made; the availability and representativeness of 'historical data'; and the relationship between theory and 'facts'. In turn, the chapter points out some of the problems involved in doing historical and documentary research in educational settings. We finish by looking at a detailed case study of research that has made use of archival materials in an account that takes the figure of a woman educator activist as its central focus. The discussion will focus primarily on methodological approaches and strategies and their influence on the final outcome of the study.

The aspiration to discover what happened in the past and what it was like to live in the past is traditional to the nature of history. The challenge of accessing the voice of the past through time and space is something that excites historians. 'The past is a foreign country', sighs old Leo as he looks backs on his childhood with nostalgia in L. P. Hartley's influential novel *The Go-Between*, adapted as a film in 2015: 'they do things differently there'. Historians make history through the production of knowledge, explanations and interpretations of what has gone before. In discussing questions of sources and interpretations I shall endeavour to pass on the *pleasures* of working as an historian. It will be argued that the uses and limitations of historical sources can only be fully appreciated when they are understood in their social context as historical products. There is no straightforward sense in which history simply 'speaks for itself'. A *very* brief history of the study of history since the mid-nineteenth century will help show why.

16.2 Some preliminary considerations: theory and method

American historian Bonnie G. Smith looked at what happened when the practice of scientific history took root in nineteenth-century universities in Western Europe. In *The Gender of History* (1998) she argued that Enlightenment thinking influenced the making of a *professional* discipline in which empirically minded men defined themselves and their intellectual products in opposition to an older, more popular *amateur* history read for moral instruction and entertainment, which they deemed trivial. In such a context, history was no longer regarded as a branch of literature and a tradition of women's scholarship (as authors of textbooks, biographies or memoirs, translators and editors of original documents) disappeared from view. Consequently, when we imagine a great historian we automatically think of a man, we accept as natural titles like Malcolm Bradbury's *The History Man*, published in 1975, because professionalization and historical science developed at a time of separate spheres, when it was assumed a woman's place was in the home. Thus the making of a professional discourse involved Othering the scholarship, style and preferences of those without the ideological means to achieve disciplinary ascendancy.

Foundational claims over scientific, *empirical* history were intrinsic to the formation of this new, university-led discipline constructed upon a theory of knowledge that had its origins in the belief that knowledge derived from observation of the material world, the core tenets being: rigorous examination and knowledge of historical evidence, verified by references; impartial research, devoid of a priori beliefs and prejudices; an inductive method of reasoning, arising out of the sources themselves and moving from the particular to the universal (see also Chapter 1 of the present volume). By 1900 the assumptions about historical practice implicit within the study of history encouraged an approach consisting of the collecting and reading of the papers which official authorities drew up for the purposes of the conduct of their affairs, or which they

used in conducting them. To be steeped in primary or original sources, which were generated at the time of the event under consideration, helped lend intellectual authority among the historical profession. Scholarly reputations were built on the principles of the search for objective truth: the production of irrefutable, factual information located at the heart of the historical enquiry (Tosh, 2008, pp. 2–5).

Within this approach 'the facts' speak for themselves *independently* of a particular point of view. In *New Perspectives on Historical Writing*, British cultural historian Peter Burke (2001, pp. 3–6) stressed that the range of documents considered by traditional *empiricist* historians tended to be remarkably narrow. In the 1960s and 1970s many aspects of this account were energetically challenged (e.g. see Thompson, 1963; Hobsbawm, 1964; Rudé, 1964; Jones, 1971; Samuel, 1975). Social history, sometimes described as the 'history of the people' or 'history from below', emerged as an alternative to conventional political history, both in terms of its objects of interest and its belief in deep-rooted economic and social factors as agents of historical change. 'History from below' as practised by social historians used the language of class, including a Marxian approach to society that could be applied to a wide range of historical cases, as indeed Marx applied them. Revisionist studies in the history of education tried to question the Whiggish assumption that the course of historical development was an unbroken chain of ascent from a benighted past to an enlightened present. In their introduction to *Children, School and Society*, published in 1981, Anne Digby and Peter Searby expressed their dissatisfaction with a view of education from Westminster or Whitehall rather than the home or the schoolroom and their aspiration to provide a corrective to the dreary sequence of institutional growth that characterized former narrow, excessively bureaucratic histories of education.

A broadening of attention to other documentary sources was an important feature of the broad body of social history, allied with a willingness to supplement documents with other sources of evidence. For example, the revival of oral history derived from a new generation of historians steeped in the politics of the New Left, civil rights and feminism (e.g. Rowbotham, 1975; Thompson, 1978). Recovering lost voices provided a means to empower women, the working-class and minority communities, allowing them to speak for themselves, thereby contesting the national consensus, enlarging the explanatory concepts available to historians, generating new perspectives and radical critiques of education, youth and structural racism and sexism.

The 'take-off' of cultural history from the late 1980s onwards ruled out a fundamentally positivistic concern with getting at the truth, giving readers 'the facts'. While I shall not explore the minutiae of these approaches here, a *post-structural approach* to history entails remaking ourselves as readers and writers, giving us new methodological tools with which to approach the task of assessing and interpreting sources. Here meaning is looked for in a culture's language and systems of representation. Perception of empirical reality was constituted through multiple refracting perspectives: one that is constantly changing, subject to variation over time as well as in space. Thus, rather than a historical practice based on straightforward readings of state papers and official data, the same material artefacts or texts may be used, but read against the grain, looking for contested meanings and omissions. The linguistic turn opened up new ways of interpreting texts, which may contain different rhetorical strategies and voices as opposed to being written as supposedly objective, and especially the relationship between them – 'intertextuality'.

For historians, many post-structuralist topics and methods are a legacy of the work of Michel Foucault. Foucault studied what he termed 'the history of systems of thought' (e.g. Foucault, 1970). He argued that documents are not of interest because of what they tell us about the author, but because they inform us about the mechanisms through which power is exercised. That is, documents are a medium through which power is expressed. In adopting an interpretivist or discourse analysis approach, one would believe that the critical analysis of a document involves questioning why the document was produced, what is being said (overtly and covertly) and what is not being said (see also Chapter 3 of the present volume). Post-structuralism treats texts of all kinds as systems of signification (collections of signs which conform to some internal system), whose meanings can be ascertained in part by deconstruction, acknowledging that meaning can be self-referential and not entirely taken from the context in which it was produced or from authorial intent.

The collection and presentation of historical material is inevitably selective, and, to some extent at least, this selection and interpretation relies on the questions asked of the material, or the theoretical perspective which is brought to bear on any particular piece of research. No general consensual version of history is possible and monolithic accounts are unlikely to be either adequate or satisfactory. Different groups do have different interests, experiences and cultural forms, and do provide alternative definitions and accounts of these. Much of the historian's skill lies in the creative

and self-aware use of the sources from which history is made. Let us now turn to the task of assessing and interpreting those raw materials. It is important to appreciate the richness and the limitations of each type.

16.3 The requirements and process of documentary analysis

When discussing documentary sources it is conventional to differentiate between 'primary' and 'secondary'. The former encompass every kind of evidence which people have left of their past activities, produced during the period being studied. The latter discuss the period studied but are created sometime after it or in some way removed from the actual events that are the focus. Simply put, primary analysis is an interpretation of raw materials, whereas secondary analysis involves an examination of the interpretations of others. Obviously, it is possible for some sources to act as both primary and secondary sources, depending upon the exact context of the information we are interested in. We can perceive this in my study of the 'career' chances for twentieth-century women historians, which employed writings conventionally designated secondary sources, as primary sources. Thus, whereas Eileen Power's *Medieval Women* is a secondary text for a historian of the period, for me, as an example of Power's *oeuvre*, it became a primary source (Martin, J., 2014).

When we decide to use historical documents, their validity and reliability must always be held up for scrutiny. Scott (1990) identifies four potential challenges. To start we have to consider the issue of *authenticity*; who a document was written for and by (authorship); whether it constitutes a first-hand, second-hand or even more remote account; whether confidential or not, public or private, forced or voluntary and so on. At a simple descriptive level, whether the document is 'sound' or *authentic* may be challenged on several grounds – if it contains many errors, is one of many versions, is inconsistent in relation to other similar documents and in terms of 'ownership'. It is not always the case that the identity of the author is apparent.

Credibility is a second potential challenge. In other words, is the document we are analysing reliable? Is it undistorted, 'sincere' and 'accurate'? For a document to be credible, we need to be aware of the purpose of the document. Was it produced to describe events, to persuade (such as a school brochure) or to self-protect (such as a ministerial memorandum)? The purpose of a communication, then, can provide an important context for understanding its content. This is not to say that you should be suspicious of every document you encounter. However, there is always a possibility that the author of an official document did not believe what he or she recorded, while personal documents may be produced for a host of reasons, depending on the mood of the moment.

Third, we need to ask whether the document is *representative*. Are we looking at a unique view or does it represent a 'general mood of the time'? Assessing the typicality, or otherwise, of evidence centres on the two aspects of 'survival' and 'availability'. Not every document will make its way into an archive: documents have differential survival rates and those which do survive do not always provide all the information required. The answers to a great many questions are simply not available, since the necessary records either never existed or failed to survive. With respect to the UK national archive, selection of public records takes place in two stages. At the outset, records which are considered worthless are destroyed, and those which have been identified as valuable for future administrative need or future research are kept for further review when the record is fifteen to twenty-five years old. The UK's Freedom of Information Act (2000) governs access to information held by most public authorities, with two forms of exemption: 'absolute' and 'qualified'. In the case of the latter, a public interest test must be made, balancing the public interest in maintaining the exemption against the public interest in disclosing the information. A classic example is data on school exclusion, which would be subject to a 100-year rule because disclosure could cause distress to living individuals.

Finally, we need to pay attention to the *meaning* of the document. There are three aspects to this. These are: the *intended content* of a text, the *received content* of a text and the *internal meaning* of a text. Acknowledging the complications of text comprehension, Scott (1990) describes the process of understanding a text hermeneutically according to his four criteria (authenticity, credibility, typicality and meaning). To some extent a heuristic tool, the hermeneutic circle requires closing the loop whereby knowledge and understanding of the text as a whole is achieved through 'dialogue' within boundaries set by the frames of reference of the researcher and those who produced the text.

16.4 Some problems surrounding the use of documentary sources

Documents are selective in terms of the information presented. Some documents are produced with research in mind (most institutions and some individuals have deliberately sought, with an eye on the future, to generate accounts of their activities); others are produced for

personal use and are less self-conscious. Either way, the act of recording will also be informed by the social, cultural, economic and political landscape of which they are a part.

It is important to ask who created the source and how it was understood by contemporaries. When political texts are employed, intellectual historian Quentin Skinner (2002) takes this process a step further. First, by insisting that the works of political thinkers be understood within the context out of which their works were produced, and second, that they be understood as acts of rhetorical communication – to consider the intentions of the author and how they were received.

A less obvious problem is that those who work with historical documentary evidence can have both too little and too much available to them. You might never find exactly what you need; on the other hand, where, in the large amount of twentieth-century material for example, do you start? In reality, our understanding of educational history is informed by a selective reading of documents. It is highly unlikely, particularly for undergraduate students, that you will have had the time or opportunity to read *everything* about a person (for example, an education minister) or an event (for example, the imposition of a legally enforced national curriculum). Similarly, the *types* of document we read vary in terms of information and accuracy: some are very opinionated or subjective whilst others may be highly factual and descriptive.

The categorization of historical documents largely follows the dominant definitions of a particular period and if we are to read the silences we need also to look at material which gives little hint that evidence we need may be lurking inside it. There are several consequences of this approach. First of all, for much of the time one is working in the dark. Decisions about what to look at and what to ignore may be a hit-and-miss affair. Second, this kind of research is time-consuming, frustrating, often unrewarding and frequently leads to a feeling of wasted time and effort. Third, the amount of material which historical researchers often have to handle makes some kind of selective reading or sampling, whether deliberate or otherwise, inevitable. But on what basis should choices be made? The collection and presentation of raw materials is inevitably selective, and to some extent at least this selection and interpretation relies on the questions asked of the material, or the theoretical perspective which is brought to bear on any particular piece of research.

One method of selection is to focus on 'significant' events or periods, guided by information from secondary sources. One drawback of this approach is the possible risk of interpreting a set of extraordinary circumstances as being more generally applicable. It means we cannot explain change over time, or understand apparent continuities and apparent breaks in activity. Alternately, one could adopt a more random approach, for example, the selection of, say, one newspaper a month, or more systematic sampling (see Chapter 12 of the present volume) of every tenth newspaper. An obvious drawback to this method is the difficulties it presents in following up stories. The best solution to the problem may be the use of a variety of sources simultaneously so that an overall pattern begins to emerge which suggests directions for future research. There can be no 'formula' for decisions of this kind. A 'feel' for the period, the relevant questions and the sources is ultimately what guides the methodology of any historical research project, and this can only properly be gained as part of the research process itself. Ideally it may be that the research should be considered finished when all the classes of document relevant to it have been exhausted, but this is rarely a practical proposition. There is a sense, inevitably, in which the research is over whenever it is time to stop.

Quality appraisal is a never-ending process. This does *not* mean that only error-free, typical documents (from written to oral) which have a common interpretation can be used. What it *does* mean is that we must be at least aware of any challenges to reliability that may exist, or that others may interpret the information held within differently.

16.5 The voice of the past: whose account counts?

A move away from structuralism in all the social sciences is important in accounting for the increasing numbers of historians who have turned to biography in the last thirty years. In a widely read textbook on the study of history, Ludmilla Jordanova (2000, p. 41) likens biography to 'holistic history'. Barbara Finkelstein (1998), Diana Jones (1998) and Peter Figueroa (1998) all indicate clearly the considerable strength of the biographical approach for an understanding, and bringing to life, of the history of education. Educational biography offers a frame of reference within which to assess the relative power of material and ideological circumstances, the meaning of policy and practice, the utility of formal and informal schooling and the relationship between learning and teaching. Researchers utilize any form of writing that includes a construction of the self (diaries, memoirs, letters, autobiography and biography, travel writing), oral testimony, photographs and material objects (see also Plummer, 2001).

Kathleen Weiler's (1998) study of women teachers in two rural California counties from 1850 to 1950 relies heavily on oral testimony. Texts and testimonies explore the social contexts of teaching, employed to understand what teaching meant to women teachers, what it provided them and how it shaped their categories of *experience*. Building on the work of gender historian Joan Scott (1986) and influenced by Foucault, three key concepts inform Weiler's approach – *knowledge*, *language* and *subjectivity*. Used to convey the constructed quality of memory and experience, subjectivity includes the struggle and contest over identity, the process of identification and an unstable, shifting subject constructed both through dominant conceptions and resistance to those conceptions.

Peter Cunningham and Peter Gardner (2004) also used interviews as a source to help reconstruct what being a student teacher meant to various groups in early-twentieth-century England. They wanted to write a different kind of history concerned with the day-to-day experience of ordinary teachers as opposed to the administration of education. For them this was not solely a matter of restoring 'lost voices' or interlocutors; it was also about recording and interpreting events previously excluded both for contemporaries and for future generations. It was about the creation of a more accurate historical record and therefore a more 'useable' past that includes possibilities we might not even have considered because the record of the road not followed was less likely to survive (possibly destroyed by people with different priorities). Opening themselves to this recognition produced a history-writing that is wider in scope and does not just reflect the standpoint of authority.

Oral testimonies also formed the core of a project exploring work and identity in three main occupational sectors, including teachers, in twentieth-century England. Overall the team conducted forty interviews with three generations of men and women teachers: retired, mid/late working life and younger teachers or people who were new entrants, with interviews taking place in London and the south-east and the north-west of England. Many of the interviews with older people were conducted in people's homes, allowing, in these cases, for a more reflexive account of working life, whereas those spoken to in the workplace gave shorter answers to the interviewers' prompts: the pressure of a working day pre-empting any long conversations, but not precluding articulate insights into the narration of the 'teacherly self'. Whilst they all talked about 'making a difference', 'postmodern' teachers expressed themselves in terms of a kind of entrepreneurial culture, whereas earlier generations articulated the vocabulary and presuppositions of moral citizenship. But the notion of 'teacher resilience', whereby a set of values understood as a structure of feeling – following Raymond Williams (1961) – emerged as something that endures across generations and this was partly explained by the importance of 'emotional labour' in teaching (Kirk and Wall, 2011).

Another example of what historical and archival resources have to offer educational researchers was provided in 2001 by Jonathan Rose, whose *Intellectual Life of the British Working Classes* was one of the first examine the reading practices of past generations. There is some evidence for select members of the well-connected, articulate, document-preserving classes, but what of the little recorded majority? Rose employs various kinds of autobiography and memoir written by those from working-class or other modest backgrounds, people who had usually received very little formal schooling, at least until the middle years of the twentieth century. He also makes good use of library records, educational archives, oral histories and Mass Observation, and early social surveys to create a detailed history of working-class reading.

Using image as historical evidence is a relatively new addition in the history of education pioneered in *Silences and Images* (1999), edited by Ian Grosvenor, Martin Lawn and Kate Rousmaniere. Taking representations of teachers as an example, António Nóvoa (2000) analyses his personal archive of over 600 images from published sources that spans two centuries and a range of continents. Nóvoa notes a consistency of themes equating to what he terms a 'grammar of schooling', consisting of secondary teachers undertaking pupil assessment and male primary teachers represented as disciplining figures. In so doing, he combines quantitative analysis and iconography (understood to mean a range of, or system of, types of image used to convey particular meanings) used as a way of 'reading' visual sources (see also Chapter 36 of the present volume).

Christine Wall (2008) drew on careers literature available in University College London's Institute of Education library on open access and material published by the largest teaching union, the National Union of Teachers (NUT), held in the Trades Union Congress (TUC) Library Collections at London Metropolitan University, to study the formation of gendered teacher identities between 1940 and 2000 in Britain. In so doing, Wall paid particular attention to visual representations of teachers on the front covers of the house journal of the NUT, published as *The Schoolmaster and Woman Teachers' Journal* until 1962, when it became *The Teacher*. Her analysis involved, first, a quantitative

'sorting' of images and from this a closer reading of selected images employed to depict the occupation of teaching ensued. The smaller number of images was selected on the basis of a particular iconography: a set of noticeably recurring, thematic compositions conflating the role of woman teacher with motherhood. One series of compositional similarities that stood out, for example, was the standard Christian iconography of the Madonna and Child.

16.6 A worked example: a biographical approach to the history of education

This section reports a worked example of my own practice as a researcher in the history of education. It indicates several key points in planning and 'doing' such research, the personal motivations and commitments of the researcher-as-historian, and the processes involved, focusing on my biographical project on Mary Bridges Adams (née Daltry, 1855–1939), one of twenty-nine women members of the London School Board (LSB). Set up under the 1870 Education Act, school boards were the most advanced democratic bodies of their day. Ratepayers elected them every three years by secret ballot, and women could both vote and stand for office. Multiple voting and the possibility of giving your vote to one candidate favoured the representation of electoral minorities, especially working people and women. For example, the nine women elected in 1879 constituted 18 per cent of all LSB members. Women's numerical representation in the House of Commons did not match this until the 1997 general election, following the Labour Party's adoption of all-women shortlists (1993–6). My narrative exposes some of the trials, tribulations and benefits of historical and documentary research, with the intention of providing guidance and understanding to researchers in the field (see Martin, J., 2013).

The background to the research

From the 1890s, Mary Bridges Adams (she did not hyphenate her surname but others, including her son, did) played an active public role in the British labour movement, even though women did not achieve the vote in general elections until 1918. At a local level, she spent seven years as a member of the LSB, then the largest and most powerful organ of local government in the world. Mary's voice rose out in particular. She was in a minority of one as a socialist woman of working-class social origin. A unionized worker who called herself the 'representative of organized labour', she joined the National Union of Gas Workers and General Labourers because, she said, she was a gas worker on the platform and a general labourer at home. How influential was she?

By 1900, Mary was well-known as a participant within the broader labour movement and as a campaigner for improvements in working-class education. During the First World War, she was in close touch with the European anti-war movement and threw herself into Russian émigré politics. Guiding campaigns in defence of the right of asylum, she had a range of contacts among suffragettes, trade unionists and international socialists. She urged people to fight the abandonment of industrial rights and guarantees, such as the right to strike and restrictions on the use of child labour, to back the unofficial rank-and-file industrial movement on Clydeside and the educational work of the Scottish Marxist John Maclean (1879–1923). Foes thought her an awful woman; friends like George Bernard Shaw (1856–1950) remembered the power of her oratory. The aim of this project was to research and write a significant, original and debate-changing biography to consider the main project of 'making socialists' from the standpoint of gender. Such an assessment has its difficulties but this case outlines the reasons why a study of Mary Bridges Adams is important.

The research 'problem'

Turning to the past means much more than focusing solely upon bureaucrats and politicians who wielded enormous influence in the official central state. It can also involve historical detective work into those places where British women were most influential in the late nineteenth century: local education policy and practice. Mary Bridges Adams was excluded from high politics for the whole of her political career but she did not wilfully hide herself from history. In her lifetime she preserved myriad press cuttings about her activism, and her public utterances stressed her contribution to education and politics as part of the story of British socialism. A truer picture of the past requires an appreciation that British women, like British working men, played an active role in politics in the years before they obtained the national vote. Researchers have so far built up only a partial picture.

In her day, Mary was a national figure in British socialism. Nonetheless, her voice is absent from the established canons of political history, despite inclusion in the *Dictionary of Labour Biography*. The exception to this is Patricia Hollis's *Ladies Elect*, published in 1989. However, her activities do grace the footnotes of some educational histories (Simon, 1965; Kean, 1990; Manton, 2001). Building on this, the objectives of the Bridges Adams project were to: (1) offer a timely and

wide-ranging reappraisal of an era of radical social reform seen through the lens of a pivotal figure; (2) piece together the various parts of Mary's life: public and personal, open and hidden; (3) provide context and a conceptual tool for understanding developments at a crucial turning point in English education, 1890–1910; and (4) challenge political narratives and promote different ways of thinking about the place of the educational question in the study of British socialism.

Mary's life, her attitudes and actions, her role in respect of campaigns for improvements in working-class education, are accessible only through the documentation that has survived. We do not know where she was educated, the schools in which she taught or what kind of classroom teacher she was. Yet she was a prolific writer of articles and her national reputation as a speaker meant that her political activities were regularly reported, and some of her spoken words were relayed in local newspapers. Mindful of the risks of formlessness, the objective was to explore and assess the life's work of Mary Bridges Adams using a range of sources – textual, visual, oral – in ways that allow the reader to understand complexity rather than force Mary's experiences into an over-simplified pattern.

Initiating the process of researching the past: the importance of archives

It was a hot July day in 1990 when I first read Mary's passionate speech in support of free school meals in a dusty copy of the *School Board Chronicle* in the London Metropolitan Archives. Just after her election as a member for Greenwich in the autumn of 1897, there she was at a public Board meeting effectively telling the upper-middle-class membership of the LSB that they could not possibly imagine what it was like to be poor. Writing this woman's life had value for me because of her lifelong concern for class justice. If she had emerged victorious from the political battles that she fought at a crucial turning point in English education, my mother's family would not have felt the sting that came from having to leave school at thirteen or fourteen. She hooked me then and she hooks me now. Fairly quickly, I found myself feeling possessive of my subject rather like the woman researcher A. S. Byatt describes in her brilliant 1990 novel *Possession*.

My starting point was to go to sources: institutional records, personal papers, previously unknown and under-utilized contemporary material, autobiographies, biographies and biographical dictionaries, notably the *Dictionary of Labour Biography*. The *School Board Chronicle* proved crucial because it offered a blow-by-blow account of weekly debates at the meeting of the whole Board. Mary's rhetorical skills were evident, even if she did not always influence decision making. Ahead of her time, she supported the extension of opportunities for all working-class children and specifically attacked the idea of a meritocratic 'ladder of opportunity' for the few.

One of 'my women' at the heart of what started life as a collective investigation of women and educational policy making in late Victorian and Edwardian England (Martin, 1999), Mary was little more than a footnote in the history of education when I began my learning journey. Education politics provided early opportunities for Victorian women and, initially, my main research questions focused on the workings of gender and power on the London School Board, investigating the 'success' factors that facilitated women's careers in public life and the impact of their presence. Mary was one of these pioneer political women, serving from 1897 to 1904 (when the Board was abolished under the 1903 Education Act). When it came to interpreting the sources, meaning could be imputed, not always demonstrated. It is hard to apply key sociological concepts such as power, authority and control to second-hand accounts of a given historical situation. Ambitious plans to employ all sources quickly evaporated given the constraints of time and space. A more realistic decision was taken to focus on the official material on the LSB and the Board's official organ *The School Board Chronicle* that included details of debate at the weekly meetings of school boards throughout England and Wales with extensive coverage of events in London. Other published commentary consulted included the teachers' press, contemporary periodicals and local newspapers, supported by reference to the archives of other relevant institutions, persons and parliamentary papers.

As my gaze turned to the search for Mary's story, I tracked down the references that followed Mary's entry in the *Dictionary of Labour Biography*. Texts were sampled to address specific aspects of my main questions about gender and power: What was the way in which Mary's life unfolded within, and was shaped by, and helped to shape, a particular political, economic, social and cultural context? What were Mary's distinctive qualities – personal and political? What was the impact of her contribution to developments in working-class education, as a committed democrat, socialist and internationalist? What were the dilemmas and contestations that she encountered? What were the criticisms of her?

I constructed my account of Mary's public life from a wider variety of sources, including her own published letters and articles culled from the newspapers of the day, reports in the socialist and educational press,

official records, memoirs and other autobiographical writings, present-day books and articles. I benefited enormously from an oral history interview with Mary's grandson, Nicholas, and the support of his widow, Jenifer. Both offered rare vignettes of a personal kind.

The LSB *Minutes* contain much informative detail, such as data on attendance at meetings, voting records and motions of policy. A search of the index took me to Mary's first appearance via the correspondence pages for 3 May 1895. On that day, six working-class political organizations wrote to request that she inherit the Greenwich seat of a recently deceased Board member. 'Mrs. Bridges Adams, from her learning, great scholastic experience, lucidity of thought and expression, aptness of resource and charm of presence would add distinction to the Board', Woolwich Gas Workers wrote. 'She had the full support, during the last Election of all the Labour Bodies and polled the largest number of votes of any defeated candidate.' In contravention of established protocol, Board members voted to co-opt a male lawyer. Keir Hardie (1856–1915), leader of the UK's Independent Labour Party, angrily protested how the established parties closed ranks to keep a socialist out, with the one dissentient hastily explaining his error (*Labour Leader*, 18 May 1895, p. 8).

Besides the published *Minutes*, background information on the achievements of the LSB was gleaned from the annual report and address of the chairman (available on open access). I was able to order relevant records produced by the sub-committees on which Mary served, together with those on the Board schools for which she became a manager. The amount of information I gathered from the committee records varied. Sometimes I would spend what seemed an eternity hunting down documents that turned out to have nothing much of interest. Sometimes I would use files that were a gold mine of information, such as the 1899 Report on a Special Committee of the General Purposes Committee, particularly helpful on the question of Mary's campaign for school meals, or the 1907 Report on the Bostall Wood Open-air School that ran for three months in the summer of 1907. The experimental open-air school was Mary's initiative, conducted on land owned by the Royal Arsenal Co-operative Society (RACS). The support of the RACS, the largest of its kind in Greater London, was critical to Mary's successful candidature for the LSB. Information about their association can be found in the Half-Yearly Reports and the Bulletin of the Society, known as *Comradeship*.

Tuberculosis was the prime cause of child deaths at the time and doctors claimed they could identify a child at risk, estimated as 10 per cent of the school population. In this context, a new category of 'pre-tuberculous' child became the focus of work on the health benefits of fresh air, sunshine, healthy food and daily exercise. Mary wanted to establish a national system of open-air recovery schools and asked the RACS to donate some of its land at Bostall Wood, Plumstead, for an experiment. The cooperators agreed to her request, the London County Council accepted their offer, and the mixed school opened on 22 July 1907, with 113 weak children. A close reading of press cuttings filed by the cooperators that survive within the RACS Papers in Woolwich, London, shows that 143 newspapers discussed the venture, but only *Clarion*, *Justice*, the *Lancashire Post* and the *Morning Leader* mention Mary's contribution. Her supporters noticed this. Under the headline 'Credit where it is not due', *Justice*, the weekly paper of the Marxist Social Democratic Federation, accused the Conservative councillor Ernest Gray (1857–1932) of trying to gain recognition for a scheme which was not of his making.

Widening the search: uncovering public and private resources and some practical considerations

Much of Mary's evidence is missing because her son destroyed the letters written by her to him, and all photographs of her. As a consequence, her personal papers are only fragments and her surviving letters are mostly short. Widening the search, I was able to track down a mysterious suitcase of papers left with Mary by a leading Russian émigré deported after the Revolution in 1917, now the Mary Bridges-Adams Collection on the British Labour Movement and Russian Socialists, 1905–39, held in the Rare Book and Manuscript Library at Columbia University. Besides Russian letters, they included illuminating correspondence with Mary's patron, the Countess of Warwick (1861–1938).

In association with the study I have compiled a modest database of biographical information to investigate Mary's networking through the use of prosopography, a historical method involving the examination of a number of lives in a given place, to show that socialism was both a lifestyle and a form of organized political activism. This approach facilitated an assessment of social and intellectual backgrounds from a grounded and qualitative perspective, showing the sequencing of connections located in time and space, social history and social geography. All political movements are as much the history of social and intellectual networks as they are of campaigns and lobbying. Making sense of Mary's political career, her circle of influence connected to leftist counter-cultures in Glasgow,

Lancashire, London, the Rhondda and West Yorkshire. Biographical approaches helped generate what Clifford Geertz (1973) called '*thick descriptions*' in ethnography (see Chapter 15 of the present volume). Mary's life is historically placed. The history-writing is a graphic encapsulation of the cultural milieu of which she was a part, to convey a sense of how it felt to be there, the motivations of the struggle, from the point of view of participants who shared her vision of the future.

Accordingly, the works of other historians, political writers and journalists of different hues, biographical writings of fellow travellers and contemporaries were used to contextualize Mary's experience of maturing in the 1870s and 1880s. It is not too difficult to reconstruct some kind of picture of the social structure and life of the nineteenth-century South Wales mining village in which she was born or the Elswick district of Newcastle-upon-Tyne in which she grew up, with the aid of secondary sources, contemporary histories, trade directories, business records, government reports, maps, census material, newspapers, autobiographies and so on. Local history collections were mined to reinsert Mary's presence into the social and political landscape of the period. The best starting point for information relating to local government and politics is the local and regional newspapers for the place in question. In time, knowledge and understanding based on reading the *School Board Chronicle* were supplemented by reports in local newspapers.

My own experience of intermittently researching and writing Mary's biography speaks directly to how the Internet age is affecting scholarship. The expanded capabilities of the web are changing our methods of historical research. Now, digitized guides serve as time-saving devices for the kind of historical detective work described here. Proper integration of a *longue durée* perspective requires me to say that if I were starting the research now it would be far easier to track down the letters produced by Bedford College, for example, that showed how Mary obstinately fought her way into tuition in the Classics.

Up to 2002, I had used the Internet to *prepare* to visit traditional archives, but never to retrieve actual material. So, when I started 'looking for Mary', a local archives service found her in the 1871 Census listed as a fifteen-year-old pupil-teacher (an apprenticeship scheme for training teachers in school settings, common at the time) living with her family at the Robin Adair public house in Elswick. More recently, I was able to use subscriber databases to supplement the family history and the history for the streets in which she lived and those of her political supporters. But it remains the case that the paucity of sources means that I can only speculate where she trained to teach. No school records for the locality have survived (before 1910) and the names of pupil teachers do not appear in the Newcastle School Board *Minutes* until the late 1870s. No clues were found in the Newcastle directories.

Visual remains have been hard to come by, apart from the passport-sized studio photographs of the newly elected London School Board which take up several pages of the *Illustrated London News* in December 1897. Mary is shown in profile. Luxuriant, almost pre-Raphaelite-styled hair frames a strong, attractive face and she fixes the camera with a commanding gaze. This is in stark contrast to her female colleagues, their hair scraped off their foreheads and pulled behind their ears. Ten years later, there is a *Daily Mirror* photograph of two ladies in hats – Mary and the aristocratic Daisy Warwick – resplendent in an open carriage, alongside a report on the 1907 Trades Union Congress. In a staged photo shoot they look directly at the camera with panache. There may be gaps in the account but the real problem in this research centred on how to handle those questions dealing with Mary's attitudes, values, beliefs and aspirations. Writing history 'from the bottom up' meant finding creative ways to scrape that bottom for any smidgen of information.

Building up the political profile

Bridges Adams was among the thousands of women recruited to teach in the nineteenth-century elementary school system. She objected to the unequal social order that she saw strengthened by the educational process, and a vision of a better society carried her out of the classroom and into political action. In her late twenties, she decided to 'cross the river of fire' and enter the socialist movement. This was how William Morris (1834–96) characterized the life-changing experience that becoming a socialist represented in the 1880s and 1890s. Eager idealists, borne along by an almost millennial fervour, the men and women (like Mary) who made up the 'pioneering generation' of British socialists spent much time and energy spreading the word.

Creating the National Labour Education League in 1901 represented a transition in Mary's political journey, putting her on a trajectory of moving between local and national activities at several levels. Against a background of mounting tensions in the educational world, the League heralded a new step forward – the closest thing to a Labour education policy then in existence. For her, the advance of education and political progress were part of a single programme. The abolition of the School Board in 1904 did not diminish an extra-parliamentary activism which focused on

education but couched the question within wider questions of social justice and other interests. With the financial support of her aristocratic patron, Mary used her training in street-corner meetings and outdoor agitation to fight for open-air schools for malnourished and tubercular children, free school meals and medical inspection.

After 1908, Mary was closely involved with the Marxist educators of the Plebs League and the labour colleges. Like them, her conception of education for the workers was rooted in the Marxist studies promoted by the earlier Socialist League slogan: 'Educate, agitate, organise!' She advocated direct action mounted by rank-and-file agitators and Marxist pedagogues. This included support for a strongly political conception of adult education, identifying a distinctively socialist or working-class curriculum. Therefore, she opposed the liberal education philosophy espoused by the Workers Educational Association (WEA, founded in 1903). She was tireless in her efforts to win trade union backing for the principle of working-class self-organization and even secured funding to provide an educational space for politically active working-class women akin to the School of Social Science maintained by the German Social Democratic Party. In 1912, she opened Bebel House in Lexham Gardens, round the corner from the Central Labour College in London's Earls Court, and installed herself as resident principal. In these years she built alliances with radical suffragists, attested to by her attempts to reach working-class Lancashire women as political editor of the *Cotton Factory Times*. Almost every week for many years, the *Cotton Factory Times* included an editorial by her.

Recently opened Home Office files on some of the Russian émigrés with whom she worked helped reconstruct Mary's activities in the First World War, shedding light on her character and personality (though individual documents remained closed). Press cuttings kept by her opponents in the WEA were deeply revealing and the librarian at the TUC Library Collections kindly brought them to my attention when they were deposited there. Some of Mary's surviving letters were excavated from the Sheehy Skeffington Papers held in the National Library of Ireland, which include Mary's letter of sympathy concerning the murder of Francis Sheehy Skeffington in Dublin at Easter in 1916 and active support for his widow Hanna's campaign for a public inquiry.

Closing the loop

Mary's activities are useful for plotting women's roles in British leftist 'oppositional networks'. The experience was a contradictory one, but being a woman was only part of this. There was also her preparedness to challenge orthodoxy, demonstrated by her writings and action, all of which suggests a deep commitment to furthering the cause of socialism in a time of intense conflict over the shape and purpose of education. We know she troubled the establishment elite, but in assessing her contributions to the conflicts of the years 1890 to 1910, we need to question the conventional wisdoms since, more often than not, they vindicated the wisdom of the powers that be. In so doing we need to go back to the margins, to listen to the testimony of those to whom she was closest. Mary's specific utility as a historical subject is to represent the common, unnamed socialist woman who fought to bring class consciousness into being at a specific conjuncture. For Mary, education was the path to a new social order.

16.7 Conclusion

To those who would do the spade work, different approaches are possible even with the existing sources. It *is* possible to recreate 'lost lives' and events by going beyond the official record and digging for the raw material of history. There is a remarkable amount of unexploited personal and ordinary information out there and digitization is opening up all kinds of possibilities. Ultimately, there is great joy and sense of satisfaction to be had when a historical 'puzzle' seemingly falls into place. Despite the attrition of memories and histories I *did* manage to tell Mary's story and thereby reveal a valuable history long overlooked. I was uplifted when, in closing the hermeneutic circle, a colleague commended my journey through social histories, biography and politics (Martin, 2010) as elucidating the fictional past contrived in A. S. Byatt's *The Children's Book* published in 2009: embedded in the thoughts, beliefs and feelings of late-Victorian and Edwardian England.

But whatever the category of evidence, the past does not in any automatic way 'speak for itself'. It *can* prove impossible to locate information we 'expect' to find, so be prepared for frustrations and disappointments and allow your research questions to be guided by the material available, rather than establishing an experimental hypothesis approach. Outstanding history-writing involves conveying to readers something of the processes by which the raw materials of history have been produced.

To return to the notion of a 'foreign country' with which our narrative began: they *did* do things differently there, but we owe a duty to past, present and future generations to represent *all* those pasts and *all* those interlocutors as accurately as possible (see also

Lowenthal, 2015). When it comes to our educational past, historical and documentary research needs to include not just the leaders but the people who inhabit the classrooms and the forms, dimensions and meaning of their experience, to bring history into and out of the community and ensure that the unknown ideas from the underclasses, the unprivileged and the defeated, are told with integrity and not quietly forgotten. In this way, a theoretically informed history of education that gives recognition to alternative trajectories and the road not followed can make a fine contribution to the work of creating a better future.

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Surveys, longitudinal, cross-sectional and trend studies

CHAPTER 17

There are many different kinds of survey; each has its own characteristics and key issues. We set these out in this chapter, addressing such matters as:

- what is a survey?
- some preliminary considerations
- planning a survey
- low response and non-response, and how to reduce them
- survey sampling
- longitudinal, cross-sectional and trend studies
- strengths and weaknesses of longitudinal, cohort and cross-sectional studies
- postal, interview and telephone surveys
- comparing methods of data collection in surveys

17.1 Introduction

We advise readers to take this chapter in conjunction with Chapters 12 (sampling), 24 (questionnaires), 25 (interviews) and data-analysis techniques (Part 5). Many researchers reading this book will probably be studying for higher degrees within a fixed and maybe short time frame; that may render longitudinal study out of the question for them. Nevertheless longitudinal study is an important type of research, and we introduce it here. More likely, researchers for higher degrees will find cross-sectional survey research appropriate, and it is widely used in higher degree research.

In many quarters, Internet surveys are becoming the predominant method of surveys, through email (with a questionnaire as an attachment, or embedded in the email, or with a hyperlink link to a website, social networking site, special interest group, listserv, discussion group etc.), with companies providing free or low-cost software to design questionnaires and, indeed, to conduct the survey and collect data for researchers. Given the rise and widespread usage of Internet surveys, we devote an entire, separate chapter (Chapter 18) to this. However, we include reference to Internet surveys in Table 17.3 in this chapter, for purposes of comparison with other means of survey design and conduct.

17.2 What is a survey?

Many educational research methods are descriptive; that is, they set out to describe and to interpret what is. Such studies look at individuals, groups, institutions, methods and materials in order to describe, compare, contrast, classify, analyse and interpret the entities and the events that constitute their various fields of enquiry. We deal here with several types of survey research, including longitudinal, cross-sectional and trend or prediction studies.

Typically, surveys gather data at a particular point in time with the intention of describing the nature of existing conditions, or identifying standards against which existing conditions can be compared, or determining the relationships that exist between specific events. They may vary in their levels of complexity, from those which provide simple frequency counts to those which present relational analysis.

Surveys may be further differentiated in terms of their scope and complexity. A study of contemporary developments in post-secondary education, for example, might encompass the whole of Europe; a study of subject choice, on the other hand, might be confined to one secondary school.

17.3 Advantages of surveys

A survey has several characteristics and several claimed attractions; typically it is used to scan a wide field of issues, populations, programmes, people etc. in order to measure or describe any generalized features. It is useful (OECD, 2012; Dillman *et al*., 2014) in that it often:

- gathers data on a one-shot basis and hence is economical and efficient;
- represents a wide target population (hence there is a need for careful sampling, see Chapter 12);
- generates numerical data;
- provides descriptive, inferential and explanatory information;
- manipulates key factors and variables to derive frequencies (e.g. the numbers registering a particular opinion or test score);

- gathers standardized information (i.e. using the same instruments and questions for all participants);
- ascertains correlations (e.g. to find out if there is any relationship between gender and test scores);
- presents material which is uncluttered by specific contextual factors;
- captures data from multiple-choice, closed questions, test scores or observation schedules;
- supports or refutes hypotheses about the target population;
- generates accurate instruments through piloting and revision;
- makes generalizations about, and observes patterns of response in, the targets of focus;
- gathers data which can be processed statistically;
- uses large-scale data gathered from a wide population in order to enable generalizations to be made about given factors or variables.

Examples of surveys are:

- test scores (e.g. from students nationally, internationally, locally);
- students' preferences for particular courses, for example, humanities, sciences;
- attitudes to, and opinions of, quality of teaching;
- surveys of groups of people's values over time;
- surveys of factors (e.g. income levels, social class membership, inequality) over time;
- opinion polls;
- reading and mathematics performance surveys.

Surveys in education often use test results, self-completion questionnaires and attitude scales. Here a researcher may be seeking to gather large-scale data from as representative a sample as possible in order to say with a measure of statistical confidence that certain observed characteristics occur with a degree of regularity, or that certain factors cluster together (see Chapter 43) or that they correlate with each other (correlation and covariance), or that they change over time and location (e.g. results of test scores used to ascertain the 'value-added' dimension of education, maybe using regression analysis and analysis of residuals to determine the difference between a predicted and an observed score), or regression analysis to use data from one variable to predict an outcome on another variable.

Surveys can be *exploratory*, in which no assumptions or models are postulated, and in which relationships and patterns are explored (e.g. through correlation, regression, stepwise regression and factor analysis). They can also be *confirmatory*, in which a model, causal relationship or hypothesis is tested (see the discussion of exploratory and confirmatory analysis in Chapter 43). Surveys can be descriptive or analytic (e.g. to examine relationships). Descriptive surveys simply describe data on variables of interest, whilst analytic surveys operate with hypothesized predictor or explanatory variables that are tested for their influence on dependent variables or relationships between variables.

Many surveys combine nominal data on participants' backgrounds and relevant personal details with other data (e.g. attitude scales, data from ordinal, interval and ratio measures) (see Chapter 38). Surveys are useful for gathering factual information, data on attitudes and preferences, beliefs and predictions, opinions, behaviour and experiences – both past and present (Weisberg *et al*., 1996; Aldridge and Levine, 2001; Dillman *et al*., 2014). Their attraction lies in their appeal to generalizability or universality within given parameters, their ability to make statements which are supported by large data and their ability to establish the degree of confidence which can be placed in a set of findings.

On the other hand, if a researcher is concerned to catch local, institutional or small-scale factors and variables – to portray the specificity of a situation, its uniqueness and particular complexity, its interpersonal dynamics, and to provide explanations of why a situation occurred or why a person or group of people returned a particular set of results or behaved in a particular way in a situation, or how a programme changes and develops over time – then a survey approach may be unsuitable. Its explanatory potential or fine detail is limited; it is lost to broad-brush, often descriptive generalizations which are free of temporal, spatial or local contexts. Williams *et al*. (2016) note that having a two-phase process of a postal survey – an initial screening survey followed by the topic-based survey sent to eligible people – is also a useful device for obtaining more in-depth data. In a survey the individual instance is sacrificed to the aggregated response (which has the attraction of anonymity, non-traceability and confidentiality for respondents and opportunity for trends and patterns to be discovered).

Surveys typically, though by no means exclusively, rely on large-scale data, for example, from questionnaires, test scores, attendance rates, results of public examinations etc., all of which enable comparisons to be made over time and between groups. This is not to say that surveys cannot be undertaken on a small-scale basis, as indeed they can; rather it is to say that the generalizability of such small-scale data will be slight. In surveys the researcher is usually an outsider; indeed questions of reliability and possible bias can attach

themselves to researchers conducting survey research on their own subjects, for example, participants in a course that they have been running. Further, it is critical that attention is paid to rigorous sampling, otherwise the basis of the survey's applicability to wider contexts is seriously undermined. Non-probability samples tend to be avoided in surveys if generalizability is sought; probability sampling will tend to lead to generalizability of the data collected.

17.4 Some preliminary considerations

A fundamental decision by the researcher is whether a survey is the appropriate means of answering the research purposes and research questions (Magee *et al*., 2013). Assuming that it is, three prerequisites to the design of any survey are: the specification of the exact purpose of the enquiry; the population and issues on which it is to focus; and the resources that are available. Hoinville and Jowell's (1978) consideration of each of these key factors in survey planning can be illustrated in relation to the design of an educational enquiry.

The purpose of the enquiry

First, a survey's general purpose must be translated into a specific central aim. Thus, 'to explore teachers' views about in-service work' is somewhat nebulous, whereas 'to obtain a detailed description of primary and secondary teachers' priorities in the provision of in-service education courses' is reasonably specific.

Having decided upon and specified the primary objective of the survey, the second phase of the planning involves the identification and itemizing of research questions which will enable the objective to be addressed. The third phase, usually driven by the research questions, is to identify subsidiary topics that relate to its central purpose. In our example, subsidiary issues might well include: the types of courses required; the content of courses; the location of courses; the timing of courses; the design of courses; and the financing of courses.

The fourth phase follows the identification and itemization of subsidiary topics and involves formulating specific information requirements relating to each of these issues. For example, with respect to the type of courses required, detailed information would be needed about the duration of courses (one meeting, several meetings, a week, a month, a term or a year), the status of courses (non-award bearing, award bearing, with certificate, diploma, degree granted by college or university), the orientation of courses (theoretically oriented involving lectures, readings, etc., or practically oriented involving workshops and the production of curriculum materials).

As these details unfold, consideration has to be given to the most appropriate ways of collecting items of information (interviews with selected teachers, postal questionnaires to selected schools, online questionnaires etc.).

The population upon which the survey is focused

The second prerequisite to survey design, the specification of the population (e.g. people, issues) to which the enquiry is addressed, affects decisions that researchers must make both about sampling and resources. In our hypothetical survey of in-service requirements, for example, we might specify the population as 'those primary and secondary teachers employed in schools within a thirty-mile radius of Loughborough University'. In this case, the population is readily identifiable and, given sufficient resources to contact every member of the designated group, sampling decisions do not arise.

Things are rarely so straightforward, however. Often the criteria by which populations are specified ('severely challenged', 'under-achievers', 'intending teachers' or 'highly anxious') are difficult to operationalize. Populations, moreover, vary considerably in their accessibility; students and student teachers are relatively easy to survey, travellers' children and headteachers are more elusive. More importantly, in a large survey, researchers usually draw a sample from the population to be studied; rarely do they attempt to contact every member. We deal with the question of sampling shortly.

The resources available

Resources are not simply financial. For example, survey design can be costly in terms of time, and consideration of resources has to include human, material, financial, administrative, temporal, geographical, technical (e.g. computer-related) costs. An important factor in designing and planning a survey is financial cost. Sample surveys are labour-intensive, the largest single expenditure being fieldwork, where costs arise out of interviewing time, travel time and transport costs of the interviewers themselves. There are additional demands on the survey budget. Training and supervising the panel of interviewers can often be as expensive as the costs incurred during the time that they actually spend in the field. Questionnaire construction, piloting, printing, posting, coding, together with computer programming and processing all eat into financial resources.

Mode of data collection

There are two main issues to be addressed here:

1. Will the researcher be completing the survey by entering data, or will the participants be self-administering the survey?
2. How will the survey be administered, for example, a postal survey, a telephone survey, an Internet survey, by face-to-face interviews, group-administered surveys, self-administered surveys, drop-off surveys, email? A full account of the interview as a research technique is given in Chapter 25.

Dillman *et al*. (2014) advise researchers to use multiple and mixed modes of delivery/administration, as this helps response rates.

Self-reporting

There can be a large difference in the responses gained from self-reporting and those obtained from face-to-face survey interviews or telephone interviews (Dale, 2006, p. 145; Dillman *et al*., 2014). Many surveys ask respondents not only to administer the questionnaires themselves but also to report on themselves. This may introduce bias, as respondents may under-report (e.g. to avoid socially undesirable responses) or over-report (to give socially desirable answers). Self-reporting also requires the researcher to ensure that: respondents all understand the question, understand it in the same way and understand it in the way intended by the researcher (Kenett, 2006, p. 406). The difficulty here is that words are inherently ambiguous (see Chapter 24 on questionnaire design), so the researcher should be as specific as possible. The researcher should also indicate how much contextual information the respondent should provide, what kind of answer is being sought (so that the respondent knows how to respond appropriately), how much factual detail is required and what constitutes relevant and irrelevant data (e.g. the level of detail or focus on priority issues required) (pp. 407–8). Further, surveys that rely on respondents' memory may be prone to the bias of forgetting or selective recall.

Ethics

Ethical issues are discussed in Chapters 7, 8 and 18, and we refer readers to these; here we note the importance of gaining the informed consent of respondents. Whilst completion of the survey might be taken as giving consent, this may not always be the case, and the completion of a consent form may be needed (though some participants may be suspicious of this), and indeed Dillman *et al*. (2014) note that asking for consent requires the researcher to make it clear what the consent is being given for, as, for example, to ask for consent before the questions have been asked is asking participants to take a leap of faith. We also note in Chapters 7 and 28 that informed consent is complex, as it is unclear what is being consented to, and for how long, and for what purposes and uses, and that these problems are exacerbated when data are archived for future use as secondary data sets. Informed consent should also include the right not to participate or to withdraw at any time.

Ethical issues here also concern attention to confidentiality, anonymity, privacy and non-traceability. In paper-based surveys this may be easy to guarantee, but, as we indicate in Chapter 18, for electronic and Internet-based (e.g. website and email surveys), no such absolute guarantees are available. Such computer-related problems raise the matter of data security and identity protection. In electronic and paper surveys, telephone interviewing and face-to-face surveys, the researcher might not ask for, or require, identifying features, or might remove these when storing and archiving data.

However, in group interviews these may not be so easy to protect (e.g. members of the group may talk to others), and in electronic/Internet-based surveys, the service provider can log and track participants, and data miners and hackers can break into data, particularly email, even when security steps have been taken. We discuss this in Chapter 18.

The researcher can, and should, take all reasonable steps to protect confidentiality, anonymity, privacy and non-traceability and indicate to respondents what those steps are, recognizing that where there are limits (e.g. in electronic surveys), this may lead to some respondents not taking part.

Underpinning ethical issues in surveys is the requirement of *primum non nocere*: primarily, do no harm. The researcher must take every step necessary to address this. This concerns access to, collection, storage, use, dissemination and reporting of data, and subsequent archiving of data or locating the data in the public domain, with immense care being taken with regard to identification and sensitive information. This raises issues not only of removing identifying features, removing certain data, aggregating or anonymizing data, but who owns the data and what rights the owner has, once the data have been given to the researcher. The researcher has a duty of care and of trust here.

17.5 Planning and designing a survey

Whether the survey is large scale and undertaken by some governmental bureau, or small scale and carried

out by the lone researcher, the collection of information typically involves one or more of the following data-gathering techniques: structured or semi-structured interviews, self-completion (e.g. postal and Internet questionnaires), telephone interviews, Internet surveys, standardized tests of attainment or performance, and attitude scales.

Planning a survey involves knowing: (a) what exactly you wish to find out, and why; (b) what data you need to be able to answer (a); (c) what questions you will ask to acquire the data. Researchers must also consider: sample selection and access to the sample; distribution/data collection and return of surveys; measurement design and data types; ethical issues; piloting; analysis and reporting.

Sapsford (1999, pp. 34–40) suggests that there are four main considerations in planning a survey:

- *problem definition* (e.g. deciding what kinds and contents of answers are required; what hypotheses there are to be tested; what variables there are to explore);
- *sample selection* (e.g. what is the target population; how can access and representativeness be assured; what other samples will need to be drawn for the purpose of comparison);
- *design of measurements* (e.g. what will be measured, and how (i.e. what metrics will be used – see Chapter 24 on questionnaires); what variables will be required; how reliability and validity will be assured);
- *concern for participants* (e.g. protection of confidentiality and anonymity; avoidance of pain to the respondents; avoiding harm to those who might be affected by the results; avoiding over-intrusive questions; avoiding coercion; informed consent; see Chapters 7 and 8).

Typically surveys proceed through well-defined stages, outlined in Figure 17.1. Though these are set in a

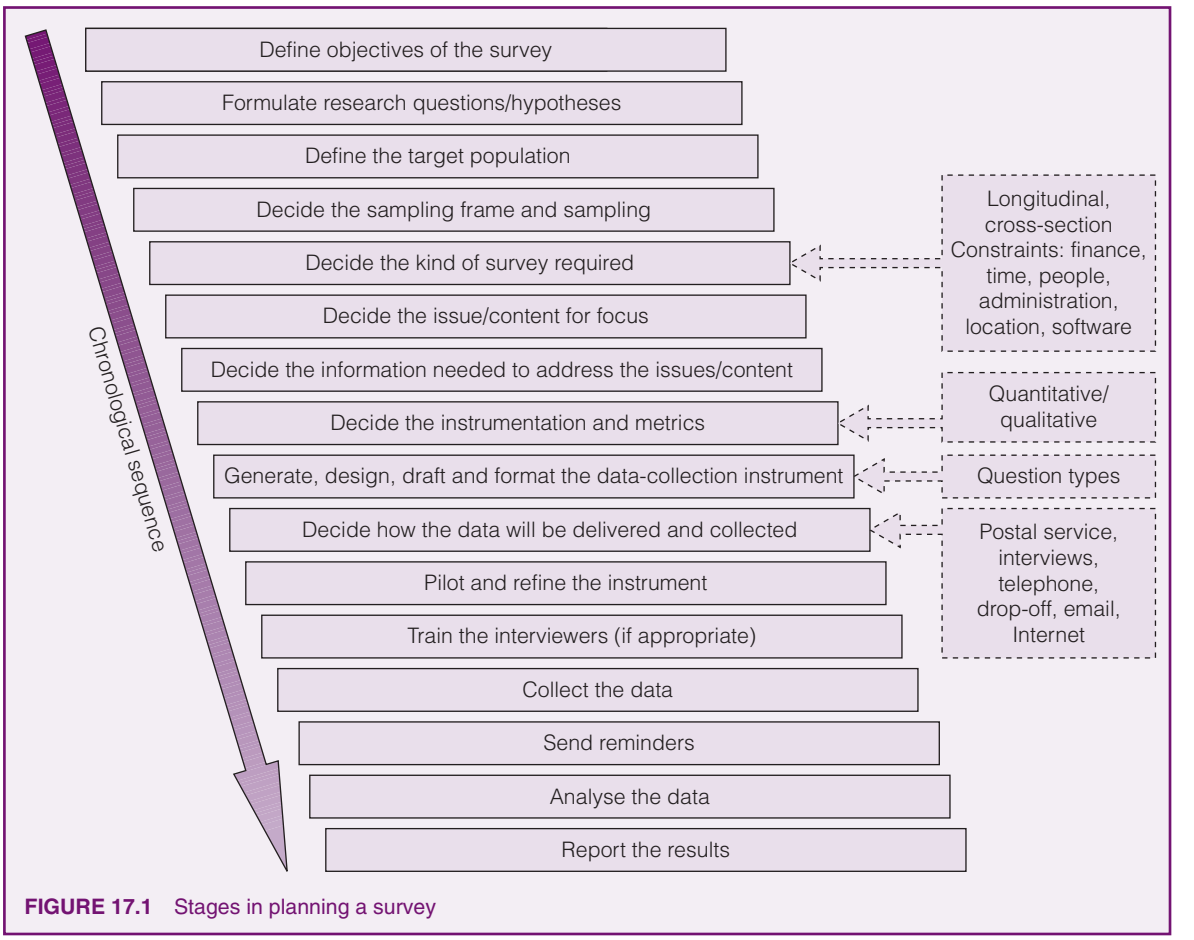

FIGURE 17.1 Stages in planning a survey

sequence, the sequence may alter and the process is iterative and recursive. The process moves from the general to the specific. A general research topic is operationalized into component issues and questions, and, for each component, questions are set. As with questionnaires (Chapter 24), it is important, in the interests of reliability and validity, to have several items or questions for each component issue, as this does justice to the all-round nature of the topic.

Rosier (1997, pp. 154–62) suggests that the planning of a survey must include clarification of:

- the research questions to which answers need to be provided;
- the conceptual framework of the survey, specifying in precise terms the concepts that will be used and explored;
- operationalizing the research questions (e.g. into hypotheses);
- the instruments to be used for data collection, for example, to chart or measure background characteristics of the sample (often nominal data), academic achievements (e.g. examination results, degrees awarded), attitudes and opinions (often using ordinal data from rating scales) and behaviour (using observational techniques);
- sampling strategies and sub-groups within the sample (unless the whole population is being surveyed, e.g. through census returns or nationally aggregated test scores etc.);
- pre-piloting the survey (to generate items for the survey);
- piloting the survey;
- data-collection practicalities and conduct (e.g. permissions, funding, ethical considerations, response rates);
- data preparation (e.g. coding, data entry for computer analysis, checking and verification);
- data analysis (e.g. statistical processes, construction of variables and factor analysis, inferential statistics);
- reporting the findings (answering the research questions).

Ruel *et al*. (2015) comment that researchers need to consider:

- the kind of survey to be used;
- ethical issues;
- questionnaire and instrument design and appearance;
- question construction (measures, responses and measurement error);
- validity and reliability;
- sampling;
- response rates, non-responses and attrition;
- the medium of delivery, completion and return of the survey;
- data entry and data cleaning;
- data analysis and reporting;
- missing data;
- data archiving.

It is important to pilot and pre-pilot a survey. The difference between the pre-pilot and the pilot is this: the pre-pilot is usually a series of open-ended questions that are used to generate items and categories for closed, typically multiple-choice questions, whilst the pilot is used to test the draft of the actual survey instrument itself (see Chapter 24).

A rigorous survey formulates clear, specific objectives and research questions; ensures that the instrumentation, sampling and data types are appropriate to yield answers to the research questions; and ensures that as high a level of sophistication of data analysis required can be done (i.e. as the data will sustain).

Attention must be given to: the mode of data collection; respondent effort (too much and this can lead to non-response); question wording, sequence and format.

Some challenges in planning surveys

A survey is no stronger than its weakest point, and we consider a range of issues here in order to strengthen each aspect of a survey (e.g. OECD, 2012). Surveys must minimize errors caused by:

- poor sampling (e.g. failure to represent or include sufficiently the target population);
- poor question design and wording (e.g. failure to catch accurately the views of, or meanings from, the respondents or to measure the factors of interest);
- incorrect or biased responses;
- low response or non-response.

The first of these – a sampling matter – may be caused by a failure correctly to identify the population and its characteristics, or a failure to use the correct sampling strategy, or systematically to bias the sample (e.g. using a telephone survey based on telephone directory entries, when key people in the population – the poor – may not have a telephone, or may have a cellphone rather than a fixed line (the young, the middle aged but not the elderly), or using an Internet- or email-based survey when many respondents do not have access). We address sampling issues in Chapter 12 and below.

The second of these is a failure to operationalize the variables fairly (i.e. a validity issue) or a failure in the

wording or meanings used or inferred, such that incorrect responses are collected (a reliability issue) (e.g. people may not understand a question, or may misinterpret it, or interpret it differently). We address this in Chapter 14 and below.

The third problem is that some participants may deliberately over-report or under-report the real situation in – often sensitive – matters. For example, teenage alcohol, smoking or drug use, underage sexual relations, bullying, domestic violence, petty criminality may be *systematically* under-reported (i.e. be biased), whereas the popularity of a teacher or students might be over-reported (i.e. biased). Bias obtains where there is a *systematic* skewing or distortion in the responses.

Further, some questions may rely on memory, and memory can be selective and deceptive (e.g. people may not remember accurately). Also, some responses will depend on a person's state of mind at the time of completing the survey – asking a teacher about teacher stress and tiredness late on a Friday afternoon in school with a difficult class could well elicit a completely different response from asking her directly after a week's holiday. Some questions may be so general as to be unhelpful (e.g. 'how stressed do you feel?'), whereas others might be so specific as to prevent accurate recall (e.g. 'how many times have you shouted at a class of children in the past week?') (one solution to the latter might be to ask participants to keep a diary of instances).

Fowler (2009, p. 15) suggests that a respondent's answer is a combination of the true response plus an error in the answer given, with errors coming from many sources.

The fourth of these – low response or non-response – is a problem that besets researchers, and is so significant that we devote a separate section to it below.

Dillman *et al*. (2014) identify four key errors to be avoided in surveys which seek to represent a wider population:

- coverage error (poor and incomplete representation of the population in the sample). For example, a coverage error might be made if telephone or Internet surveys are used, as not everyone has a telephone (particularly a landline) or access to, and familiarity with, the Internet;
- sampling error (including inaccurate estimates of the population);
- non-response error (the difference between a representative result and that obtained from non-response of different individual or groups, i.e. a skewed response); and
- measurement error: inaccurate and unreliable response because of (a) the metrics, scales and units of measurement used; (b) socially desirable responses and respondent acquiescence (the tendency to agree with an interviewer rather than disagree) in face-to-face survey interviews; (c) questionnaire features, for example, length, difficulty, questions asked, complexity, order effects, interviewer effects, survey mode (post, telephone, email, interview, Internet etc.).

17.6 Survey questions

Though we go into detail about questions and questionnaires in Chapter 24, here we give advice on some important issues in writing and asking questions in surveys (Creswell, 2012; OECD, 2012; Abascal and Diaz de Rada, 2014; Champagne, 2014; Dillman *et al*., 2014; Colorado State University, 2016):

- Ensure that the questions cover the topics and research questions comprehensively and with the appropriate scales of measurement and scales (e.g. 1–5, –4 to +4, 'strongly disagree' to 'agree').
- Keep the survey simple and short, and use whole, short sentences.
- Consider respondent effort: avoid overloading the respondent with thinking, recalling, reading and responding.
- Ensure that the questions apply to all the respondents.
- Consider the order of the questions (questions are not independent of each other, and the answer to one question may affect the answer to another in the respondent's mind, e.g. the primacy effect, 'carry over' and 'anchoring effect' (Dillman *et al*., 2014, p. 235), i.e. what comes first affects what comes later and respondents use the early questions as a standard against which they compare the later questions).
- Arrange the order and organization of the survey in a way that is easy for the respondent to understand (subheadings in a written survey are important here).
- Group together questions that cover similar topics, with subheadings in written surveys, to parallel what would naturally happen in a conversation (NB if respondents see two questions as similar then, for consistency, they will give answers which are similar).
- Start the survey with questions that respondents will find meaningful and interesting, and will be able to answer.

- If you are using branching questions, ask all the branching questions before you ask the follow-up questions.
- Ensure that the wording is comprehensible to the respondent (use easy words) and judge how the respondent will regard and feel about the question asked.
- Keep sensitive questions until later in the survey.
- Avoid putting the important questions right at the end of the survey.
- Consider the willingness of the respondent to answer the questions correctly and honestly, and whether the respondent will actually know the answer (e.g. to factual questions or to questions which require long-term memory), i.e. whether the question really applies to the respondent.
- Consider what the question is asking for – for example, factual answers; attitudes, perceptions and opinions; behaviours; events – and how to make these clear to the respondent. Some factual information is easy (e.g. gender, age) but other data (e.g. attitudes, behaviours, those which rely on memory) may be less accurate.
- Use concrete, specific and precise terms (define terms concretely) so that the respondent understands exactly what is being asked for in the survey.
- Consider the suitability of question types and formats: (a) for *nominal variables*: dichotomous, multiple choice (single choice, restricted number of choices, free number of choices); (b) for *ordinal variables*: rating scales, ranking scales; (c) for *interval, ratio and continuous variables*: constant sum, percentages/marks out of ten, open number (e.g. number of hours of study in a week); (d) for *non-numerical answers*: open questions. Decide whether to have a mid-point in scale items; use large-range scales if subsequent factor analysis is intended; and ensure that response categories are exhaustive, to fit the choices that participants will really want, i.e. that they enable respondents to say what they want to say (and this underlines the importance of running a pilot).
- Avoid: double-barrelled questions (asking more than one thing in a single question); long and complex questions and vocabulary; technical language; negatively worded items; ambiguous questions; leading questions (those which influence the response and indicate a desired response); questions which may cause embarrassment.
- Consider the medium of the administration/conduct/'delivery' of the survey, for example, postal service, email, face-to-face interview, website, telephone, i.e. visual, oral and aural administration of the survey, and who enters the responses (the respondent or the interviewer).
- Consider whether it is advisable to have an interviewer present or absent, as the interviewer's presence may bias the respondent, raising issues of the respondent's concern for (a) social desirability and (b) acquiescence (defined above); acquiescence is a particular problem in questions which include 'agree', as there is a tendency to agree.

Magee *et al*. (2013) advise researchers to consider:

- how others have addressed the constructs in question; developing and writing relevant survey items clearly;
- the mode of the item, for example, a statement or a question (a question is preferable);
- the response (number and type, with no smaller than a five-point scale; odd numbers or even numbers in scaling; inclusion of positive and negative options or only positive options: avoid agreement- or positive-only responses; label each point in an ordinal scale);
- reliability and validity of items;
- ensuring that the question is interpreted by respondents in the way intended.

Given these points, it is essential that a survey be piloted, and we give guidelines to piloting in Chapter 24, for example, for content, coverage, ease of understanding, timing, redundancy, sensitivity, question types, question order, mode of delivery, ease of completion, answerability.

17.7 Low response, non-response and missing data

Response and non-response are related to contact, cooperation and ease of conduct, completion and return of the survey (Dillman *et al*., 2014). Non-response to a whole questionnaire ('unit non-response'; Durrant, 2009, p. 293) or to a specific item ('item non-response'; p. 293) is a serious problem for much survey research, though Denscombe (2009b, p. 282) notes that online surveys tend to have lower item non-response than paper-based surveys, though there may be more drop-outs before reaching the end of an online survey than in a paper-based survey.

Dale (2006, p. 148) suggests that 'non-respondents almost invariably differ from respondents', and that this affects the validity and reliability of the responses obtained, and their analysis. If non-response is received from a very homogeneous sample then this might be

less of a problem than if the sample is very varied. Further, if non-response is received randomly across a sample then this might be less of a problem than if the non-response was from a particular sub-sector of the respondents (e.g. a very low or a very high socio-economic group), as this would bias the results (cf. Dale, 2006, p. 148). A subset of non-response to a whole questionnaire is item non-response, and here missing data should not be ignored (Dale, 2006, p. 15).

Rubin (1987), Little and Rubin (1989), Allison (2001), Dale (2006, pp. 149–50) and Durrant (2006, 2009) review a range of different 'imputation methods' for handling and weighting non-response, i.e. methods for filling in missing data with 'plausible values' in order to render a set of data complete and yet to reduce bias in the non-responses, i.e. that bias which might be caused by the non-responses having different values from the non-missing responses (Durrant, 2009, p. 295). These depend on whether the non-response is largely confined to a single variable or many variables. The researcher has to determine whether there are patterns of non-response, as these affect the method for handling non-response. For example, if the non-response is randomly distributed across several variables, with no clear patterns of non-response, then this may be less problematic than if there is a systematic non-response to one or more variables in a survey (Durrant, 2009, p. 295; Dillman *et al*., 2014). Durrant (2009) sets out several ways of calculating missing values, including:

- calculating missing values from regression techniques using auxiliary variables (p. 296);
- 'hot deck' methods, in which sub-groups of participants (based on their scores on auxiliary variables) are constructed and the researcher compares their results to the non-missing results of the respondent who had omitted a particular response (p. 297);
- 'nearest neighbour' techniques, in which the results from a person whose data diverge as little as possible from those of the missing person are used to replace the missing values.

Durrant (2006, 2009) and Dillman *et al*. (2014) identify further, statistical methods of calculating missing scores, such as multiple and fractional imputation and propensity score weighting. Durrant makes the point that how one calculates the values of missing data depends on a range of factors such as the purpose of the analysis, the variable(s) in question, the kinds of data, any patterns of missing data, and the characteristics and fittingness of the assumptions on which the particular intended imputation method is based. The National Centre for Research Methods (2016) also suggests that using means of groups and sub-groups responding to a particular item can be used for imputation. Here one looks for patterns of missing data (any groups of units/cases or items) and calculates an average value (e.g. on a scaled item) for groups/sub-groups of cases (individuals), and reporting standard error.

Ary *et al*. (2002) note that non-respondents may be similar to late responders, so it might be possible to use data from late responders to indicate the possible responses from non-respondents. This requires the researcher to identify late responders.

Missing data within a survey can have many causes. For example, people may not be present on the day of its administration, or they may not understand the question, or they may take exception to the question or overlook it by mistake. Pampaka *et al*. (2016) give the example of the administration of a school survey on bullying, where students may be absent without predictable reasons, or they are representing their school in a competition (e.g. high-performing and highly motivated students), or they may be more likely to be bullied (p. 19). All these, the authors note, lead to biased data. They note that missing data are a particular problem in longitudinal surveys and surveys across phase transitions. They note that statistical analysis (e.g. stepwise regression, which ignores missing data) is dangerous if there are missing data, and they argue for multiple imputation methods. However, they also note that multiple imputation methods are essentially speculative, based on simulations (p. 21).

Pampaka *et al*. (2016) distinguish between missing data from units (individuals) and items, but both can lead to a biased response. There are many ways to address this, for example, by simply analysing incomplete data, or by weighting, and by imputation. Weighting is designed to ensure a better representation of the population, and it can be used to adjust data for non-response, to bring the data into the correct matching of the population. If the incomplete data are random, i.e. all cases have equal probability of being missing (as in their example of those students who are absent for unpredictable reasons), then the analysis may be unbiased (the claim of randomness for equality of distributions, see Chapter 20 on experiments).

For further guidance on weighting, standard error and imputation, we refer the reader to the sources indicated above and to the guidance from the National Centre for Research Methods (www.restore.ac.uk).

In some cases (e.g. when all the students in a class complete a questionnaire during a lesson) the response rate may be very high, but in other circumstances the response rate may be very low or zero, either for the

whole survey or for individual items within it, for several reasons, for example:

- the survey never reaches the intended people;
- people refuse to answer;
- people may not be available (e.g. for a survey administered by interview), for example, they may be out at work when a telephone survey administrator calls;
- people may not be able to answer the questions (e.g. language, reading, speaking or writing difficulties);
- people may not actually have the information requested;
- people may overlook some items in error;
- the survey was completed and posted but failed to return;
- the pressure of competing activities on the time of the respondent;
- potential embarrassment at their own ignorance if respondents feel unable to answer a question;
- ignorance of the topic/no background in the topic;
- dislike of the contents or subject matter of the interview;
- fear of possible consequences of the survey to himself/herself or others;
- lack of clarity in the instructions;
- fear or dislike of being interviewed (or of the interviewer);
- sensitivity of the topic, or potentially insulting or threatening topic;
- betrayal of confidences;
- losing the return envelope or return address;
- the wrong person may open the mail, and fail to pass it on to the most appropriate person.

Non-response can lead to responses that are systematically different (i.e. biased) than those from the whole sample or population, as the responses from those who did not respond might be distinctively different from those who actually responded.

Later in this chapter we discuss ways of improving response rates. However, here we wish to insert a note of caution: some researchers suggest that, for non-responders to an item, an average score for that item can be inserted. This might be acceptable if it can be shown that the sample or the population is fairly homogeneous, but, for heterogeneous populations or samples, or those where the variation in the sample or population is not known, it may be dangerous to assume homogeneity and hence to infer what the missing replies might have been, as this could distort the results.

Let us suppose that, out of a sample of 200 participants, 90 per cent reply (180 participants) to a 'yes/no' type of question, for example, for the question 'Do you agree with public examinations at age 11?', and let us say that 50 per cent (90 people) indicate 'yes' and 50 per cent indicate 'no'. If the 10 per cent who did not reply (20 people) had said 'yes' then this would clearly swing the results as 110 people say 'yes' (55 per cent) and 90 people say 'no' (45 per cent). However, if the response rates vary, then the maximum variation could be very different, as in Table 17.1 (cf. Fowler, 2009, p. 55). Table 17.1 assumes that, if 100 per cent had replied, 50 per cent said 'yes' and 50 per cent said 'no'; the rest of the table indicates the possible variation depending on response rate.

Table 17.1 indicates the possible variation in a simple 'yes/no' type of question. If a rating scale is chosen, for example a five-point rating scale, the number of options increases from two to five, and, correspondingly, the possibility for variation increases even further.

Improving response rates in a survey

A major difficult in survey research is securing a sufficiently high response rate to give credibility and reliability to the data. In some surveys, response rates can be as low as 20–30 per cent, and this compromises the reliability of the data very considerably. There is a difference between the *intended* and the *achieved* sample (Fogelman, 2002, p. 105). Punch (2003, p. 43) suggests that it is important to plan for poor response rates (e.g. by increasing the sample size) rather than trying to adjust sampling *post hoc*. He also suggests that access to the sample needs to be researched before the survey

TABLE 17.1 MAXIMUM VARIATION FOR LOW RESPONSE RATES IN A YES/NO QUESTION FOR A 50/50 DISTRIBUTION

Response rate (%)	*Variation in the true value of 'yes' and 'no' votes (lowest % to highest % in each category)*
100	50–50
90	45–55
80	40–60
70	35–65
60	30–70
50	25–75
40	20–80
30	15–85
20	10–90
10	5–95

commences, maybe pre-notifying potential participants if deemed desirable. He argues that a poor response level may also be due to the careless omission of details of how and when the questionnaire will be returned or collected. This is a matter that needs to be made clear in the questionnaire itself. In the case of a postal survey a stamped addressed envelope should always be included.

Kenett (2006) and Fowler (2009, p. 52) report that responses rates increase when people are interested in the subject matter of the survey, or if the subject is very relevant to them, or if completing the survey brings them a sense of satisfaction. Denscombe (2009b, p. 288) reports that response rates increase if the 'respondent burden' (the effort required by the respondent to answer a question) is low.

Further, the design, layout and presentation of the survey may also exert an influence on response rate. It is important to include a brief covering letter that explains the research clearly and introduces the researcher. The timing of the survey is important, for example, schools will not welcome researchers or surveys in examination periods or at special periods, for example, Christmas or inspection times (Fogelman, 2002, p. 106).

Finally, it is important to plan the follow-up to surveys, to ensure that non-respondents are called again and reminded of the request to complete the survey. Fowler (2009, p. 57) indicates that between a quarter and a third of people may agree to completing a survey if a follow-up is undertaken.

There are several possible ways of increasing response rates to mailed surveys (Aldridge and Levine, 2001; Diaz de Rada, 2005; Fowler, 2009, p. 56; Denscombe, 2014; Dillman *et al*., 2014; Williams *et al*., 2016), including:

- use follow-ups and polite reminders (e.g. by mail, email, telephone call) in which the reminder is short, polite, indicating the value of the respondent's participation and, if the reminder is postal, another clean copy of the questionnaire;
- use multiple and mixed modes of responding (i.e. avoid relying on a single mode, such as post, email, website, cellphone app, interview);
- give advance notification of the survey (e.g. by telephone, post or email);
- indicate how the survey is important and the benefits from it, and how (and what) the respondents can help in answering the survey;
- indicate the institutional affiliation (with a logo) that is sponsoring or supporting the survey and support for the survey from high-status or influential persons;
- provide information about the research through a covering letter and/or advance notification;
- avoid making the survey look like junk mail;
- thank the participants in advance;
- indicate that others have already answered the survey (do not be dishonest);
- give pre-paid stamped addressed envelopes for return of the survey;
- offer incentives for return (though increasing the financial incentive to a high figure does not bring commensurate returns in response rates);
- for a follow-up reminder, include a cover page, as this increases response rates;
- make it easy to answer the survey, keeping the respondent effort and burden to a minimum;
- make the questionnaire topic interesting, the design attractive and the questions interesting, clear and easy to answer, with easy-to-follow instructions and spacing of the text. Make instructions about responses and return very clear and easy;
- keep the survey short, easy to read and complete, and very clear;
- make response modes easy: giving too many kinds can lower response rates;
- avoid open-ended questions unless these are really important (as the quality of responses is usually poor to open-ended questions: people tend not to write anything or to write very little). Avoid placing open-ended questions at the start of a questionnaire;
- consider asking the respondents for an interview to complete the survey questionnaire;
- deliver the questionnaire personally rather than through mail;
- ensure that the questions or items are non-judgemental (e.g.in sensitive matters);
- avoid asking for sensitive or personal information unless it is absolutely necessary, particularly if asking for identifying features of children;
- indicate you own contact details, relevant and authentic professional information about yourself and how you can be reached;
- assure confidentiality, anonymity, privacy and security of information;
- send an email reminder to participants very shortly after the distribution of the survey.

Cooper and Schindler (2001, pp. 314–15) and Fowler (2009, p. 58) report that the following factors make little or no appreciable difference to response rates:

- personalizing the introductory letter;
- writing an introductory letter;
- promises of anonymity;

- questionnaire length (it is not always the case that a short questionnaire produces more returns than a long questionnaire, but researchers will need to consider the effect of a long survey questionnaire on the respondents – they may feel positive or negative about it, or set it aside temporarily and forget to return it later);
- size, reproduction and colour of the questionnaire;
- deadline dates for return (it was found that these did not increase response rate but did accelerate the return of questionnaires).

Potential respondents may be persuaded to participate depending on, for example:

- the status and prestige of the institution or researcher carrying out the research;
- the perceived benefit of the research;
- the perceived importance of the topic;
- personal interest in the research;
- interest in being interviewed, i.e. the interview experience;
- personal liking for, or empathy with, the researcher;
- feelings of duty to the public and sense of civic responsibility;
- loneliness or boredom (nothing else to do);
- sense of self-importance.

Dillman (2007) suggests that response rates can be increased if, in sequence: (a) non-respondents are sent a friendly reminder after ten days, stressing the importance of the research; (b) non-respondents are sent a further friendly reminder ten days after the initial reminder, stressing the importance of the research; (c) a telephone call is made to the respondents (if the number is known) shortly after the second reminder, indicating the importance of the research.

Fowler (2009, p. 60) suggests that the initial questionnaire might also include a statement to say that completion and return of the questionnaire will ensure that no follow-up reminders will be sent (though this may be regarded by some respondents as presumptuous).

17.8 Survey sampling

Sampling is a key feature of a survey approach, and we advise readers to look closely at Chapter 12 (sampling). Researchers must take sampling decisions early in the overall planning of a survey (see Figure 17.1) in light of the population from which they want to sample, and this involves, for example:

- identifying the target population (who, how large and what are their characteristics of interest?);
- deciding whether a sample or the whole population is necessary (e.g. it may be possible to have a whole population if access and size render it feasible, such as all the staff of a school);
- the sampling frame (all those to be included in the sample);
- the sampling strategy (probability and non-probability) and type of sample;
- sampling error;
- weighted samples for small groups (e.g. before the survey is conducted and post-stratification: after the survey has been conducted).

Often the researcher will not know the population size or heterogeneity of the characteristics of the population, and, in this event, it is advisable to have as large a sample as possible (see Chapter 12 for determining sample size).

We have already seen that due to factors of expense, time and accessibility, it is not always possible or practical to obtain measures from a population. Indeed Wilson *et al*. (2006, p. 352) draw attention to the tension between the need for large samples in order to conduct 'robust statistical analysis', and issues of resources such as cost and practicability (p. 353). Researchers endeavour, therefore, to collect information from a smaller group or subset of the population in such a way that the knowledge gained is representative of the total population under study, i.e. a sample. Unless researchers identify the total population in advance, it is virtually impossible for them to assess how representative the sample is which they have drawn. Chapter 12 addresses probability and non-probability samples, and we refer readers to the detailed discussion of these in that chapter. The researcher will need to decide the sampling strategy to be used on the basis of fitness for purpose, for example:

- a probability and non-probability sample;
- the desire to generalize, and to whom;
- the sampling frame (those who are eligible to be included);
- the sample size;
- the representativeness of the sample;
- access to the sample;
- the anticipated response rate.

Even if the researcher has taken extraordinary care with the sampling strategy, there may still be problems (e.g. response rate, respondent characteristics or availability) that can interfere with the best-laid strategies.

In addition to the sampling strategy to be used, there are the issues of sample size and selection. We discussed

this in Chapter 12, but here we wish to address the issue of practicability. For example, let us say that, in the interests of precision, the researcher wishes to have a sample in which there are four strata (e.g. age groups in a primary school), and that each stratum comprised 50 students, i.e. 200 students in total. If that researcher wished to increase the sample size of one stratum by, say, 20 students, this would necessitate an overall increase of 80 students (20×4) in the sample. Do the benefits outweigh the costs here?

An alternative to increasing the *total* size of the sample would be to increase the size of one stratum only, under certain conditions. For example, let us say that the researcher is studying attitudes of males and females to learning science, in a secondary school which had only recently moved from being a single-sex boys' school to a mixed sex school, so the ratio of male to female students is 4:1. The researcher wishes to include a minimum of 200 female students. This could require a total of 1,000 students in the sample (200 females + $\{200 \times 4\}$ male students in the sample); this could be unmanageable. Rather, the researcher could identify two female students for each male student (i.e. 400 females) and then, when analysing the data, could give one quarter of the weight to the response of the female students, in order to gain a truer representation of the target population of the school. This would bring the total sample to 600 students, rather than 1,000, involved in the survey. Oversampling a smaller group (in this case the females) and then weighting the analysis is frequently undertaken in surveys (cf. Fowler, 2009, p. 27).

In sampling, the probability might also exist of excluding some legitimate members of population in the target sample; however, the researcher will need to weigh the cost of excluding these members (e.g. the very hard to reach) against the cost of ensuring that they are included – the benefit gained from including them may not justify the time, cost and effort (cf. Fowler, 2009, p. 179). Similarly, the precision gained from stratified sampling (see Chapter 12) may not be worth the price to be paid in necessarily increasing the sample size in order to represent each stratum.

In many cases a sampling strategy may be in more than one stage. For example, let us consider the instance of a survey of 1,000 biology students from a population of 10,000 biology students in a city. In the first stage, a cluster group of, say, ten schools is identified (A), then, within that, a cluster by age group of students (B), and then, within that, the cluster of individuals in that group who are studying biology (C), and, finally, the sample (D) is taken from that group. The intention is to arrive at (D), but in order to reach this point a series of other steps has to be taken.

This raises the matter of deciding the steps to be taken. For example, the researcher could decide the sampling for the survey of the biology students by taking the random sample of 1,000 students from ten schools. The researcher lists all the 1,000 relevant students from the list of 10,000 students, and decides to select 100 students from each of the ten schools (a biology student, therefore, in one of these ten schools has a one in ten chance of being selected). Alternatively, the researcher could decide to sample from five schools only, with 200 students from each of the five schools, so students in each of these five schools have a one in five chance of being selected. Alternatively, the researcher could decide to sample from two schools, with 500 students, so students in each of these two schools have a one in two chance of being selected. There are other permutations. The point here is that, as the number of schools decreases, so does the possible cost of conducting the survey, but so does the overall reliability, as so few schools are included. It is a trade-off.

In order to reduce sampling error (the variation of the mean scores of the sample from the mean score of the population), a general rule is to increase the sample size, and this is good advice. However, it has to be tempered by the fact that the effect of increasing the sample size in a small sample reduces sampling error more than in a large sample, for example, increasing the sample size from 50 to 80 (30 persons) will have greater impact on reducing sampling error than increasing the sample size from 500 to 530 (30 persons). Hence it may be of little benefit simply to increase sample sizes in already-large samples.

The researcher has to exercise his or her judgement in attending to sampling. For example, if it is already known that a population is homogeneous, then the researcher may feel it a needless exercise in having too large and unmanageable a sample if the results are not likely to be much different from those of a small sample of the same homogeneous group (though theoretical sampling (see Chapter 37) may suggest where a researcher needs to include participants from other small samples). As Fowler (2009, p. 44) remarks, the results of a sample of 150 people will describe a population of 15,000 or 25 million with more or less the same degree of accuracy. He remarks that samples of more than 150 or 200 may yield only modest gains to the precision of the data (p. 45), though this, of course, has to be addressed in relation to the population characteristics, the number, size and kind of strata to be included, and the type of sample being used. Sampling

errors, he notes (p. 45) are more a function of sample size than of the proportions of the sample to the population. Further, he advocates probability rather than non-probability samples, unless there are persuasive reasons for non-probability samples to be used.

Whilst sample sizes can be calculated on the basis of statistics alone (e.g. confidence levels, confidence intervals, population size, statistical power and so on, see Chapter 12), this is often not the sole criterion, as it accords a degree of precision to the sample which takes insufficient account of other sampling issues, for example, access, variation or homogeneity in the population, levels of literacy in the population (e.g. in the case of a self-administered questionnaire survey), number and type of variables and costs.

Sampling is one of several sources of error in surveys, as indicated earlier in this chapter.

17.9 Longitudinal and cross-sectional surveys

The term 'longitudinal' describes a variety of studies that are conducted over a period of time. A clear distinction is drawn between longitudinal and cross-sectional studies. The longitudinal study gathers data over an extended period of time: a short-term investigation may take several weeks or months; a long-term study can extend over many years. Where successive measures are taken at different points in time from the same respondents, the term 'follow-up study' or 'cohort study' is used in the British literature, the equivalent term in the US being the 'panel study'. The term 'cohort' is a group of people with some common characteristic.

Where different respondents are studied at one or more different points in time, the study is called 'cross-sectional', i.e. a cross-section of the population is taken to investigate the topic(s) of interest. Where a few selected factors are studied continuously over time, the term 'trend study' is employed. One example of regular or repeated cross-sectional social surveys is the General Household Survey, in which the same questions are asked every year, though they are put to a different sample of the population each time. The British Social Attitudes Survey is an example of a repeated cross-sectional survey, using some 3,600 respondents.

A famous example of a longitudinal (cohort) study is the UK's National Child Development Study, which started in 1958. The British General Household Panel Survey interviewed individuals from a representative sample each year in the 1990s. Another example is the British Family Expenditure Survey. These latter two are cross-sectional in that they tell us about the population at a given point in time, and hence provide aggregated data.

By contrast, longitudinal studies can also provide individual-level data, by focusing on the same individuals over time (e.g. the Household Panel Studies which follow individuals and families over time (Ruspini, 2002, p. 4). Lazarsfeld introduced the concept of a panel in the 1940s, attempting to identify causal patterns and the difficulties in tracing these (Ruspini, 2002, p. 13)).

Longitudinal studies

Longitudinal studies can be of the survey type or of other types (e.g. case study). Here we confine ourselves to the survey type. Longitudinal studies can include trend studies, cohort studies and panel studies (Creswell, 2012), and we discuss these below. A useful centre for longitudinal studies in education is at the University of London: www.cls.ioe.ac.uk/default.aspx.

Longitudinal studies can use repeated cross-sectional studies, which are conducted regularly, each time with a largely different sample or, indeed, an entirely new sample (Ruspini, 2002, p. 3), or use the same sample over time. They enable researchers to: 'analyse the duration of social phenomena' (p. 24); highlight similarities, differences and changes over time in respect of one or more variables or participants (within and between participants); identify long-term ('sleeper') effects; and explain changes in terms of stable characteristics, for example sex, or variable characteristics, such as income. The appeal of longitudinal research is its ability to establish causality and to make inferences. Ruspini adds to these the ability of longitudinal research to 'construct more complicated behavioural models than purely cross-sectional or time-series data' (p. 26); they can catch the complexity of human behaviour. Further, longitudinal studies can combine numerical and qualitative data.

Retrospective analysis is not confined to longitudinal studies alone. For example, Rose and Sullivan (1993, p. 185) and Ruane (2005, p. 87) suggest that cross-sectional studies can use retrospective factual questions, for example, previous occupations, dates of birth within the family, dates of marriage and/or divorce, though Rose and Sullivan (1993, p. 185) advise against collecting other types of retrospective data in cross-sectional studies, as the quality (e.g. reliability) of the data diminishes the further back one asks respondents to recall previous states or even facts.

It is important in longitudinal studies to decide when and how frequently to collect data over time, and this is informed by issues of fitness for purpose as well as practicability. Further, in order to allow for attrition

(dropout) of the sample, it is wise to have as large a sample as practicable and possible at the start of the study (Wilson *et al*., 2006, p. 354).

Cohort studies

A cohort study focuses on a specific population in which all its members have the specific defining characteristic that is of interest to the researcher (e.g. the National Child Development Study in the UK; the Millennium Cohort Study). In a cohort study the specific population is tracked over a specific period of time but selective sampling within that sample occurs. This means that different members of a cohort are included each time. For example, the population might be eighteen-year-olds in the UK; at one time point (say, when they are twenty-five years old) the population might be sampled, and then at another time point (say, when they are thirty-five) the same population might be sampled but different members of the population will be in the sample.

Cohort studies and trend studies can be *prospective* longitudinal methods, in that they are ongoing in their collection of information about individuals or their monitoring of specific events. *Retrospective* longitudinal studies, on the other hand, focus upon individuals who have reached some defined end-point or state. For example, a group of young people may be the researcher's particular interest (intending social workers, convicted drug offenders or university dropouts, for example), with questions such as: 'Is there anything about your previous experience that can account for your present situation?' Retrospective longitudinal studies will specify the period over which to be retrospective, for example, one year, five years.

Panel studies

In contrast to a cohort study, in a panel study exactly the same individuals are tracked over time. An example of this is the Panel Study of Income Dynamics in the US. Another example from the UK is the '7 Up' study which started in 1964 and tracks a small group of individuals every seven years, yielding insights into social and cultural stratification, reproduction and the self-fulfilling prophecy.

Whilst this type of study has the attraction of tracking the same people over time, this same requirement also has its disadvantages in terms of keeping contact with those individuals and addressing attrition. Panel studies are useful for investigating causality and change over time.

Trend studies

Trend studies focus on factors (e.g. mathematics performance) rather than people, and these factors are studied over time. New samples – different people – are drawn at each stage of the data collection, but focus on the same factors, and if random samples are used, they can be representative of the wider population. By taking different samples the problem of reactivity is reduced (see below: 'pre-test sensitisation'), i.e. earlier surveys affecting the behaviour of participants in the later surveys. This is particularly useful if the research is being conducted on sensitive issues, as raising a sensitive issue early on in the research may change an individual's behaviour, which could affect the responses in a later round of data collection. By drawing a different sample each time, this problem is overcome.

Trend or prediction studies have an obvious importance to educational administrators or planners. Like cohort studies, they can be of relatively short or long duration. Essentially, the trend study examines recorded data to establish patterns of change that have already occurred in order to predict what will be likely to occur in the future. In trend studies, two or more cross-sectional studies are undertaken with identical age groups at more than one point in time in order to make comparisons over time (e.g. the Scholastic Aptitude and Achievement tests in the US and the National Assessment of Educational Progress results). A major difficulty that researchers face in conducting trend analyses is the intrusion of unpredictable factors that invalidate forecasts formulated on past data. For this reason, short-term trend studies tend to be more accurate than long-term analyses. Trend studies do not include the same respondents over time, so the possibility exists for variation in data due to the different respondents rather than the change in trends. Gorard (2001b, p. 87) suggests that this problem can be attenuated by a 'rolling sample' in which a proportion of the original sample is retained in the second wave of data collection, and a proportion of this sample is retained in the third wave, and so on.

Cross-sectional studies

A cross-sectional study is one that produces a 'snapshot' of a population at one particular point in time. The epitome of the cross-sectional study is a national survey in which a representative sample of the population consisting of individuals of different ages, different occupations, different educational and income levels, and residing in different parts of the country, is interviewed on the same day. In education, cross-sectional studies can involve indirect measures of the nature and rate of changes in the physical and intellectual development of samples of children drawn from representative age levels. The single 'snapshot' of the cross-sectional study provides researchers with data for either a retrospective or a prospective enquiry.

A cross-sectional study can also bear several hallmarks of a longitudinal study of parallel groups (e.g. age groups) which are drawn simultaneously from the population. For example, drawing students aged five, seven, nine and eleven at a single point in time would bear some characteristics of a longitudinal study in that developments over age groups could be seen, though, of course, it would not have the same weight as a longitudinal study conducted on the same age group over time. This is the case for international studies of educational achievement, requiring samples to be drawn from the same population (Lietz and Keeves, 1997, p. 122) and for factors that might influence changes in the dependent variables to remain constant across the age groups.

Cross-sectional studies, catching a frozen moment in time, may be ineffective for studying change or causality. If changes are to be addressed through cross-sectional surveys, then this suggests the need for repeated applications of the survey, or the use of trend analysis.

The main types of longitudinal study are illustrated in Figure 17.2.

17.10 Strengths and weaknesses of longitudinal, cohort and cross-sectional studies

Longitudinal studies of the cohort analysis type have an important place in the armoury of educational researchers. Longitudinal studies have considerable potential for yielding rich data that can trace changes over time, and with great accuracy (Gorard, 2001b, p. 86). On the other hand, they suffer from problems of attrition (participants leaving the research over time, a particular problem in panel studies which research the same individuals over time), and they can be expensive to conduct in terms of time and money (Ruspini, 2002, p. 71). Gorard (2001b) reports a study of careers and identities that had an initial response rate of between 60 and 70 per cent in the first round, and then risked dropping to 25 per cent by the third round, becoming increasingly more middle class in each wave of the study; the same publication discusses a Youth Cohort Study in which only 45 per cent of the respondents took part in all three waves of the data collection. Ruspini (2002, p. 72) identifies an attrition rate of 78 per cent in the three waves of the European Community Household Panel survey of the UK in 1997.

Ruspini also indicates how a small measurement error in a longitudinal study may be compounded over time. She gives the example of an error in income occurring at a point in time (p. 72) that could lead to 'false transitions' appearing over time in regard to poverty and unemployment.

Further, long-term studies, Gorard (2001b, p. 86) avers, face 'a threat to internal validity' that stems from the need 'to test and re-test the same individuals'. Dooley (2001, p. 120) terms this 'pre-test sensitisation'; it is also termed 'panel conditioning' or 'time-in sample bias' (Ruspini, 2002, p. 73). Here the first interview in an interview survey can cause changes in the second interview, i.e. the first interview might set up a self-fulfilling prophecy that is recorded in the second interview. He gives the example of a health survey in the first round of data collection, which may raise

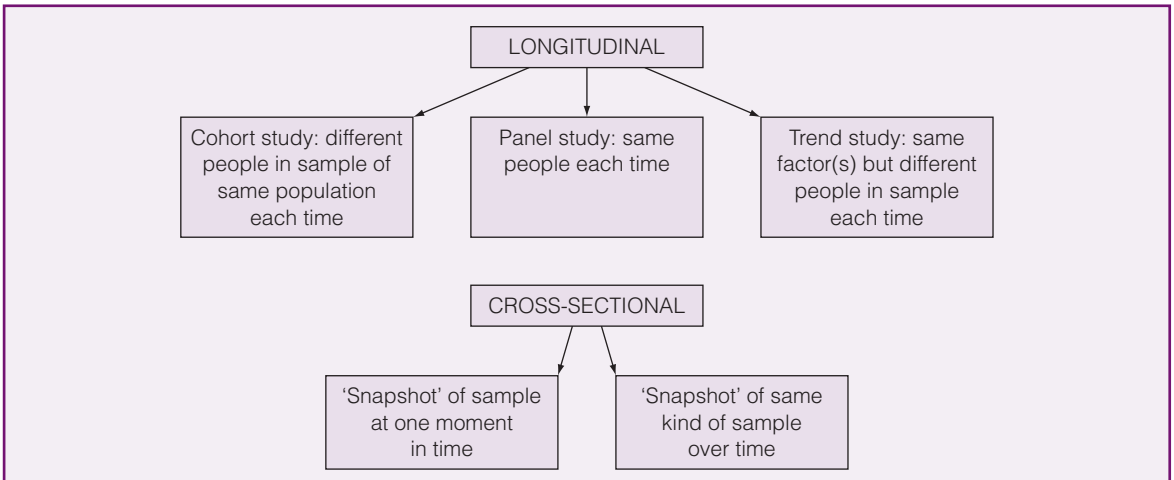

FIGURE 17.2 Types of survey

participants' awareness of the dangers of smoking, such that they reduce or give up smoking by the time the second round takes place. Trend studies overcome this problem by drawing different populations at each round of data collection.

Dooley (2001) also identifies difficulties caused by changes in the research staff over time in longitudinal surveys. Changes in interviewee response, he suggests, may be due to having different researchers rather than to the respondents themselves. Even using the same instruments, different researchers may use them differently (e.g. in interviewing behaviour).

To add to these matters, Ruspini (2002, p. 73) suggests that longitudinal data are affected by:

- history (events occurring may change the observations of a group under study);
- maturation (participants mature at different speeds and in different ways);
- testing (test sensitization may occur – participants learn from exposure to repeated testing/interviews);
- the timing of cause and effect (some causes may produce virtually instantaneous effects and others may take a long time for the effects to show);
- the direction of causality not always being clear or singular.

A major concern in longitudinal studies concerns the comparability of data over time. For example, though public examinations may remain constant over time (e.g. GCSE, A levels), the contents and format of those examinations do not. (This rehearses the argument that public examinations are becoming easier over time.) This issue concerns the need to ensure consistency in the data-collection instruments over time. Further, if comparability of data in a longitudinal study is to be addressed then this means that the initial rounds of data collection will need to anticipate and include all the variables that will be addressed over time.

Longitudinal studies are more prone to attrition than cross-sectional studies, and are more expensive to conduct in terms of time and cost. On the other hand, whereas trend studies change their populations, thereby disabling micro-level – individual-level – analysis from being conducted, longitudinal analysis enables such individual-level analysis to be performed. Indeed whereas cross-sectional designs (even if they are repeated cross-sectional designs) may be unsuitable for studying developmental patterns and causality within cohorts, in longitudinal analysis this is a strength. Longitudinal data can supply 'satisfactory answers to questions concerning the dynamics and the determinants of individual behaviour' (Ruspini, 2002, p. 71), issues which are not easily addressed in cross-sectional designs.

Retrospective longitudinal studies rely on participants' memories which may be faulty; the further back one's memory reaches, the greater is the danger of distortion or inability to recall. Memory is affected by, for example (Ruspini, 2002, p. 97):

- the time that has elapsed since the event took place;
- the significance of the event for the participant;
- the amount of information required for the study – the greater the amount, the harder it is to provide;
- the contamination/interference effect of other memories of a similar event (i.e. the inability to separate similar events);
- the emotional content or the social desirability of the content;
- the psychological condition of the participant at interview.

Further, participants will look at past events through the lens of hindsight and subsequent events rather than what those events meant at the time. Moreover, it is not always easy for these participants to recall their emotional state at the time in question. Factually speaking, it may not be possible to gather data from some time past, as they simply do not exist (e.g. medical records, data on income) or they cannot be found, recovered or accessed.

Cohort studies of human development conducted on representative samples of populations are uniquely able to identify typical patterns of development and to reveal factors operating on those samples which elude other research designs. They permit researchers to examine individual variations in characteristics or traits, and to produce individual development curves. Cohort studies, too, are particularly appropriate when investigators attempt to establish causal relationships, as this involves identifying changes in certain characteristics which result in changes in others.

Cross-sectional designs are inappropriate in causal research as they cannot sustain causal analysis unless they are repeated over time, as causality has a necessary time dimension. Cohort analysis is especially useful in sociological research because it can show how changing properties of individuals fit together into changing properties of social systems as a whole. For example, the study of staff morale and its association with the emerging organizational climate of a newly opened school would lend itself to this type of developmental research. A further strength of cohort studies in schools is that they provide longitudinal records whose

value takes account of the known fallibility of any single test or assessment. Finally, time, often a limiting factor in experimental and interview settings, is generally more readily available in cohort studies, allowing the researcher greater opportunity to observe trends and to distinguish 'real' changes from chance occurrences (see Bailey, 1994).

In longitudinal, cohort and trend studies the characteristics of respondents are likely to affect results (Robson, 1993, p. 128). For example, their memory, knowledge, motivation and personality may affect their responses, and indeed they may withhold information, particularly if it is sensitive.

Longitudinal research indicates the influence of biological factors over time (e.g. human development), environmental influences and intervention influences (Keeves, 1997a, p. 139) and their interactions. Addressing these, the appeal of longitudinal analysis is that it enables researches to conduct causal analysis. Time series studies in longitudinal research also enable emergent patterns to be observed over time, by examining a given range of variables over time, in addition to other factors. This enables individual and group profiles to be examined over time and development, indicating similarities and differences within and between individuals and groups in respect of given variables.

Longitudinal studies suffer several disadvantages (though the gravity of these weaknesses is challenged by supporters of cohort analysis). The disadvantages are, first, that they are time-consuming and expensive, because the researcher is obliged to wait for growth data to accumulate. Second, there is the difficulty of sample mortality. Inevitably during the course of a long-term cohort study, subjects drop out, are lost or refuse further cooperation. Such attrition makes it unlikely that those who remain in the study are as representative of the population as the original sample. Sometimes attempts are made to lessen the effects of sample mortality by introducing aspects of cross-sectional study design, that is, 'topping up' the original cohort sample size at each time of retesting with the same number of respondents drawn from the same population. The problem here is that differences arising in the data from one survey to the next may then be accounted for by differences in the persons surveyed rather than by genuine changes or trends.

A third difficulty has been termed the 'control effect' (sometimes referred to as 'measurement effect'). Often, repeated interviewing results in an undesired and confusing effect on the actions or attitudes under study, influencing the behaviour of subjects, sensitizing them to matters that have hitherto passed unnoticed, or stimulating them to communicate with others on unwanted topics (see Riley, 1963). Fourth, cohort studies can suffer from the interaction of biological, environmental and intervention influences (Keeves, 1997a, p. 139). Finally, cohort studies in education pose considerable problems of organization due to the continuous changes that occur in pupils, staff, teaching methods and the like. Such changes make it highly unlikely that a study will be completed in the way that it was originally planned.

Cohort studies, as we have seen, are particularly appropriate in research on human growth and development. Why then are so many studies cross-sectional rather than cohort studies? The reason is that they have a number of advantages over cohort studies: they are less expensive; they produce findings more quickly; they are less likely to suffer from control effects; and they are more likely to secure the cooperation of respondents on a 'one-off' basis. Generally, cross-sectional designs are able to include more subjects than are cohort designs.

The strengths of cohort analysis are the weaknesses of the cross-sectional design. The cross-sectional study is a less effective method for the researcher who is concerned to identify individual variations in growth or to establish causal relationships between variables. Sampling in a cross-sectional study is complicated because different subjects are involved at each age level and may not be comparable. Further problems arising out of selection effects and obscuring irregularities in growth weakens the cross-sectional study so much that one observer dismisses the method as a highly unsatisfactory way of obtaining developmental data except for the crudest purposes.

Douglas (1976a), who pioneered the first national cohort study in any country, makes a spirited defence of the method against the common criticisms that are levelled against it – that it is expensive and time-consuming. His account of the advantages of cohort analysis over cross-sectional designs is summarized in Box 17.1.

Cross-sectional studies require attention to sampling in order to ensure that the information on which the sample is based is comprehensive (Lietz and Keeves, 1997, p. 124). Further, there is a risk that some potential participants may decline to take part, thereby weakening the sample, or some may not answer specific questions or, wittingly or unwittingly, give incorrect answers. Measurement error may also occur if the instrument is faulty, for example, using inappropriate metrics or scales.

The comparative strengths and weaknesses of longitudinal studies (including retrospective studies),

BOX 17.1 ADVANTAGES OF COHORT OVER CROSS-SECTIONAL DESIGNS

1. Some types of information, for example, on attitudes or assessment of potential ability, are only meaningful if collected contemporaneously. Other types are more complete or more accurate if collected during the course of a longitudinal survey, though they are likely to have some value even if collected retrospectively, for example, length of schooling, job history, geographical movement.
2. In cohort studies, no duplication of information occurs, whereas in cross-sectional studies the same type of background information has to be collected on each occasion. This increases the interviewing costs.
3. The omission of even a single variable, later found to be important, from a cross-sectional study is a disaster, whereas it is usually possible in a cohort study to fill the gap, even if only partially, in a subsequent interview.
4. A cohort study allows the accumulation of a much larger number of variables, extending over a much wider area of knowledge than would be possible in a cross-sectional study. This is of course because the collection can be spread over many interviews. Moreover, information may be obtained at the most appropriate time, for example, information on job entry may be obtained when it occurs even if this varies from one member of the sample to another.
5. Starting with a birth cohort removes later problems of sampling and allows the extensive use of subsamples. It also eases problems of estimating bias and reliability.
6. Longitudinal studies are free of one of the major obstacles to causal analysis, namely, the reinterpretation of remembered information so that it conforms to conventional views on causation. It also provides the means to assess the direction of effect.

Source: Adapted from Douglas (1976b)

cross-sectional analysis and trend studies are summarized in Table 17.2 (see also Rose and Sullivan, 1993, pp. 184–8).

Several of the strengths and weaknesses of retrospective longitudinal studies share the same characteristics as those of *ex post facto* research, discussed in Chapter 20.

17.11 Postal, interview and telephone surveys

Postal surveys

There are strengths and difficulties with postal and interview surveys. Postal surveys can reach a large number of people, gather data at comparatively low cost and quite quickly, and can give assurances of confidentiality (Robson, 1993; Bailey, 1994, p. 148; Dillman *et al*., 2014). Similarly they can be completed at the respondents' own convenience and in their preferred surroundings and own time; this can enable them to check information, if necessary (e.g. personal documents), and think about responses. As standardized wording is used, there is a useful degree of comparability across the responses, and, as no interviewer is present, there is no risk of interviewer bias. Further, postal questionnaires enable widely scattered populations to be reached.

Postal surveys can also be used to gather detailed sensitive qualitative data (Beckett and Clegg, 2007), not least because the non-presence of another person (e.g. an interviewer) can increase the honesty and richness of the data, whereas the presence of an interviewer might inhibit the respondent. Further, in a postal survey, the relations of power between the researcher and the respondent are often more equal than in an interview situation (in which the former often controls the situation more than the latter) (p. 308).

On the other hand, postal surveys typically suffer from a poor response rate, even though Dillman *et al*. (2014) comment they have moved from having the lowest response rate to having response rates higher than telephone surveys. Mailed surveys are reported to have an approximately 20 per cent response rate, which is far lower than telephone and face-to-face surveys (Colorado State University, 2016). Diaz de Rada and Dominguez (2015) note that postal surveys feature greater acquiescence than other kinds of survey, with more unanswered questions.

Because researchers may not have any information about non-respondents, they may not know whether the sample is representative of the wider population. Further, respondents may not take the care required to complete the survey carefully, and, indeed, may misunderstand the questions. There is no way of checking this. Bailey (1994, p. 149) suggests that the very issues that make postal surveys attractive might also render them less appealing, for example:

TABLE 17.2 THE CHARACTERISTICS, STRENGTHS AND WEAKNESSES OF LONGITUDINAL, CROSS-SECTIONAL, TREND ANALYSIS AND RETROSPECTIVE LONGITUDINAL STUDIES

Study type	*Features*	*Strengths*	*Weaknesses*
Longitudinal studies (cohort/panel studies)	1 Single sample over extended period of time. 2 Enables the same individuals to be compared over time (diachronic analysis). 3 Micro-level analysis.	1 Useful for establishing causal relationships and for making reliable inferences. 2 Shows how changing properties of individuals fit into systemic change. 3 Operates within the known limits of instrumentation employed. 4 Separates real trends from chance occurrence. 5 Brings the benefits of extended time frames. 6 Useful for charting growth and development. 7 Gathers data contemporaneously rather than retrospectively, thereby avoiding the problems of selective or false memory. 8 Economical in that a picture of the sample is built up over time. 9 In-depth and comprehensive coverage of a wide range of variables, both initial and emergent – individual specific effects and population heterogeneity. 10 Enables change to be analysed at the *individual/micro*-level. 11 Enables the dynamics of change to be caught, the flows into and out of particular states and the transitions between states. 12 Individual level data are more accurate than macro-level, cross-sectional data. 13 Sampling error reduced as the study remains with the same sample over time. 14 Enables clear recommendations for intervention to be made.	1 Time-consuming – it takes a long time for the studies to be conducted and the results to emerge. 2 Problems of sample mortality heighten over time and diminish initial representativeness. 3 Control effects – repeated interviewing of the same sample influences their behaviour. 4 Intervening effects attenuate the initial research plan. 5 Problem of securing participation as it involves repeated contact. 6 Data, being rich at an individual level, are typically complex to analyse.

continued

TABLE 17.2 CONTINUED

Study type	*Features*	*Strengths*	*Weaknesses*
Cross-sectional studies	1 Snapshot of different samples at one or more points in time (synchronic analysis). 2 Large-scale and representative sampling. 3 Macro-level analysis. 4 Enables different groups to be compared. 5 Can be retrospective and/or prospective.	1 Comparatively quick to conduct. 2 Comparatively cheap to administer. 3 Limited control effects as subjects only participate once. 4 Stronger likelihood of participation as it is for a single time. 5 Charts aggregated patterns. 6 Useful for charting population-wide features at one or more single points in time. 7 Enable researchers to identify the proportions of people in particular groups or states. 8 Large samples enable inferential statistics to be used, e.g. to compare sub-groups within the sample.	1 Do not permit analysis of causal relationships. 2 Unable to chart individual variations in development or changes, and their significance. 3 Sampling not entirely comparable at each round of data collection as different samples are used. 4 Can be time-consuming as background details of each sample have to be collected each time. 5 Omission of a single variable can undermine the results significantly. 6 Unable to chart changing social processes over time. 7 They only permit analysis of overall, *net* change at the macro-level through aggregated data.
Trend analysis	1 Selected factors studied continuously over time. 2 Uses recorded data to predict future trends.	1 Maintains clarity of focus throughout the duration of the study. 2 Enables prediction and projection on the basis of identified and monitored variables and assumptions.	1 Neglects influence of unpredicted factors. 2 Past trends are not always a good predictor of future trends. 3 Formula-driven, i.e. could be too conservative or initial assumptions might be erroneous. 4 Neglects the implications of chaos and complexity theory, e.g. that long-range forecasting is dangerous. 5 The criteria for prediction may be imprecise.
Retrospective longitudinal studies	1 Retrospective analysis of history of a sample. 2 Individual- and micro-level data.	1 Useful for establishing causal relationships. 2 Clear focus (e.g. how did this particular end state or set of circumstances come to be?). 3 Enables data to be assembled that are not susceptible to experimental analysis.	1 Remembered information might be faulty, selective and inaccurate. 2 People might forget, suppress or fail to remember certain factors. 3 Individuals might interpret their own past behaviour in light of their subsequent events, i.e. the interpretations are not contemporaneous with the actual events. 4 The roots and causes of the end state may be multiple, diverse, complex, unidentified and unstraightforward to unravel. 5 Simple causality is unlikely. 6 A cause may be an effect and vice versa. 7 It is difficult to separate real from perceived or putative causes. 8 It is seldom easily falsifiable or confirmable.

- the standardization of wording;
- the inability to catch anything other than a verbal response;
- the lack of control over the environment in which the survey questionnaire is completed;
- the lack of control over the order in which the questions are read and answered;
- the risk that some questions will not be answered;
- the inability to record spontaneous answers;
- the difficulty in separating non-response from bad response, the former being where the intended respondent receives the survey but does not reply to it, and the latter being where the intended recipient does not receive the survey, for example, because she/he has moved house;
- the need for simplicity in format as there is no interviewer present to guide the respondent through a more complex format.

Postal surveys are an example of self-administered surveys. The anonymity and absence of face-to-face interaction between the interviewer and the respondent can render these useful for asking sensitive questions (Strange *et al*., 2003, p. 337), though Fowler (2009, p. 74) also counsels that sensitive questions can sometimes be handled better in private face-to-face interviews. In self-administered surveys, Fowler (2009, p. 72) remarks that it is advisable to keep to closed questions and make the response categories simple and explicit (e.g. ticking a box). If open questions are to be asked then, he indicates, it is better to gather the survey data in a face-to-face interview.

Further, Diaz de Rada (2005) reports that the design, size and colour of the paper used in postal surveys affects response rates. Small-sized questionnaires were mostly returned by males and those under sixty-four years of age (p. 69), whilst larger-sized questionnaires were mostly returned by females and those over the age of sixty-five (p. 70). He recommends using paper size 14.85 × 21 cm (i.e. a sheet of A4-sized paper folded in half), white paper, and including a cover page (p. 73) (though this inevitably increases the number of pages in a questionnaire, and this can be off-putting for respondents). He reports that paper size has no effect on the quality of the responses.

Interview surveys

Whereas postal surveys are self-administered, interview surveys are supervised and hence potentially prone to fewer difficulties. Interview methods of gathering survey data are useful in that the presence of the interviewer can help clarify queries from the respondents and can stimulate the respondent to give full answers to an on-the-spot researcher rather than an anonymous researcher known only through an introductory letter (Robson, 1993). Indeed face-to-face encounters can improve response rates. Further, as interviews can be flexible, questioners are able both to probe and to explain more fully (Bailey, 1994, p. 174). Interviews are also useful when respondents have problems with reading and writing. Using non-verbal behaviour to encourage respondents to participate is also possible. Moreover, with interviews there are greater opportunities to control the environment in which the survey is conducted, particularly in respect of privacy, noise and external distractions.

The effective interviewer, Fowler (2009, p. 128) claims, is business-like and assertive whilst being engaging, friendly and kind. Fowler argues for great care with choosing interviewers and training them, as much can hang on their behaviour.

The potential for trust, rapport and cooperation between the interviewer and the respondent is strong in face-to-face encounters (Dooley, 2001, p. 122; Gwartney, 2007, p. 16). Further, interviewers can either ensure that the sequence of the survey protocol is strictly adhered to or they can tailor the order of responses to individual participants, making certain that all questions are answered. Interview surveys, moreover, can guarantee that it is the respondent alone who answers the questions, whereas in postal surveys the researcher never knows what help or comments are solicited from, or given by, other parties. Bailey (1994) adds that the opportunity for spontaneous behaviour and responses is also possible in interview surveys, and interviews can use more complex structures than postal questionnaires, the researcher being on hand to take participants through the items.

On the other hand, the very features which make interview methods attractive may also make them problematic. For example, interview survey methods may be affected by the characteristics of the interviewer (e.g. sex, race, age, ethnicity, personality, skills, perceived social status, clothing and appearance). They may also be affected by the conduct of the interview itself (e.g. rapport between the interviewer and the interviewee), and interviewees may be reluctant to disclose some information if they feel that the interview will not be anonymous or if sensitive information is being requested. The flexibility which the interview gives also contributes to the potential lack of standardization of the interview survey, and this may render consistency, and thereby reliability, a problem.

Interview surveys are costly in time for the researcher and the interviewee, and, as they are conducted at a fixed time, they may prevent the interviewee

from consulting records that may be important to answer the questions. Further, they may require the interviewer to travel long distances to reach interviewees, which can be expensive both in time and travel costs (Bailey, 1994, p. 175). If interviews are intended to be conducted in the participants' own homes, then participants may be unwilling to admit strangers. Moreover, neighbourhoods may be dangerous for some researchers to visit (e.g. a white researcher with a clipboard going into a non-white area of great deprivation, or a black researcher going into a conservative white area).

Telephone surveys

Telephone surveys are located between mailed questionnaires and personal interviews (Arnon and Reichel, 2009). Dillman *et al*. (2014) note the rapid decline in telephone interviewing (p. 11) with the reduction in landlines, the rise in cellphones, the lack of listing of call numbers and the rise in screening callers. However, telephone interviews have the attraction of overcoming bias in the researcher or the interviewee that may be caused by social characteristics or matters of age, dress, race, ethnicity, appearance etc. (e.g. Gwartney, 2007, p. 16). Indeed Denscombe (2014) suggests that people are 'more honest and open' on the phone than in a postal questionnaire (p. 12).

Telephone surveys require the interviewer to be an articulate, clear speaker and a good listener, and able to key in interviewee responses onto a computer whilst listening and speaking (Denscombe, 2014, pp. 42–3). They have the advantage of reducing costs in time and travel, for when a potential respondent is not at home, a call-back is cheap and the time to redial is short (Dooley, 2001, p. 122; Arnon and Reichel, 2009, p. 179), and, using Internet services such as Skype, telephone surveys can be almost free of charge and include face-to-face viewing. Revisits to often distant locations, on the other hand, can incur considerable expense in time and travel. Furthermore, if the intended participant is unable or unwilling to respond, then it is a relatively easy matter to maintain the required sample size by calling a replacement. Again, where respondents are unable or unwilling to answer all the questions required, then their partial replies may be discarded and further substitutes sought from the sample listing. It is easy to see why telephone interviews must always have a much longer list of potential respondents in order to attain the required sample size.

Not everyone has a telephone (e.g. the poor, the young) and this may lead to a skewed sample (Arnon and Reichel, 2009, p. 179). Nor, for that matter, is everyone available for interview, particularly if they work. Further, many people are 'ex-directory', i.e. their numbers are withheld from public scrutiny. In addition, Dooley (2001, p. 123) reports that younger, single and higher occupational status groups use electronic facilities that screen out and delete researchers' calls and these could lead to a skewed sample. Indeed Fowler (2009, p. 75) indicates that telephone surveys tend to elicit more socially desirable answers than face-to-face interviews.

Even when the telephone is answered, the person responding may not be the most suitable one to take the call; she/he may not know the answer to the questions or have access to the kind of information required. For example, in an inquiry about household budgets, the respondent may simply be ignorant about a family's income or expenditure on particular items. A child may answer the call, or an elderly person who may not be the householder. Interviewers will need to prepare a set of preliminary screening questions or arrange a call-back time when a more appropriate person can be interviewed.

Telephone interviewing has its own strengths and weaknesses. For example, more often than not a respondent's sex will be clear from their voice, so some questions may be unnecessary or inappropriate. On the other hand, it is unwise to have several multiple choices in a telephone interview, as respondents will simply forget the categories available, there being no written prompts to which the respondent can refer.

Similarly, order effects can be high: items appearing early in the interview exert an influence on responses to later ones, whilst items appearing early in a list of responses may be given greater consideration than those occurring later, a matter not confined to telephone surveys but to questionnaires in general. Dooley (2001, p. 136) indicates a 17 per cent difference in agreement recorded to a general statement question when it appeared *before* rather than *after* a specific statement, and other research demonstrates that responses to particular questions are affected by questions surrounding them. His advice is to ask *general* questions before *specific* ones, otherwise the general questions are influenced by earlier responses to specific questions. Once again, this is a matter not confined to telephone surveys but to questionnaires in general.

Further, if the questioning becomes too sensitive, respondents may simply hang up in the middle of the survey interview, tell lies or withhold information. Dooley (2001, p. 123) reports that, in comparison to face-to-face interviews, telephone respondents tend to produce more missing data, to be more evasive, more acquiescent (i.e. they tend to agree more with statements) and more extreme in their responses (e.g. opting for the extreme ends of rating scales).

Fowler (2009, pp. 73–4) also indicates that, in a telephone survey, it is unwise to have too many response scale points, that it is better to avoid long lists of items and that it is advisable to read the statement before indicating the response categories, unless a long list of items is to be given (i.e. is unavoidable), in which case he suggests that it is better to read and re-read the response categories to the respondent before the list of statements. All of these points take account of the limits of the short-term memories on which respondents often rely in a telephone interview. He also suggests (p. 73) that complex questions can be approached in a staged manner. For example, if a researcher wishes to ask about a ten-category item (e.g. income level of the teacher), then the researcher could start with a general question (e.g. above or below a particular figure), and then, once that category has been identified, proceed to a sub-category, for example, between such-and-such a figure; this avoids overload of asking a respondent to remember ten categories.

Because telephone interviews lack the sensory stimulation of visual or face-to-face interviews or written instructions and presentation, it is unwise to plan a long telephone survey call. Ten to fifteen minutes is often the maximum time tolerable to most respondents, and indeed fifteen minutes for many people is too long. This means that careful piloting must take place in order to include those items, and only those items, that are necessary for the research. The risk to reliability and validity is considerable, as the number of items may be fewer than in other forms of data collection.

Procedures for telephone interviews also need to be decided (Gwartney, 2007), for example:

- how many times to let the telephone ring before conceding that there is nobody to answer the call (Gwartney (2007, p. 99) suggests eight rings);
- how to introduce the caller and the project;
- what to say and how to introduce items and conduct the interview;
- how to determine who is receiving the call and whether he/she is the appropriate person to answer the call;
- whether to leave a message on an answerphone/voicemail/call-back facility and, if so, what that message will be;
- how to handle language problems (e.g. which language is being used, meanings/explanations/vocabulary);
- how to handle the situation if the receiver asks to call back later;
- what to say and how to control the caller's voice/tone/pitch/speed/pace of questions/repetitions/language/intonation/register;
- the caller's pronunciation, enunciation and reading out loud;
- the caller's ability to clarify, summarize, reiterate, probe (and when to stop probing), prompt (if the receiver does not understand), confirm, affirm, respond, give feedback, encourage respondents, keep respondents focused and to the point;
- how to conduct closed and open questions, sensitive, factual and opinion-based questions;
- how to indicate the nature and format of the responses sought;
- the caller's ability to handle the called person's initial hostility, refusal, reluctance to take part, feelings of invasion of privacy, lack of interest, reluctance to disclose information, feelings of being harassed or singled out, anger, antagonism, lack of interest, incomplete answers, hurriedness to complete, slowness or hesitancy, mistrust, rudeness, abusive responses, or simply saying that they are too busy;
- the caller's ability to remain neutral, impartial and non-judgemental;
- how to record responses;
- how to end the interview.

It is also advisable, in order to avoid the frequent responses to 'cold-calling' (where the called person simply slams down the telephone), for the interviewer to contact the person in advance of the call, perhaps by mail, to indicate that the call will come, when, what it is about, and to ask for the recipient's cooperation in the project.

Many of the features of telephone interviewing are similar to those of effective interviewing per se, and we advise the reader to consult the comments on interviewing earlier and also in Chapter 25.

17.12 Comparing methods of data collection in surveys

Aldridge and Levine (2001, pp. 51–4) and Fowler (2009, pp. 80–3) offer useful summary guides to the advantages and disadvantages of several methods of data collection in surveys: personal face-to-face interviewing; telephone interviewing; self-administered/self-completion versus interviewer-administered; group administered; mailed surveys; delivered (distributed) surveys (e.g. personally delivered or delivered to an institution); Internet surveys. We refer the reader to these useful sources.

Additionally, Fowler (2009) and Dillman *et al*. (2014) discuss the benefits of combining methods of data collection (e.g. face-to-face interviews with telephone interviews, Internet surveys with postal surveys, advance

TABLE 17.3 ADVANTAGES AND DISADVANTAGES OF DATA-COLLECTION METHODS IN SURVEYS

	Advantages	*Disadvantages*	*Either advantages or disadvantages*
Postal	Time to think Costs may not be too expensive Opportunity for attractive survey design and graphics Complete at respondent's convenience, with opportunity for respondent to check Can reach many people No risk of interviewer intrusion or bias Can reach scattered populations Can gather sensitive data (nobody else is present) Can offer secure confidentiality, anonymity and non-traceability Standardized wording	Cost: printing, postage Time: response time and data entry Low response rates Need for contact details Risk of superficial coverage of topics No checking on understanding or seriousness of response Missing data Respondents may misunderstand instructions or items	Self-completion Impersonal Need for simple format Completion of sensitive information
Interviews face-to-face (individual)	Opportunity for gathering in-depth data Reduction of false responses Benefits of human-to-human contact and interpersonal behaviour High response rate Useful for exploring complex issues Opportunity to explain and clarify items and take questions from respondents Flexibility in item sequence Can build trust and rapport Ensure that only the respondent answers	Potential for perceived threat and bias in face-to-face meeting Costly: time for conducting interview, data entry and travel Not possible for large-scale survey Need to train interviewers Long data-collection period Access to sample Little time to think or reflect Flexibility can reduce standardization	Location of interviews Participation Personal Interviewer and interviewee characteristics Conduct of interview affects responses Small samples Standardization
Interviews (group)	Time-saving (compared to individual) Opportunity for gathering in-depth data Reduction of false responses Benefits of human-to-human contact and interpersonal behaviour High response rate Useful for exploring complex issues	Risk of 'group think' Potential for perceived threat and bias in face-to-face meeting Threat to confidentiality Not possible for large-scale survey Scheduling time and location for whole group to be present Costly: time for conducting interview, data entry Little time to think	Participation Personal Interviewer and interviewee characteristics Conduct of interview affects responses Small samples Standardization

	Advantages	*Disadvantages*	*Either advantages or disadvantages*
	Opportunity to explain and clarify items and take questions from respondents Flexibility in item sequence Can build trust and rapport Ensure that only the respondent answers		
Telephone	Honesty Anonymity (absence of the human face) Reduction in costs: time, money and travel Rapid contact Random dialling Access to dispersed sample and distant locations Response rate higher than postal survey Short data-collection period Opportunity to explain and clarify items Opportunity to probe participants Reduced interviewer and interviewee bias	Lack of visuals and non-verbal cues: oral and aural medium only Finding telephone numbers (particularly with cellphones) Easy for respondents to refuse or quit through the survey (i.e. to hang up) Limited time (no more than ten minutes) Cold calling has a bad name Time of day for calling may be inappropriate Biased sampling (no telephone) Respondents are ex-directory Immediacy: no time to think of responses Cost (phone charges) Personal answering the call may not be suitable Multiple-choice, rating scale and ranking questions are difficult Order effects can be strong Risk of socially desirable responses, satisficing and acquiescence	Sensitive questions: absence of an interviewer may encourage or discourage honesty of response Personal and yet impersonal Well-prepared and trained interviewer
Internet-based	Cost saving: time, money, data entry by researcher Speed: rapid distribution, completion and return Wide distribution: no problem of time and distance Access to minority and marginalized groups Opportunity for large samples and data volume Rapid data entry	Security of data and confidentiality Biased sampling (no Internet, or respondents' limited Internet expertise, volunteer samples) No checking on understanding or seriousness of response Need for email addresses or posting opportunities Multiple submissions Risk of superficial coverage of topics	Honesty of responses Impersonal Anonymity, confidentiality and privacy

TABLE 17.3 CONTINUED

	Advantages	*Disadvantages*	*Either advantages or disadvantages*
	Easy access to people and dispersed populations Time to think Opportunity to complete it in stages, i.e. with time breaks Complete at respondent's convenience Opportunity for attractive survey design and graphics Higher response rates than postal surveys Environmentally friendly (no paper) Easy skip and branching arrangements Honest responses to sensitive issues Standardized wording Ease of data entry	Computer software compatibility and technical problems Limited number of items per screen Respondents give a minimal response Order effects People quit if it is too long or complex Missing data (or resentment if forced responses are required) Respondents regard it as spam Design expertise of the researcher Respondents may misunderstand instructions or items Overall low response rates Satisficing and acquiescence (see Chapter 18)	
Dropping off questionnaires	Opportunity to explain the survey face-to-face No training required for distribution staff (i.e. no interviews) Respondents have time to think and reflect Complete at respondent's convenience Higher response rates than postal survey	Costly: distribution staff and time	Impersonal

emails with interviews). Single mode surveys, write Dillman *et al*. (2014), are less effective than mixed mode surveys (e.g. telephone calls and emails, emails and websites, etc.) in terms of response rates.

Table 17.3 sets out advantages and disadvantages of these different types of survey administration.

We include Internet methods in Table 17.3, for ease of comparison with other methods, and our discussion turns to Internet surveys, devoting the next chapter entirely to this topic.

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Internet surveys

CHAPTER 18

This chapter will look at:

- the advantages and disadvantages of Internet surveys
- constructing Internet-based surveys
- ethical issues in Internet-based surveys
- sampling in Internet-based surveys
- improving response rates in Internet surveys
- technological advances

18.1 Introduction

The inclusion here of a chapter devoted to Internet surveys signals not only the prominence that these have in contemporary research but also raises key issues which Internet surveys highlight and which may not have such a high profile in more traditional surveys. Internet surveys bring a new perspective to existing issues in survey research, and we include these here. We advise readers to read this chapter in conjunction with Chapters 8, 17 and 24, and very many of the points in these three chapters apply convincingly to the present chapter.

Changes in the Internet and its uses are advancing rapidly, with access through a plethora of devices increasing exponentially. This chapter introduces issues which transcend particular mobile or computer devices and which can last over time. We recognize immediately that, in a chapter of this nature, huge technological changes will have occurred simply between the time of writing and the appearance of this book, and the future in this field has many unpredictable elements. The level of sophistication of mobile devices and their optimization for all kinds of research is advancing at breakneck speed. Could we even have imagined five years ago that email would become passé so quickly, or three years ago that SMS messaging would become yesterday's news, consigned to the older generation rather than the young digital natives of today whose life seems to revolve around apps and the absence of face-to-face communication (cf. Turkle, 2015)?

Internet surveys, whilst they have been the stuff of student evaluations of teaching for years (Morrison, 2013b), are becoming commonplace in many branches of educational research (Denscombe, 2014; Dillman *et al*., 2014; Roberts and Allen, 2015). Indeed they are becoming the predominant mode of conducting surveys, superseding paper-based surveys, be they through email or websites, on computers, cellphones, tablets and an ever-increasing range of electronic devices. Though they have much in common with paper-based surveys, they also have their own particular features, and we comment on these in this chapter.

Internet-based surveys can operate through, for example:

- an email with an introductory letter and questionnaire attachment (which requires the researcher to know the email address of the recipient);
- an email directing readers to a website where the survey can be found, or with a hyperlink to that site;
- an email with a survey embedded in it;
- a website which contains the survey: a web-based questionnaire;
- a general request for participation, placed in an electronic environment, such as an advertisement and connection to a survey placed on listservs, contact groups (e.g. special interest groups, newsgroups, discussion groups), blogs, social network sites and forums;
- a general advertisement;
- a dedicated website (one's own or others');
- public messages and advertising on social networking sites;
- companies who provide Internet survey services.

Internet surveys concern: the design of the survey (e.g. a questionnaire); its distribution and access to it; and data collection, storage and accessing data. We discuss these below.

18.2 Advantages of Internet surveys

An Internet survey claims several advantages in comparison to a paper survey:[1]

- *Costs*: it reduces costs (e.g. of postage, paper, printing, data entry by researchers, telephones, processing data, interviewer costs) and increases efficiency.

- *Speed*: it reduces the time taken to distribute, complete, gather and process data (data entered onto a web-based survey can be processed automatically as soon as the respondent enters the data rather than being keyed in later by the researcher), i.e. real-time data capture and processing.
- *Population and samples*: wider and much larger populations and samples can be accessed easily, enabling greater generalizability where Internet users come from a wide, diverse population. Internet surveys can yield representative data as they can reach a wider audience.
- *Contact*: e-surveys overcome spatial and temporal constraints (e.g. researchers and participants separated from each other in time, location and physical distance).
- *Volume*: a much larger volume of data can be collected.
- *Access*: researchers can reach populations that are otherwise difficult to reach (e.g. rare, minority, stigmatized, marginalized or deviant cases, as anonymity and non-traceability might be effective here).
- *Convenience*: respondents can complete the survey at a time to suit themselves, and they can complete the survey over time (i.e. they do not need to do it all at one sitting) and anywhere, i.e. in self-chosen and familiar settings.
- *Responses*: response rates may be higher (though some evidence challenges this). Participants tend to respond more quickly and more fully, reflectively and incisively, particularly when e-reminders are sent. Data are of a higher quality (richer, fuller responses with greater depth and reflection by participants). There are higher item completion and response, higher item variability and fewer missing values (though some evidence challenges this).
- *Ease*: it is easy to enter responses (e.g. click a radio button, check/tick a box).
- *Environment*: it is environmentally friendly (little or no paper).
- *Attractiveness*: graphics, different colours and fonts can be used.
- *Design flexibility*: skip-patterns and branching can be created and organized by the computer, so that participants do not have to understand complicated instructions, with automated, flexible navigation through the questionnaire consequent to the answers from respondents and boxes that they check/tick. It can enable diverse questions to be asked (through branching and skip functions).
- *Response checking*: the software can prompt respondents to complete missed/skipped items or to correct errors (e.g. two ticks for a single item in a rating scale), i.e. preventing them from continuing until a screen or item is completed: a 'forced response'. The computer can check incomplete or inconsistent replies.
- *Progress*: for each screen, an on-screen progress bar can show how much of the questionnaire has been completed (e.g. 50 per cent completed, 75 per cent completed).
- *Accuracy*: fewer missing or incorrect entries, as human error is reduced in entering and processing online data, these being done automatically.
- *Exportability*: data can be exported/imported into software (e.g. Excel, SPSS) for processing and subsequent analysis.
- *Anonymity, honesty and authenticity*: respondents may be more honest if their responses are anonymous and not face-to-face, i.e. a reduction in researcher effects, particularly if sensitive issues are being explored. Because of volunteered participation (i.e. an absence of coercion), greater authenticity of responses may be obtained.

With regard to costs, Watt (1997) notes that cost savings make a difference in comparison to a telephone survey, but that an Internet-based survey is only slightly less costly than a mail survey unless a web-based survey gathers data from more than around 500 participants, as the costs in terms of development and design time are considerable (though survey software has mitigated this). Fricker and Schonlau (2002) and Fox *et al*. (2003) suggest that the claims that Internet-based surveys are cheaper and faster are not always borne out by the evidence, and that, if Internet survey development, programming, testing and modification time, initial contact time and follow-up time to ensure an increased response rate are factored in, then the savings may not be as strong as the claims made. More recently, many Internet surveys have become less costly but not in terms of time for survey design and development.

18.3 Disadvantages of Internet surveys

An Internet survey also has several potential and actual disadvantages in comparison with a conventional survey (here the same references as those given above for 'advantages of Internet surveys' also give disadvantages, see note 1), for example:

- *Spam*: recipients and servers may regard the request to participate as spam or junk mail, and ignore or delete it.

- *Expertise*: respondents may not have sufficient Internet expertise to complete it correctly.
- *Sampling*: some target groups may not have access to the Internet and some respondents/groups may not be available or may not answer (non-response), particularly if the questions are sensitive. There may be sampling bias/skew, as the researcher has less control over the population and sampling, and respondents self-select. Random sampling may be impossible (which may affect statistics used, i.e. preventing use of some parametric statistics). Personal details may be withheld or unverifiable, hence sub-sampling and parametric analysis may be impossible.
- *Abandonment and dropout*: it is easy for respondents to simply stop altogether, or to send incomplete surveys, or not to send them at all. This is particularly the case if surveys are long or if researchers try to coerce respondents into completion by the use of a forced response (making them unable to continue until every item has been completed on a single screen). As a general rule, Internet surveys should be shorter than paper-based surveys or non-response can occur.
- *Computer difficulties*: the different configuration and software of computers may affect access to the survey, its layout, presentation and speed of connection. The computer or server may 'crash', 'freeze' or refuse to work, particularly if the survey is long or contains a lot of graphics. Error messages may appear. The survey may require software that respondents do not have or which downloads very slowly. Servers, computer networks, connections or the 'system' may go down. Surveys embedded in emails should be short, with few or no graphics or embedded objects, as the recipients' computer may not receive these.
- *No interviewer*: this is an impersonal medium, with no opportunities for in-depth probes.
- *Security, privacy and confidentiality*: these are not absolute, as hackers, data miners and spammers may intercept and track participants, and results are stored by software providers. Emails are particularly vulnerable.
- *Design matters*: technical expertise is needed if the researcher is going to write and design her/his own survey, i.e. not using commercially produced, open access or free software.
- *Instructions and answering*: if instructions are misunderstood, unclear, too complicated or too many, this may lead to irrelevant, unreliable or no responses, and if respondents are unclear how to answer then they are likely to simply skip items or stop.
- *Time*: surveys embedded in emails may require subsequent manual data entry by the researcher.
- *Response rates*: these tend to be low in Internet surveys (calculated in relation to those who accessed the survey). Response rates drop off if the survey is long or too complicated.
- *Misreporting*: there may be fake and false reporting: respondents may give deliberately fake, incorrect or socially desirable responses, or complete the survey to obtain a promised reward. There may be multiple submissions from the same person. Verifying the identity or details of participants may be impossible.
- *Satisficing*: respondents, particularly in a long survey, will enter any response rather than no response, compromising the quality, accuracy and reliability of the response (discussed below). The quality of responses becomes increasingly questionable as a long survey progresses.

Several of the positive claims made for Internet surveys are questionable. For example, Fricker and Schonlau (2002) and Fox *et al*. (2003) note that, in comparison to conventional surveys: (a) response rates may not be higher; (b) time taken in the several stages of the survey – from design to data collection and analysis – may not be shorter, even though delivery time is shorter; (c) data quality may be no better: coverage of items, sampling, response and non-response, honesty; and (d) potential respondents may not have access to the Internet and may be computer illiterate.

18.4 Constructing Internet-based surveys

Much Internet survey design can use any of the many online Internet survey templates and (often free) services available, and the companion website provides websites which provide such services. At the time of writing, widely used providers include: SurveyMonkey; Zoomerang; Free Online Surveys; SmartSurvey; Survey Planet; Google Forms. We provide the websites of these and others on the companion website. Several of these also automatically collate and present results so that they can be downloaded into, for example, Excel, SPSS, SAS or STATA.

For researchers wishing to construct their own Internet surveys with software and templates, there are several points of guidance below. Internet surveys can be made more attractive than their paper-based counterparts, with graphics, fonts, colours etc., but there are cautions, and we indicate these below.

Dillman *et al*. (1998a, 1998b, 1999, 2014) set out several concerns for Internet surveys, some technical

and some presentational. In terms of technical matters, they found that the difference between simple and 'fancy' versions of questionnaires (the former with few graphics, the latter with many, using sophisticated software) could be as much as three times the size of the file to be downloaded, thereby increasing download time. Respondents with slow browsers or limited power either spent longer in downloading the file or, indeed, the machine crashed before the file was downloaded. Download speeds continue to vary in different parts of the world and at different times of the day. They also found that recipients of plain versions were more likely to complete a questionnaire than those receiving fancy versions, as it took less time to complete the plain version. Utilizing advanced page layout features does not translate into higher completion rates, indeed more advanced page layout reduced completion rates. Similarly, Fricker and Schonlau (2002) report studies indicating a 43 per cent response rate to an email survey compared to a 71 per cent response rate for the same mailed paper questionnaire, and that higher response rates in an Internet survey are typically only obtained from specialized samples (e.g. undergraduates).

For presentational matters, Dillman *et al*. (1998a, 1999, 2014) comment that in a paper-based survey the eyes and the hands focus on the same area, whilst in an Internet survey the eyes focus on the screen whilst the hands often focus on the keyboard or the mouse, rendering completion more difficult. This is one reason to avoid asking respondents to type in many responses to open-ended questions, and to replace this with radio buttons or clicking a check box. The researchers also found that 'check-all-that-apply' lists of factors had questionable reliability, as respondents tended to complete those items at the top of the list and ignore the rest. Hence they recommend avoiding the use of large check-all-that-apply lists in a web-based survey.

It is important to keep the introduction to the questionnaire short (no more than one screen) and informative (e.g. about how to move on) and to avoid giving a long list of instructions. Further, as the first question in a survey tends to raise in respondents' minds a particular mindset, care is needed in setting the first question, to entice participants and not to put them off participating (e.g. not too difficult, not too easy, interesting, straightforward to complete, avoiding drop-down boxes and scrolling). Dillman *et al*. (1998a, 1998b, 1999, 2014) make recommendations about the layout of the screen, for example, keeping the response categories close to the question for ease of following; using features like brightness, large fonts and spacing for clarity; and avoiding too many changes of font and font size. They also suggest following the natural movement of the eyes from the top-left (the most important part of the screen, hence the part in which the question is located) to the bottom-right quadrants of the screen (the least important part of the screen which might contain the researcher's logo). They comment that the natural movement of the eye is to read prose unevenly (e.g. saccadically), with the risk of missing critical words, particularly on long lines; hence they advocate keeping lines and sentences short. It is also useful to include a progress bar to indicate how much of the questionnaire has been completed.

Some respondents may have less developed computer skills than others, and may not be familiar with web-based questionnaires, for example, with radio buttons, scroll bars, drop-down menus, where to insert open-ended responses. Hence the survey designer must not overestimate the capability of the respondent to use the software. Indeed explanations on how to respond may have to be outlined in the survey itself.

Dillman *et al*. (1999, 2014) suggest that the problem of differential expertise in computer usage can be addressed in three ways:

1. Place the instructions for how to complete the item next to the item itself (not all placed together at the start of the questionnaire).
2. Ask the respondents at the beginning about their level of computer expertise; if they are more expert, offer them the questionnaire with certain instructions omitted, and if they are less experienced, direct them to instructions and further assistance.
3. Have a minimized 'floating window' that accompanies each screen and which can be maximized to give further instructions.

Some web-based surveys prevent respondents from proceeding until they have completed all the items on the screen (a forced response). Whilst this might ensure coverage, it can also anger respondents – such that they give up and abandon the survey. Some web-based surveys prevent respondents from having a deliberate non-response (e.g. if they do not wish to reveal particular information, or if, in fact, the question does not apply to them, or if they do not know the answer). The advice of Dillman *et al*. (1999, 2014) is generally to avoid forced responses and to give respondents categories of 'prefer not to answer'/'decline to answer', 'don't know', 'not applicable' and 'other'. It is much easier for participants in a web-based survey to abandon the survey – a simple click of a button – so more attention has to be given to keeping them participating than in a paper-based survey.

The location of the instruction (e.g. to the right of the item, underneath the item, to the right of the answer box) is important. Locating the instruction too far to the right of the answer box (e.g. more than nine characters of text to the right) can mean that it is outside the foveal view (two degrees) of the respondent's vision, and hence can be overlooked. Redline *et al*. (2002) advocate making an instruction easier to detect by locating it within the natural field of vision of the reader, setting it in a large font to make it bolder and using a different colour. If the researcher wishes to include skips and branches then this can be done automatically 'behind the scenes', i.e. if the participant gives a particular response then the computer automatically takes him or her past a skipped part or to a branching part.

Redline *et al*. (2002) identify many other variables that impact on the success of Internet surveys:

- the greater the number of words, the more the reader will be absorbed with the question than with the instructions;
- if there are more than seven response categories per item the reader may make errors;
- response-order effects: respondents in a self-administered survey tend to choose earlier rather than later items in a list (the primacy effect);
- if respondents are asked to write an open-ended response they may overlook instructions, as they are absorbed in composing their own response, and the instruction may be out of their field of vision when writing their answer;
- items located at the bottom of a page are more likely to elicit a non-response than items further up a page, and instructions near the bottom of a page are more likely to be overlooked, so avoid this;
- if instructions are located too far from the answer box they may be overlooked.

This advice applies not only to online survey questionnaires but also to paper-based surveys.

There are several 'principles' for designing web-based questionnaires (e.g. Schaefer and Dillman, 1998; Dillman *et al*., 1999; Dillman and Bowker, 2000, pp. 10–11; Shropshire *et al*., 2009; Dillman *et al*., 2014):

- Consider the capabilities and configurations of the respondents' computers and the respondents themselves.
- Ensure that the layout/presentation of the survey will be the same across platforms, servers, browsers and respondents, and avoid differences in the visual appearance of questions that may happen as a result of different computers, configurations, operating systems, screen displays (e.g. partial and wrap-around text) and browsers.
- Enable the survey to run on computers, cellphones, iPads and other different devices.
- Ensure that security, confidentiality and privacy are in place.
- Start the web questionnaire with an interesting welcome screen that motivates respondents to continue, makes it clear that it is easy to complete, gives clear instructions on how to proceed and contains information and a check box for informed consent.
- Provide a PIN number if you wish to limit access to those people in the sample.
- Ensure that the first question can be seen in its entirety on the first screen, and is easy to understand and complete.
- Embed visual images in a survey and place interest-based questions early, as this reduces premature dropout from the survey.
- Ensure that the layout of each question is similar to a paper format, as respondents may be familiar with this.
- Ensure that the use of colour keeps figure/ground consistency and readability, so that it is easy to navigate through the questionnaire with navigational flow unimpeded, and so that the measurements used in questions are clear and sustained.
- Ensure consistency in colours, fonts, layout.
- Keep the line length short, to fit screen size and respondent focus.
- Minimize the use of drop-down boxes and direct respondents to them where they occur.
- Give clear instructions for how to move through the questionnaire using the computer, and keep instructions for computer actions at the point where the action is needed, rather than placing them all at the start of the questionnaire.
- Avoid forced responses (requiring respondents to answer each question before being able to move on to the next question/screen).
- Ensure that questionnaires scroll easily from question to question, unless order effects are important.
- If multiple choices are presented, keep them to a single screen; if this is not possible then consider double columns, with navigational instructions.
- Consider providing a progress bar to indicate how far the respondent has reached in the survey (it may or may not be advisable if the questionnaire is quite long, hence judgement is required).
- Avoid tick-all-those-that-apply kinds of question.
- Enable respondents to save their survey and complete it later, and to keep their own copy (backup) of their completed survey.

- Have a 'thank you' screen for when the respondent submits the completed survey.
- Provide a 'help' button for further explanation and contact details of the researcher.

Additionally, Heerwegh *et al*. (2005) report that personalizing the survey (i.e. using the recipient's name in the salutation) increases response rates by 8.6 per cent (e.g. starting a survey letter with Dear [name of specific person]), though care has to be taken to ensure consistency, for example, it is counter-productive to start an Internet survey letter with Dear [name of person] and then, later, to refer to 'student', 'colleague' etc. (i.e. a depersonalized version). Personalizing a survey increases the chances of a respondent *starting* the survey (p. 92) rather than dropping out during the survey (i.e. they might still drop out later). Whether participants continue and complete the survey depends on other factors, for example: difficulty in completing the items; relevance of the topic to the respondents; and user-friendliness of the survey. They also report (p. 94) that personalizing an e-survey increases participant honesty on sensitive matters (e.g. number of sexual partners), increases adherence to survey instructions (p. 96) and increases the tendency of respondents to answer questions in a socially desirable way.

Denscombe (2009b, pp. 286–7) reports that, for online surveys, fixed-choice questions tend to have a 'lower item-response rate than open-ended questions', and, for open-ended questions, item non-response is lower in online surveys than in paper-based surveys.

Christian *et al*. (2009) report that if a survey questionnaire presents the positive end of a scale first then, whilst it may not make a difference to the response, it does increase response time (which might lead to dropping out). They also note that if the positive categories are given lower numbers (e.g. '1' and '2') and the negative categories are given high numbers (e.g. '4' and '5'), then this can increase response time. Further, they report that displaying categories in several columns increases response time, as does giving the poles of rating scales numbers rather than words.

Mora (2011b) notes that more positive results are obtained if the scale runs from –2 to +2 or from –4 to +4, that scales with the positive label on the left and higher numerical ratings on the left had significantly higher ratings, that scales with 'definitely agree' on the left and 'definitely disagree' on the right tended to have higher agreements, and higher scores were recorded for positively worded items. The percentage of affirmative responses was higher in a paper-based survey than in an Internet-based survey (Dillman *et al*., 2003; Morrison, 2013b).

Toepel *et al*. (2009) suggest that account has to be taken of the 'cognitive sophistication' of the respondents, as those with less cognitive sophistication tend to be affected by contextual clues more than those with more cognitive sophistication. Context effects also occur when a particular item is affected by the items around it or which precede it, in effect providing cues for the respondent, or in which a particular mindset of responses is created in the respondent (Friedman and Amoo, 1999).

The importance of the visual aspect of questionnaires is heightened in Internet surveys (Smyth *et al*., 2004), and this concerns the layout of questions, instructions and response lists, the grouping of items, the colours used, the spacing of response categories and the formatting of responses (e.g. writing in words or checking boxes). Smyth *et al*. report that respondents use 'preattentive processing' when approaching Internet surveys, i.e. they try to take in and understand the whole scene (or screen) before attending to specific items, hence visual features are important, for example, emboldened words, large fonts, colours, brightness, section headings, spacing, placing boxes around items. This rests on Gestalt psychology which abides by the principles of: (a) *proximity* (we tend to group together those items that are physically close to each other); (b) *similarity* (we tend to group together those items that appear alike); (c) *prägnanz* (figures or items with simplicity, regularity and symmetry are more easily perceived and remembered).

Smyth *et al*. (2004) also suggest (p. 21) that headings and separation of sections take on added significance in Internet-based surveys. Separating items into two sections with headings had a 'dramatic effect' on responses, as respondents felt compelled to answer both sub-groups (70 per cent gave an answer in both sub-groups whereas only 41 per cent did so when there were no headings or sectionalization). They also found that separating a vertical list of items into sub-groups and double columns should be avoided. They report that asking for open-ended responses (e.g. writing their subject specialisms) can be more efficient than having them track down a long list of subjects (e.g. from a drop-down menu) to find the one that applies to them, though this can be mitigated by placing simple lists in alphabetical order. Finally, they found that placing very short guides underneath the write-in box rather than at its side (e.g. dd/mm/yy for 'day/month/year') increased response rates, and that placing instructions very close to the answer box improved response rates.

Dillman *et al*. (2003) also found that having respondents use a 'yes/no' format and having a 'forced choice' (no option but to answer) for responding

resulted in increased numbers of affirmative answers, even though this requires more cognitive processing than non-forced choice questions (e.g. 'tick[check]-all-that-apply' questions) (p. 23). This is because respondents may not wish to answer questions in the outright negative (p. 10). Even if they do not really have an opinion, or they are neutral, or the item does not really apply to them, they may choose a 'yes' rather than a 'no' category. They may leave a blank rather than indicating a 'no'.

Dillman *et al*. (2003) report that respondents tend to select items higher up a list than lower down a list of options (the primacy effect), and opt for the 'satisficing' principle (they are satisfied with a minimum sufficient response, selecting the first reasonable response in a list and then moving on rather than working their way down the list to find the optimal response), i.e. item order is a significant feature, making a difference to responses of over 39 per cent (p. 7). This is particularly so when respondents are asked for opinions and beliefs rather than topics seeking factual information. They also suggest that the more difficult the item is, the more respondents will move towards 'satisficing'. 'Satisficing' and the primacy effect were stronger in Internet surveys than paper-based surveys (p. 22), and changing 'check-all-that-apply' to forced responses ('yes/no') did not eliminate response order effects. Similarly, Diaz de Rada and Dominguez (2015) report that participants change their minds about participation as the survey proceeds, but, rather than withdrawing altogether, move towards satisficing, giving answers that require minimum effort rather than thinking deeply, and that they give affirmative answers in the spirit of acquiescence or 'don't know' answers.

Dillman *et al*. (2003) report that the order of response categories can have an effect on responses, citing a study that found that asking college students whether their male or female teachers were more empathetic was affected by whether the 'male' option was placed before or after the 'female' option: female teachers were evaluated more positively when respondents were asked to compare them to male teachers than when male teachers were compared to female teachers (p. 6). Respondents compare the second item in light of the first item in a list rather than considering the items independently.

Internet-based surveys, then, raise several challenges and problems. Some of these are indicated in Table 18.1, together with possible solutions.

18.5 Ethical issues in Internet-based surveys

In Internet surveys, issues of informed consent, anonymity, privacy and confidentiality, non-traceability, protection from harm, the precautionary principle and data security are important (e.g. Fox *et al*., 2003; Hammersley and Traianou, 2012). Chapter 8 addressed ethical issues in online research and these apply to Internet surveys. Ethics in Internet surveys also concerns the offering of incentives to participate, to ensure that they are appropriate and not excessive. Marshall and Rossman (2016) suggest that researchers must consider several ethical issues in researching online communities (pp. 182–3):

- how public and private the data are;
- the sensitivity of the topic;
- the degree of interaction between the researcher and the participants and between participants;
- the vulnerability of the participants.

Given that the URL identifies a specific location and is held on servers, and given that some survey providers have control over this, it is impossible to guarantee total security of identity and information here. Rather, steps have to be taken to protect data in terms of collection, storage, access and electronic transfer (just as with non-Internet surveys).

To address security and confidentiality of identity, the researcher may require no identification details from the participant and ask for none in the survey. Or the researcher may take steps to protect data privacy, anonymity and confidentiality, through password protection, one-way scrambling of the machine number when the data are being submitted ('encoding it in a manner that cannot subsequently be decoded'; Fox *et al*., 2003, p. 178). However, this does not give any absolute guarantee that hackers, data miners or spammers will not intercept and access the data, particularly where it can be linked to an email address. An email survey can reveal the identity and traceability of the respondent. Security (e.g. through passwords and PIN numbers) is one possible solution, though this, too, can create problems as respondents may feel that they are being identified and tracked, and indeed some surveys may deposit unwelcome 'cookies' onto the respondent's computer, for future contact.

Completing a survey may be taken to indicate informed consent, and Roberts and Allen (2015) note the American Educational Research Association's (2000) Code of Ethics which indicates (Clause 13.01.b)

TABLE 18.1 PROBLEMS AND SOLUTIONS IN INTERNET-BASED SURVEYS

Problem (sampling)	*Possible solution*
Some subsample groups may be under-represented in the respondents	Adjust the results by weighting the sample responses (see the comments on a 'boosted sample' and 'weighting' in Chapter 12)
There may be coverage error (not everyone has a non-zero chance of being included)	Disclose the sample characteristics in reporting
Non-response and volunteer bias	Follow-up messages posted on websites and electronic discussion groups. Use emails to contact potential participants. Require the respondents to submit their replies screen by screen. (This enables the researcher not only to use some data from incomplete responses, but also enables her to identify in detail patterns of non-response, i.e. responding is not an all-or-nothing affair (either submit the whole questionnaire or none of it) but can be partial (a respondent may answer some questions but not others))
Problem (ethics)	*Possible solution*
Respondents may wish to keep their identity from the researcher, and an email address identifies the respondent (in the case of sensitive research, e.g. on child abuse or drug abuse, this may involve criminal proceedings if the identity of the respondent is known or able to be tracked by criminal investigators who break into the site). Non-traceability of respondents may be problematic	Direct respondents to a website rather than to using email correspondence. Provide advice on using non-traceable connections to access and return the survey (e.g. an internet café, a library, a university). Advise the respondent to print off the survey and return it by post to a given address. Avoid asking respondents to enter a password or to give an email address. Prevent access to unprotected directories and confidential data
Respondents may not know anything about the researcher, or if it is a *bona fide* piece of research and not simply a marketing ploy	Include the researcher's affiliation (e.g. university), with a logo if possible
Informed consent	Ensure that it is easy for respondents to withdraw at any time (e.g. include a 'Withdraw' button at the foot of each screen)
Problem (technical: hardware and software)	*Possible solution*
The configuration of the questionnaire may vary from one machine to another (because of web browsers, connection, hardware, software) and can lead to dropout	Opt for simplicity. Test the survey on different computer systems/browsers to ensure consistency. Avoid surveys that require real-time completion
The screen as set out by the survey designer may not appear the same as that which appears on the respondent's screen	Opt for simplicity. Use a commercial survey software system for generating the questionnaire. Avoid high level programs
Slow network connections or limited bandwidth can slow down loading	Keep the use of graphics to a minimum. Advise on the possible time it takes to load
Respondents may not have the same software, or the same version of the software as the sender, rendering downloading of the questionnaire either impossible or distorting the received graphics	Avoid the use of graphics and more advanced software programs

Problem (technical: hardware and software)	*Possible solution*
Graphics may be corrupted/incompatible between the sender and the user, i.e. between one kind of machine, user platform and software and another. Hardware may differ between sender and receiver	Opt for simplicity. Use commercially available web-based surveying systems and packages. Use image files (e.g. .jpeg, .gif) to reduce loading time. Avoid pop-ups if possible as they reduce response rate
The greater the use of graphics and plug-ins (e.g. using Java and Applets), the longer it takes to download, and, particularly – though not exclusively – if respondents do not have broadband access then time-consuming downloads could result in either the respondent giving up and cancelling the download, or creating a bad mood in the respondent	Keep software requirements as low-tech as possible. Avoid questionnaires that use sophisticated computer graphics
There may be slow loading times due to internet congestion	Avoid sophisticated graphics and 'fancy' presentations as these take longer to download
The physical distance between points on an attitude scale may spread out because of configuration differences between machines	Indicate how best the questionnaire may be viewed (e.g. 800 × 400)
The construction procedures for wrap-around text may vary between computers	Keep lines of text short
Email questionnaires may distort the layout of the questionnaire (some email software uses HTML, others do not)	Avoid sending a questionnaire directly using email; rather, post it on a website (e.g. so that respondents visit a website and then click a box for immediate transfer to the questionnaire). Consider using an email to direct participants to a website (e.g. the email includes the website which can be reached by clicking in the address contained in the email). Use an email that includes an attachment which contains the more graphically sophisticated survey instrument itself
Problem (respondents)	*Possible solution*
Respondents may be unfamiliar or inexperienced with the internet and the media	Keep the questionnaire simple and easy to complete
Respondents may send multiple copies of their completed questionnaire from the same or different addresses	Have a security device that tracks and limits (as far as possible) respondents who may be returning the same questionnaire on more than one occasion. Use passwords (though this, itself, may create problems of identifiability). Collect personal identification items. Check for internal consistency across submissions
There may be more than one respondent to a single questionnaire (the same problem as in, for example, a postal questionnaire)	Include questions to cross-check the consistency of replies to similar items
Respondents may not be used to pull-down menus	Provide clear instructions
Drop-down boxes take up more space on a screen than conventional questionnaires	Avoid their overuse
Respondents dislike the situation where the computer prevents them from continuing to the next screen until all the items on a particular screen have been completed	Avoid this unless considered absolutely necessary

continued

TABLE 18.1 CONTINUED

Problem (respondents)	*Possible solution*
The language of email surveys can risk offending potential participants ('flaming')	Check the language used to avoid angering the participants
Respondents' difficulty in navigating the pages of the online survey	Keep instructions to the page in question. Make the instructions for branching very clear (font size, colour, etc.)
Problem (layout and presentation)	*Possible solution*
A page of paper is longer than it is wide, but a screen is wider than it is long, and a screen is smaller than a page, i.e. layout becomes a matter of concern	Remember that screen-based surveys take a greater number of screens than their equivalent number of pages in a paper copy. Sectionalize the questionnaire so that each section fills the screen, and does not take more than one screen
The layout of the text and instructions assumes greater importance than for paper questionnaires	Opt for clarity and simplicity
The layout uses a lot of grids and matrices	Avoid grids and matrices: they are a major source of non-response
The order of items affects response rates	Locate requests for personal information at the beginning of the survey. Include 'warm-ups' and early 'high hurdles' to avoid dropout
Respondents may be bombarded with too much information in an introductory message	Place the advertisement for the survey on user groups as well as for the general public, inviting participants to contact such-and-such a person or website for further information and the questionnaire itself, i.e. separate the questionnaire from the advertisement for/introduction to the questionnaire
Respondents may be overloaded with instructions at the beginning of the survey	Avoid placing all the instructions at the start of the questionnaire, but keep specific instructions for specific questions
Respondents may be overloaded with information at the beginning of the survey	Keep the initial information brief and embed further information deeper in the survey
Respondents may have to take multiple actions in order to answer each question (e.g. clicking on an answer, moving the scroll bar, clicking for the next screen, clicking to submit a screen of information)	Keep the number of actions required in order to move on to a minimum
Respondents may not be able to see all the option choices without scrolling down the screen	Ensure that the whole item and options are contained on a single screen
Respondents may not understand instructions	Provide a helpline, email address or contact details of the researcher. Pilot the instrument
Instructions about options may be unclear	Use radio buttons for single choice items, and try to keep layout similar to a paper layout
Respondents only read part of each question before going to the response category	Keep instructions and words to a necessary minimum

Problem (reliability)	*Possible solution*
Respondents may alter the instrument itself. The researcher relinquishes a greater amount of control to the respondents than in conventional questionnaires	Include technological safeguards to prevent alteration and have procedures to identify altered instruments
Respondents may be forced to answer every question even when they consider some response categories inappropriate	Pilot the survey. Include options such as 'don't know' and 'do not wish to answer' and avoid forcing respondents to reply before they can move on
Respondents may not be telling the truth – they may misrepresent themselves	Include questions to cross-check replies (to try to reduce the problem of respondents not telling the truth)
Problem (dropout)	*Possible solution*
Respondents may lose interest after a while and abandon the survey, thereby losing all the survey data	Have a device that requires respondents to send their replies screen by screen (e.g. a 'Submit' button at the foot of each screen), section by section, or item by item. Put each question or each section on a separate screen, with 'submit' at the end of each screen. Adopt a 'one-item-one-screen' technique
Respondents may not know how long the questionnaire is, and so may lose interest	Include a device for indicating how far through the questionnaire the respondent has reached: a progress bar at the bottom or the side of the survey
Internet surveys take longer to complete than paper-based surveys	Keep the internet survey as short, clear and easy to complete as possible
People do not want to take part, and it is easier for someone to quit or cancel an internet-based survey than a paper-based survey (simply a click of a button)	Increase incentives to participate (e.g. financial incentives, lottery tickets (if they are permitted in the country))
Diminishing returns (the survey response drops off quite quickly). Newsgroup postings and electronic discussion group data are removed, relegated or archived after a period of time (e.g. a week), and readers do not read lower down the lists of postings	Ensure that the website is re-posted each week during the data collection period
Non-participation may be high (i.e. potential participants may not choose to start, in contrast to those who start and who subsequently drop out)	Increase incentives to participate. Locate personal informational questions at the start of the survey
Error messages (e.g. if an item has not been completed) cause frustration and may cause respondents to abandon the questionnaire	Avoid error messages if possible, but, if not possible, provide clear reasons why the error was made and how to rectify it

that waivers of consent may apply to Internet surveys if there is minimal risk or if the obtaining of consent may be impractical. Nevertheless this does not exonerate the researcher from indicating to participants that, whilst every reasonable step has been taken to protect confidentiality and to prevent unwanted access, it cannot be a watertight guarantee, even if this means that some respondents decline to participate. Transparency and honesty trump the researcher's personal wishes for responses here.

Researchers can provide initial information about ethical matters at the front of the survey, with rights: (a) to withdraw; (b) not to answer specific questions; and (c) to withdraw their consent freely. Researchers can provide a check box for participants to give consent, and indicate to what they are giving consent. Such consent, Roberts and Allen (2015) aver, should be free of coercion, and care should be taken to ensure that this is the case for potentially vulnerable participants (e.g. those with special needs, minorities, children etc.).

18.6 Sampling in Internet-based surveys

Watt (1997) suggests that there are three types of Internet sample:

- an *unrestricted* sample (anyone can complete the questionnaire, but it may have limited representativeness);
- a *screened* sample (quotas are placed on the subsample categories and types, e.g. gender, income, job responsibility etc.);
- a *recruited* sample: respondents complete a preliminary classification questionnaire and then, based on the data received, are recruited or not.

Regardless of sampling type, sampling bias is a major concern for Internet-based surveys (Coomber, 1997; Roztocki and Lahri, 2002; Schonlau *et al*., 2009), for example, 'sampling representativeness and validity of data' (Hewson *et al*., 2003, p. 27). The view of over-representation of some and under-representation of others is challenged (Hewson *et al*., 2003) by results showing that samples taken from users and non-users of the Internet did not differ in terms of income, education, sexual orientation, marital status, ethnicity and religious belief. Nonetheless, they did differ in terms of age, with Internet samples containing a wider age range than non-Internet samples, and in terms of sex, with Internet samples containing more males. Hewson *et al*. report overall a greater diversity of sample characteristics in Internet-based samples, though they caution that this is inconclusive, and that the characteristics of Internet samples, like non-Internet samples, depend on the sampling strategy used. Stewart and Yalonis (2001) suggest that one can overcome the possible bias in sampling through simple stratification techniques.

A problem in sampling in Internet surveys is estimating the size and nature of the population from which the sample is drawn, a key feature of sampling. Researchers may have no clear knowledge of the population characteristics or size. The number of Internet users is not a simple function of the number of computers or the number of servers (e.g. many users can employ a single computer, cellphone, iPad or server, and many users have all of these or more than one smartphone). Further, it is difficult to know how many or what kind of people see a particular survey on a website (e.g. more males than females), i.e. the sampling frame is unclear. Moreover, certain sectors of the population may be excluded from the Internet, for example, those not wishing to or unable (e.g. because of cost or availability or ability) to have access to the Internet.

Internet-based surveys are based largely on volunteer samples (see Chapter 12), obtained through general posting on the web (e.g. an advertisement giving details and directing volunteers to a site for further information), or, for example, through announcements to specific newsgroups and interest and user groups on the web, for example, SchoolNet. Lists of different kinds of user (USENET) groups, newsgroups and electronic discussion groups (e.g. listservs) can be found on the web. Several search engines exist that seek and return web mailing lists, such as: www.liszt.com (categorized by subject); Catalist (the official catalogue of listserv lists at www.lsoft.com/catalist.html); and Meta-List.net (www.meta-list.net), which searches a database of nearly a quarter-of-a-million mailing lists. Dochartaigh (2002) and Denscombe (2014) provide useful material on web searching for researchers.

In Internet surveys the researcher is using non-probability, volunteer sampling, and this may decrease the generalizability of the findings (this may be no more a problem on Internet-based surveys than on other surveys). Opportunity samples (e.g. of students, or of particular groups) may restrict the generalizability of the research, but this may be no worse than in conventional research, and may not be a problem so long as it is acknowledged. Volunteers may differ from non-volunteers in terms of personality (e.g. they may be more extravert or concerned for self-actualization (Bargh *et al*., 2002)) and may select themselves into, or out of, a survey, again restricting the generalizability of the results.

One method to try to overcome the problem of volunteer bias is to strive for very large samples, or to record the number of hits on a website, though these are crude indices. Another method of securing the participation of non-volunteers in an Internet survey is to contact them by email (assuming that their email addresses are known), for example, a class of students, a group of teachers. However, email addresses themselves do not give the researcher any indication of the sample characteristics (e.g. age, sex, nationality etc.). Gwartney (2007, p. 17) suggests that online surveys might be most appropriate with 'closed populations', i.e. employees in a particular organization, as this will enable the researcher to know some of the characteristics and parameters of the respondents.

18.7 Improving response rates in Internet surveys

Despite mobile phone optimization and increasing access to, and country-wide penetration of, the Internet, response rates for Internet surveys are typically lower

than for a paper-based survey and their equivalent mail surveys (Solomon, 2001), as is the rate of completion of the whole survey (Witmer *et al*., 1999; Reips, 2002a; Morrison, 2013b). Witmer *et al*. (1999) found that short versions of an Internet-based questionnaire did not produce a significantly higher response rate than the long version (p. 155). Solomon (2001) suggests that response rates can be improved through the use of personalized email, follow-up reminders, using simple formats and pre-notification of the intent to survey.

Reips (2002a) provides useful guidelines for increasing response rates on an Internet survey, for example, by having several websites and postings on several discussion groups that link potential participants or web surfers to the website containing the questionnaire. He also suggests utilizing a 'high-hurdle technique', where 'motivationally adverse factors are announced or concentrated as close to the beginning' as possible (p. 249), so that any potential dropouts self-select at the start rather than during the data collection. A 'high-hurdle' technique, he suggests, comprises:

- *seriousness*: inform the participants that the research is serious and rigorous;
- *personalization*: ask for an email address or contact details and personal information;
- *impression of control*: inform participants that their identity is traceable;
- *patience: loading time* – use image files to reduce loading time of web pages;
- *patience: long texts* – place most of the text in the first page, and successively reduce the amount on each subsequent page;
- *duration*: inform participants how long the survey will take;
- *privacy*: inform the participants that some personal information will be sought;
- *preconditions*: indicate the requirements for particular software;
- *technical pre-tests*: conduct tests of compatibility of software;
- *rewards*: indicate that any rewards/incentives are contingent on full completion of the survey.

Some of these strategies could backfire on the researcher (e.g. the disclosure of personal and traceable details), but the principle here is that it is often better for the participant not to take part in the first place rather than to drop out during the process. (Frick *et al*. (1999) found that early dropout was not increased by asking for personal information at the beginning.)

Reips (2002a) also advocates the use of 'warm-up' techniques in Internet-based research in conjunction with the 'high-hurdle' technique. He suggests that most dropouts occur earlier rather than later in data collection, or indeed at the very beginning (non-participation), and that most such initial dropouts occur because participants are overloaded with information early on. He suggests that it is preferable to introduce some simple-to-complete items earlier on to build up an idea of how to respond to the later items and to try out practice materials.

Researchers can try several ways to improve response rates (e.g. Schaefer and Dillman, 1998; Frick *et al*., 1999; Crawford *et al*., 2001; Dillman *et al*., 2009, 2014; Mora, 2010; Monroe, 2012; Morrison, 2013b; Denscombe, 2014):

- send an advance introductory letter by email, indicating the purposes, contents and time needed for the survey;
- consider incentives (e.g. a lucky draw, payment);
- have a welcome screen, which includes the institution (and its logo) and messages of support from senior people;
- make the instructions and questions clear and easy to answer;
- avoid asking for unnecessary identifying information (e.g. email addresses);
- keep it short (taking no more than 10–15 minutes (at most) to complete);
- keep the design consistent, clear, uncomplicated, attractive and easy to understand;
- send follow-up reminders (a maximum of three reminders);
- state anonymity and non-traceability (it may be impossible to offer 100 per cent guarantees here, but researchers can state that all steps have been taken to address these);
- personalize the survey: 'Dear ____' [name];
- avoid 'forced responses' if possible, and include the options (where relevant) of 'decline to answer', 'don't know', 'not applicable' or 'other';
- avoid items which require too much respondent effort (e.g. too much memory recall, comprehension, knowledge of technical vocabulary, concepts);
- avoid wordy questions, unclear concepts or asking more than one thing in the same question.

Response rates can also be improved through ease of question formats and ease of answering, for example, with check boxes or radio buttons for:

- yes/no questions;
- multiple-choice questions (select one by using a radio button);

- multiple-choice questions (select an exact number or as many as you wish);
- a matrix of multiple questions with the same response scales (e.g. rating scales);
- horizontal scales (preferable to vertical scale);
- drop-down lists with a single choice.

Further, make it easy to enter responses for continuous rating scales (e.g. percentage points); use single line texts with an open answer; in rank order questions and constant sum items, avoid having too many items to rank and items for point distributions respectively (see Chapter 24).

Some researchers approach survey companies to carry out their Internet survey. Using a professional company can address sampling matters; alternatively they may not perform very well, hence caution, 'vetting' and checking the company's previous experience are important. Denscombe (2014, p. 17) offers useful guidance for researchers who are considering using such services, addressing, for example: contracts and costs; security, privacy and sharing of data (particularly personal information) and trustworthiness; limits to the size of the survey; how the researcher accesses the data and in what format, and for how long the data can be accessed; how to prevent multiple submissions; password protection; design features (e.g. sample formats and templates); tracking (e.g. logged data on respondents and their contact details).

As the Internet becomes more popular for surveys, software resources for conducting these are becoming increasingly attractive and easy to use. Whilst there are plentiful advantages and considerations in Internet surveys, we also counsel researchers to be aware of the risks, ethics and considerations involved, as with all forms of research. Internet surveys have many advantages over their paper, telephone and face-to-face interview counterparts; they also bring their own concerns which we have addressed in this chapter.

18.8 Technological advances

In an era of rapid technological change it is invidious to be too prescriptive or narrow with regard to the technology for, design and conduct of, and access to, Internet surveys. Smartphones and mobile phone optimization, increasing user-friendliness, improved compatibility and integration between devices (and the Internet of Things), the ability of the same survey to be delivered in multiple formats to different devices, a huge and rapid increase in the range and types of mobile devices for accessing the Internet almost anywhere in the world and at any time, real-time communication, location software, immense strides in presentational and response software, increasing speed and connectivity, cloud computing, storage facilities for massive amounts of data, apps for everything and new social networking sites appearing almost daily, are all accumulating and advancing so quickly that even to name them here risks becoming instantly out of date. Simply keeping pace with developments is a full-time occupation. Researchers are advised to consult journals on digital technologies for social science research in order to keep up with the field.

Note

1 See, for example: Coomber (1997); Watt (1997); Dillman *et al*. (1998b, 2014); Dillman and Bowker (2000); Aldridge and Levine (2001); Roztocki and Lahri (2002); Archer (2003); Fox *et al*. (2003); Deutskens *et al*. (2005); Evans and Mathur (2005); Glover and Bush (2005); Joinson and Reips (2007); Fowler (2009); Bennett and Nair (2010); Farrell and Peterson (2010); Harlow (2010); Mora (2010, 2011a); Minnaar and Heystek (2013); Akbulut (2015); Diaz de Rada and Dominguez (2015).

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Case studies

CHAPTER 19

Case studies are important sources of research data, either on their own or to supplement other kinds of data, and constitute an approach to research in their own right. This chapter sets out key areas for attention in case studies:

- what is a case study?
- types of case study
- advantages and disadvantages of case study
- generalization in case study
- reliability and validity in case studies
- planning a case study
- case study design and methodology
- sampling in case studies
- data in case studies
- writing up a case study
- what makes a good case study researcher?

We provide researchers with an overview of key issues in the planning, conduct and reporting of a case study.

19.1 What is a case study?

It could be argued that any research in social science is a case. Case study might include experiment, action research, survey, naturalistic research, participatory research, historical research etc., and case study research uses multiple methods for data collection and analysis. In other words, it operates as many other types of research. Indeed Hamilton's and Corbett-Whittier's (2013) frequently cited *Case Study in Education Research* in many places reads like a general introductory volume on research methods and writing up research.

So a key question is 'what distinguishes a case study from other forms of research?' A case study has many definitions, indeed has been termed a 'contested terrain' (Yazan, 2015). For example, it has been defined as a specific instance that is frequently designed to illustrate a more general principle (Nisbet and Watt, 1984, p. 72). It is 'the study of an instance in action' (Adelman *et al*., 1980), 'the study of the particularity and complexity of a single case, coming to understand its activity within important circumstances' (Stake, 1995, p. xi). It is the 'detailed examination of a small sample' (Tight, 2010, p. 337) and an in-depth investigation of a specific, real-life 'project, policy, institution, program or system' from multiple perspectives in order to catch its 'complexity and uniqueness' (Simons, 2009, p. 21).

Whilst Creswell (1994, p. 12) defines the case study as a single instance of a bounded system, for example a child, a clique, a class, a school, a community, others would not hold to such a tight definition. For example, Yin (2009, p. 18) argues that the boundary line between the phenomenon and its context is blurred, as a case study is a study of a case in a context and it is important to set the case within its context (and rich descriptions and details are often a feature of a case study). Indeed Chong and Graham (2013) argue for a 'Russian doll' approach to understanding what a case study is, i.e. a nested approach where to understand a micro-level case involves understanding and including the meso- and macro-contextual levels in which it is nested (p. 24). A case study can sometimes be tightly bounded and other times less so; as Verschuren (2003, p. 123) argues, it is ambiguous.

Arriving at a single definition of case study is elusive and unnecessary. Is it, for example, a method, a process, a methodology, a research design, an outcome, a research strategy, a focus (Verschuren, 2003; Stake, 2005; Tight, 2010; Thomas, 2011; Yazan, 2015)? Ragin (1992) contrasts a case study approach to a 'variable' approach (p. 5), placing the case rather than specific variables at the heart of the study. In our comments below we attempt to address the several definitions of case study.

Equally taxing is defining what constitutes a 'case': whilst some authors define it as a bounded unit, this offers little purchase on our understanding, as it still does not define what constitutes a unit and what constitutes a boundary. Robson (2002, pp. 181–2) suggests that case study can include: an individual case study; a set of individual case studies; a social group study; studies of organizations and institutions; studies of events, roles and relationships. Punch (2005) notes that a case may be an individual, a group, an organization,

a community or a nation (p. 144) and Pring (2015) notes that a unit might be 'a person, institution or collection of institutions', for example, a School Board (p. 55). Indeed Tight (2010), quoting Punch (2005, p. 144), reports commentaries which argue that the unit of analysis (the 'case') in case studies is so unclear that 'almost anything can serve as a case', such that 'case study as a form of social research is not a particularly meaningful term' (Tight, 2010, p. 337) and can be replaced by terms such as 'small sample, in-depth study' (p. 38). We challenge this, arguing that researchers must make clear what their unit of analysis is, what is the level of their analysis, what constitutes the 'case', and what are their boundaries in case study research. Pring (2015) notes that, the larger the embrace of the unit, i.e. the wider the boundaries of the unit, the more complex becomes the task of unravelling, identifying and commenting on the interactions between all elements and levels of the unit.

A case study provides a unique example of real people in real situations, enabling readers to understand ideas more clearly than simply by presenting them with abstract theories or principles. Indeed a case study can enable readers to understand how ideas and abstract principles can fit together (Yin, 2009, pp. 72–3). Case studies can penetrate situations in ways that are not always susceptible to numerical analysis.

Case studies accept that there are many variables operating in a single case, and, hence, to catch the implications of these variables usually requires more than one tool for data collection and many sources of evidence. Case studies can blend numerical and qualitative data, and they are a prototypical instance of mixed methods research (see Chapter 2); they can explain, describe, illustrate and enlighten (Yin, 2009, pp. 19–20).

Verschuren (2003, p. 124), like many writers, argues that a distinguishing feature of case study research is 'holism' rather than 'reductionism'. Whilst for Yin (2009) 'holism' refers to conducting the research at the single unit of analysis chosen, which may be an individual, a group, an organization etc., for Verschuren the term 'holism' is ambiguous, as it may not necessarily mean looking at a *whole* subject, person, group or organization but only at the relevant areas of interest, taken together.

Case studies can establish cause and effect ('how' and 'why'); indeed one of their strengths is that they observe effects in real contexts, recognizing that context is a powerful determinant of both causes and effects, and that in-depth understanding is required to do justice to the case. As Nisbet and Watt (1984, p. 78) remark, the whole is more than the sum of its parts. Sturman (1999, p. 103) argues that a distinguishing feature of case studies is that human systems have a wholeness or integrity to them rather than being a loose connection of traits, and necessitate in-depth investigation. Contexts are unique and dynamic, hence case studies investigate and report the real-life, complex, dynamic and unfolding interactions of events, human relationships and other factors in a unique instance. Hitchcock and Hughes (1995, p. 316) suggest that case studies are distinguished less by the methodologies that they employ than by the subjects/objects of their inquiry, and there is frequently a resonance between case studies and interpretive methodologies. They further suggest (p. 322) that the case study approach is particularly valuable when the researcher has little control over events, i.e. behaviours cannot be manipulated or controlled (though some case studies, e.g. of therapies, may involve high levels of control).

Hitchcock and Hughes (1995, p. 317) consider that a case study has several hallmarks:

- it is concerned with a rich and vivid description of events relevant to the case;
- it provides a chronological narrative of events relevant to the case;
- it blends description with analysis of events;
- it focuses on individual actors or groups of actors, and seeks to understand their perceptions of events;
- it highlights specific events that are relevant to the case;
- the researcher is integrally involved in the case, and the case study may be linked to the personality of the researcher (cf. Verschuren, 2003, p. 133);
- an attempt is made to portray the richness of the case in writing up the report.

Similarly, Denscombe (2014) comments that case studies are characterized by: in-depth study of one setting; a focus on processes, interactions and relationships; holism; a concern for the particular; multiple methods of data collection; and focus on natural settings (pp. 54–7). Hamilton and Corbett-Whittier (2013, p. 11) add to this that case study: has its own approach to research (its own genre); has many contextual levels, from local to national; catches the complexity of a situation or context; may collect data on a single occasion or over time; often requires the researcher to spend time 'within the world of those being researched' (p. 11); and involves more than one perspective.

Case studies are set in temporal, geographical, organizational, institutional and other contexts that enable boundaries to be drawn around the case. They can be defined with reference to characteristics defined

by individuals and groups involved, and can be defined by participants' roles and functions in the case. Hitchcock and Hughes (1995) note that case studies:

- have temporal characteristics which help to define their nature;
- have geographical parameters allowing for their definition;
- have boundaries which allow for definition;
- can be defined by an individual in a particular context, at a point in time;
- can be defined by the characteristics of the group;
- can be defined by role or function;
- can be shaped by organizational or institutional arrangements.

Bassey (1999) comments that case studies in education can be conducted in order to inform decision making by policy makers, practitioners and theorists. They investigate 'interesting aspects of an educational activity, programme, or institution, or system … mainly in its natural context and within an ethic of respect for persons' such that plausible, trustworthy explanations and interpretations can be offered after collecting sufficient data in exploring the 'significant features of the case' (p. 58).

Case studies have the advantage over historical studies of including direct observation and interviews with participants (Yin, 2009, p. 11). They strive to portray 'what it is like' to be in a particular situation, to catch the close-up reality, rich detail and 'thick description' (Geertz, 1973) of participants' lived experiences of, thoughts about, and feelings for, a situation. They involve looking at a case or phenomenon in its real-life context, usually employing many types of data (Robson, 2002, p. 178). They are descriptive and detailed, with a narrow focus, and combine subjective and objective data (Dyer, 1995, pp. 48–9). It is important in case studies for events and situations to be allowed to speak for themselves, rather than to be heavily interpreted, evaluated or judged by the researcher.

This is not to say that case studies are unsystematic or merely illustrative; case study data are gathered systematically and rigorously. Indeed Nisbet and Watt (1984, p. 91) specifically counsel case study researchers to avoid:

- *journalism* (picking out more striking features of the case, thereby distorting the full account in order to emphasize these more sensational aspects);
- *selective reporting* (selecting only that evidence which will support a particular conclusion, thereby misrepresenting the whole case);
- *an anecdotal style* (degenerating into an endless series of low-level banal and tedious illustrations that take over from in-depth, rigorous analysis), i.e. the tendency of some case studies to overemphasize detail to the detriment of seeing the whole picture;
- *pomposity* (striving to derive or generate profound theories from low-level data, or by wrapping up accounts in high-sounding verbiage);
- *blandness* (unquestioningly accepting only the respondents' views, or only including those aspects of the case study on which people agree rather than areas on which they might disagree).

A key feature of case study is its rejection of a single reality; rather, there are multiple, multivalent realities operating in a situation, and the researcher's view and interpretation is only one of many. Indeed the researcher has a duty to address reflexivity and to address or report others', for example, participants' views on the case in question.

19.2 Types of case study

There are several types of case study. These can be determined by their *purposes*, for example, Denscombe (2014, p. 57): 'discovery-led' purposes which utilize description, exploration, comparison and explanation, and 'theory-led' purposes which utilize illustration and experiment. Yin (2009) identifies three types in terms of *outcomes*:

i *exploratory* (as a pilot to other studies or research questions). Exploratory case studies can be used to generate hypotheses that are tested in larger-scale surveys, experiments or other forms of research, for example, observational. However, Adelman *et al*. (1980) caution against using case studies solely as preliminaries to other studies, for example, as pre-experimental or pre-survey; rather, they argue, case studies exist in their own right as a significant and legitimate research method;
ii *descriptive* (providing narrative accounts);
iii *explanatory* (testing theories).

Yin's classification accords with Merriam (1998), who identifies three types:

i *descriptive* (e.g. narrative accounts);
ii *interpretative* (developing conceptual categories inductively in order to examine initial assumptions);
iii *evaluative* (explaining and judging).

Merriam also categorizes four common domains or kinds of case study: ethnographic, historical, psychological

and sociological. Sturman (1999, p. 107), echoing Stenhouse (1985), identifies four kinds of case study: an ethnographic case study (single in-depth study); action research case study; evaluative case study; and educational case study. Stake (1994, 1995, 2005) identifies three main types of case study:

i *intrinsic* case studies (studies that are undertaken in order to understand the particular case in question);
ii *instrumental* case studies (examining a particular case in order to gain insight into an issue or a theory);
iii *multiple/collective* case studies (groups of individual studies that are undertaken to gain a fuller or more general picture).

Hamilton and Corbett-Whittier (2013, pp. 15–19) deliberately move beyond Stake's 'intrinsic' and 'instrumental' types to suggest:

- *reflexive case study*: which includes the personal reflections of the researcher as the case/practitioner in question (raising concerns about personal bias, the need for outside perspectives and different data streams, and ethical issues with regard to colleagues);
- *longitudinal case study*: to catch changes over time, the dynamics of evolving situations and a sense of the history of an event or events, and to work with the same or different cohorts of participants (requiring sustained commitment and dedication to hard work, flexibility in design and data collection, and acceptance of changes over time);
- *cumulative case study*: case study or studies which provide a cumulative body of data about a topic, phenomenon or situation;
- *collective case study*: working separately and sometimes asynchronously to gather data about a particular phenomenon, situation or topic (e.g. a curriculum innovation);
- *collaborative case study*: working with others within and across institutions, to gather multiple perspectives and contexts.

Because case studies provide fine-grain detail, they can also be used to complement other, more coarsely grained – often large-scale – kinds of research. Case study materials in this sense can provide powerful human-scale data on macro-political decision making, fusing theory and practice.

Thomas (2011) and Thomas and Myers (2015) set out a clear and useful elements of case studies, which feature:

i the *subject*: whom and what to focus on, derived from local knowledge, a key case or an outlier case, for example, a deviant case; and the *object*: 'what is this a case of?' (Thomas, 2011, p. 515), what it is that has to be explained and in which the researcher is interested, the analytical issue that the researcher is exploring, i.e. the *explanandum*;
ii the *purpose* of the research: (the type of case study, e.g. intrinsic, instrumental, evaluative, exploratory);
iii the *approach* to be used: the kind of study, for example, theory-testing, theory-building, illustrative, descriptive, the *explanans* (the explanation or type of explanation or study to be used);
iv the *process* to be adopted: (a) a single case study (which may be retrospective, a 'snapshot') (p. 517), a diachronic study (a longitudinal study of change over time); (b) multiple cases (which might focus on: 'nested' cases, e.g. classes within a single school in which the school is the main case; 'parallel' cases which use several cases running simultaneously and independently; and 'sequential' cases with cases running consecutively, with one case affecting the subsequent case).

19.3 Advantages and disadvantages of case study

Case studies have several claimed strengths and weaknesses which have been identified for many years. Some of these are summarized in Box 19.1 (Adelman *et al*., 1980) and Box 19.2 (Nisbet and Watt, 1984).

Wellington (2015) adds to their strengths that they are illustrative and illuminating, accessible and easily disseminated, holding the reader's attention and being vivid accounts which are 'strong on reality' (p. 174). On the other hand, he notes that they are not replicable, may not be representative, typical or generalizable (p. 174). Denscombe (2014) notes the difficulties in choosing, knowing and setting boundaries to the case study, gaining access to case study settings and ensuring, where relevant, that case studies move beyond description to analysis and evaluation (p. 64).

Shaughnessy *et al*. (2003, pp. 290–9) suggest that case studies often lack a high degree of control, and treatments are rarely controlled systematically and have little control over extraneous variables. This, they argue, renders it difficult to make inferences and to draw cause and effect conclusions from case studies, and there is potential for bias in some case studies as the researcher might be both participant and observer and may overstate or understate the case (verification bias). Case studies, they argue, may be impressionistic, and self-reporting may be biased (by the participant or

BOX 19.1 POSSIBLE ADVANTAGES OF CASE STUDY

Case studies have a number of advantages that make them attractive to educational evaluators or researchers. Thus:

1. Case study data, paradoxically, are 'strong in reality' but difficult to organize. In contrast, other research data are often 'weak in reality' but susceptible to ready organization. This strength in reality is because case studies are down-to-earth and attention-holding, in harmony with the reader's own experience, and thus provide a 'natural' basis for generalization.
2. Case studies allow generalizations either about an instance or from an instance to a class. Their peculiar strength lies in their attention to the subtlety and complexity of the case in its own right.
3. Case studies recognize the complexity and 'embeddedness' of social truths. By carefully attending to social situations, case studies can represent something of the discrepancies or conflicts between the viewpoints held by participants. The best case studies are capable of offering support to alternative interpretations.
4. Case studies, considered as products, may form an archive of descriptive material sufficiently rich, varied and complex to admit subsequent reinterpretation.
5. Case studies are 'a step to action'. They begin in a world of action and contribute to it. Their insights may be directly interpreted and put to use: for staff or individual self-development; for within-institutional feedback; for formative evaluation; and in educational policy making.
6. Case studies present research or evaluation data in a more publicly accessible form than other kinds of research report, although this virtue is to some extent bought at the expense of their length. The language and the form of the presentation is hopefully less esoteric and less dependent on specialized interpretation than conventional research reports. The case study is capable of serving multiple audiences. It reduces the dependence of the reader upon unstated implicit assumptions and makes the research process itself accessible. Case studies, therefore, may contribute towards the 'democratization' of decision making (and knowledge itself). At their best, they allow readers to judge the implications of a study for themselves.

BOX 19.2 NISBET AND WATT'S (1984) STRENGTHS AND WEAKNESSES OF CASE STUDY

Strengths

1. The results are more easily understood by a wide audience (including non-academics) as they are frequently written in everyday, non-professional language.
2. They are immediately intelligible; they speak for themselves.
3. They catch unique features that may otherwise be lost in larger-scale data (e.g. surveys); these unique features might hold the key to understanding the situation.
4. They are strong on reality.
5. They provide insights into other, similar situations and cases, thereby assisting interpretation of other similar cases.
6. They can be undertaken by a single researcher without needing a full research team.
7. They can embrace and build in unanticipated events and uncontrolled variables.

Weaknesses

1. The results may not be generalizable except where other readers/researchers see their application.
2. They are not easily open to cross-checking, hence they may be selective, biased, personal and subjective.
3. They are prone to problems of observer bias, despite attempts made to address reflexivity.

Source: Adapted from Nisbet and Watt (1984)

the observer). Further, they argue that bias may be a problem if the case study relies on an individual's (selective) memory.

Dyer (1995, pp. 50–2) remarks that, reading a case study, one has to be aware that a process of selection has already taken place, and only the author knows what has been selected in or out, and on what criteria, and indeed the participants themselves may not know what selection has taken place. Indeed he observes (pp. 48–9) that case studies combine knowledge and inference, and it is often difficult to separate these; the researcher has to be clear about which of these feature in the case study data.

Case studies frequently follow the interpretive tradition of research – seeing the situation through the eyes of participants – rather than the quantitative paradigm, though this need not always be the case. Its sympathy to the interpretive paradigm has rendered case study an object of criticism. For example, Smith (1991, p. 375) argues that not only is the case study method the logically weakest method of knowing, but that studying individual cases, careers and communities is passé, and that attention should be focused on patterns and laws in historical research.

This is prejudice and ideology, perhaps, but it signifies the problem of respectability and legitimacy that case study had to conquer. Like other research methods, case study has to demonstrate reliability and validity. This can be difficult, for given the uniqueness of situations and multiple realities and perspectives, case studies may be, by definition, inconsistent with other case studies or unable to demonstrate this positivist view of reliability. Even though case studies are not obliged to demonstrate this form of reliability, nevertheless there are important questions to be faced in undertaking them, for example (Adelman *et al*., 1980; Nisbet and Watt, 1984; Hitchcock and Hughes, 1995):

- What exactly is a case?
- How are cases identified and selected?
- What kind of case study is this (what is its purpose)?
- What is reliable evidence?
- What is objective evidence?
- What is an appropriate selection to include from the wealth of generated data?
- What is a fair and accurate account?
- Under what circumstances is it fair to take an exceptional case (or a critical event – see the discussion of observation in Chapter 26)?
- What kind of sampling is most appropriate?
- To what extent is triangulation required and how will this be addressed?
- Triangulation seeks to determine a single, fixed point; what if the case study is characterized by many changing points, perspective and interpretations?
- What is the nature of the validation process in case studies?
- How will the balance be struck between uniqueness and generalization?
- What is the most appropriate form of writing up and reporting the case study?
- What ethical issues are exposed in undertaking a case study?

19.4 Generalization in case study

It is often heard that case studies, being idiographic, have limited generalizability (e.g. Yin, 2009, p. 15). Of course, the same could be said of single experiments (p. 15) and other kinds of research. Ruddin (2006) questions whether generalizability is an appropriate requirement of case study at all (p. 798), as it connotes positivism in what is not a positivistic type of research.

However, just as the generalizability of single experiments can be extended by replication and multiple experiments, so, too, case studies can be part of a growing pool of data, with multiple case studies contributing to greater generalizability. However, more pertinent is the claim by Robson (2002, p. 183) and Yin (2009, p. 15) that case studies opt for 'analytic' rather than 'statistical' generalization.

In statistical generalization the researcher seeks to move from a sample to a population, based on sampling strategies, frequencies, statistical significance and effect size. However, in analytic generalization, the concern is not so much for a representative sample (indeed the strength of the case study approach is that the case only represents itself) so much as its ability to contribute to the expansion and generalization of theory (Yin, 2009, p. 15) which can help researchers to understand other similar cases, phenomena or situations, i.e. there is a *logical* rather than *statistical* connection between the case and the wider theory. Yin (p. 43) makes the point that to assume that generalization is only from sample to population/universe is simply irrelevant, inappropriate and inapplicable to case studies. Rather, he argues (pp. 38–9) that case studies can help to generalize to a broader *theory* which can be tested in one or more empirical cases (akin, in this respect, to a single experiment or quasi-experiment) and can be shown *not* to support rival, even if plausible, theories.

Generalization requires extrapolation, and the case study researcher, whilst not necessarily being able to extrapolate on the basis of typicality or representativeness, nevertheless can extrapolate to relevant theory

(Macpherson *et al*., 2000, p. 52) and to the 'broader class' (Ruddin, 2006, p. 799) and to the testing or falsification of theory (it only takes one counter-example to disprove a theory: sighting one black swan negates the theory that all swans are white).

Case studies can make theoretical statements, but, like other forms of research and human sciences, these must be supported by the evidence presented. This requires the nature of generalization in case study to be clarified. Generalization can take various forms, for example:

- from the single instance to the class of instances that it represents (e.g. a single-sex selective school might act as a case study to catch significant features of other single-sex selective schools);
- from features of the single case to a multiplicity of classes with the same features;
- from the single features of part of the case to the whole of that case;
- from a single case to a theoretical extension or theoretical generalization.

A robust defence of generalization from case studies is made by Verschuren (2003, p. 136). First, he argues that statistical generalization is made on the basis of the homogeneity (or variability) of the population and the sample, together with the level of certainty required in the sample (see Chapter 12). So, for example, if the population is highly standardized and invariant (he uses the example of a factory that makes the same, uniform, standardized machines) the sample used for quality control could well be small, whereas in a very variable population (with many variables with a range of values in each) the sample size would have to be large. He then turns to the number of case studies which might be required for generalizability to be secure, and he argues that, in fact, a very small number of case studies could be used, each of which embraces the range of variables in question, thereby reducing the number of overall cases required; this is because 'complex issues in general have a much lower variability than separate variables' (p. 137), i.e. the researcher can generalize from a small number of case studies that represent the complex issues in general (cf. Pring, 2015, p. 57). The argument is clear: case studies include many variables; multivariable phenomena are often characterized by homogeneity rather than high variability; therefore if the researcher can identify case studies that catch the range of variability then external validity – generalizability – can be demonstrated.

A further case for generalizability from case studies (Watts, 2007; Thomas, 2010; Simons, 2015) argues that, in fact, there are universals present in each case (the case study carries 'exemplary knowledge' of a wider phenomenon) (Thomas, 2010, p. 576), even though case study is the study of the singular and the unique (Simons, 2015, p. 175). Here the narrative style which often characterizes case studies enables the reader to connect their own experiences to those reported in the case study. Simons writes that we can learn from a specific, single and singular case where it promotes 'generalized understanding' (p. 174) and offers something of 'universal significance' (p. 181). Despite our manifest differences, we gain universal understanding vicariously from single case studies, just as with poems, novels and short stories (p. 175), and apply them to our own situation (p. 177). She notes that this is nothing new; humans have been 'generalizing from the particular' (p. 184) from time immemorial. Similarly, Thomas (2010) and Thomas and Myers (2015) note that case study does not need to conform to the scientific notion of generalizability but, rather, to the contribution that it makes to the understanding and practical wisdom (phronesis) of the researcher and reader. This is echoed by Pring (2015), who notes that, rather than there being generalizability in the scientific sense, case studies can 'alert one to similar possibilities in other situations. They, as it were, "ring bells" ' (p. 56).

19.5 Reliability and validity in case studies

Whilst case studies may not have the external checks and balances found in other forms of research, nevertheless they still abide by canons of validity and reliability, for example:

- *construct validity* (through employing accepted definitions and constructions of concepts and terms; operationalizing the research and its measures/criteria acceptably);
- *internal validity* (through ensuring agreements between different parts of the data, matching patterns of results, ensuring that findings and interpretations derive from the data transparently, that causal explanations are supported by the evidence (alone), and that rival explanations and inferences have been weighed and found to be less acceptable that the explanation or inference made, again based on evidence);
- *external validity* (clarifying the contexts, theory and domains to which generalization can be made);
- *concurrent validity* (using multiple sources and kinds of evidence to address research questions and to yield *convergent validity*, e.g. triangulation of

data, investigators, perspectives, methodologies, instruments, time, location, contexts);
- *ecological validity* (fidelity to the special features of the context in which the study is located);
- *reliability* (replicability and internal consistency);
- *avoidance of bias* (e.g. the case study simply being an embodiment or fulfilment of the researcher's initial prejudices or suspicions, with selective data being gathered or data being used selectively (Yin, 2009, p. 72), or with the researcher's bias being inevitable if the researcher is a participant observer whose personality may affect the research process (Verschuren, 2003, p. 122). This can be addressed by reflexivity, respondent checks or checks by external reviewers of the data, inferences and conclusions drawn).

Of note here is Yin's (2009, pp. 41, 122–4) call for a 'chain of evidence' to be provided, such that an external researcher can track through every step of the case study from its inception to its research questions, design, data sources, instrumentation, data (evidence and the circumstances in which they were collected, e.g. time, place and functional interconnections of people, places etc.) and conclusions. It is important to note the time and place in which case study data are collected, as many actions and events are context-specific and part of a 'thick description', as this enables replication research to be planned (Macpherson *et al*., 2000, p. 56).

19.6 Planning a case study

In planning a case study there are several issues that researchers can consider:

- The particular circumstances of the case, including: (a) the possible disruption to individual participants that participation might entail; (b) negotiating access to people; (c) negotiating ownership of the data; (d) negotiating release of the data.
- The conduct of the study including: (a) the use of primary and secondary sources; (b) the opportunities to check data; (c) triangulation (including peer examination of the findings, respondent validation and reflexivity); (d) data-collection methods (in the interpretive paradigm case studies tend to use certain data-collection methods, e.g. semi-structured and open interviews, observation, narrative accounts and documents, diaries, maybe also tests, rather than other methods, e.g. surveys, experiments. Nisbet and Watt (1984) suggest that, in conducting interviews, it may be wiser to interview senior people later rather than earlier to make maximum use of discussion time with them, the interviewer having been put into the picture fully before the interview); (e) data analysis and interpretation, and, where appropriate, theory generation; (f) the writing of the report, with conclusions separated from the evidence, with essential evidence included in the main text, and balancing illustration with analysis and generalization.
- The consequences of the research (for all parties). This might include the anonymizing of the research in order to protect participants, though such anonymization might suggest that a primary goal of case study is generalization rather than the portrayal of a unique case, i.e. it might go against a central feature of case study. Anonymizing reports might render them anodyne, and the distortion that may be involved in such anonymization to render cases unrecognizable might be too high a price to pay for going public. Is it realistic and/or desirable not to identify the case and participants? Researchers must ensure that due concern has been given to ethical matters; this continues right through the case study period, from planning to conducting to reporting (see Chapter 7).

Thomas and Myers (2015) suggest that, in planning a case study, researchers must consider whether the case study is singular or multiple. They need to focus on intuition, understanding, theorization and analysis and, using thick descriptions, connect analysis with explanations.

Nisbet and Watt (1984, p. 78) suggest three main stages in undertaking a case study. Because case studies catch the dynamics of unfolding situations it is advisable to commence with a very wide field of focus, an open phase, without selectivity or pre-judgement. Thereafter 'progressive focusing' enables a narrower field of focus to be established, identifying key foci for subsequent study and data collection. At the third stage a draft interpretation is prepared which needs to be checked with respondents before appearing in the final form. The authors (p. 79) advise against generating hypotheses too early in a case study; rather, they suggest, it is important to gather data openly.

Respondent validation can be particularly useful as respondents might suggest a better way of expressing the issue or may wish to add or qualify points. There is a risk in respondent validation, however, that they may disagree with an interpretation. Nisbet and Watt (1984, p. 81) indicate the need to have negotiated rights to veto. They also recommend that researchers consider: (a) promises that respondents can see those sections of the report that refer to them (subject to controls for

confidentiality, e.g. of others in the case study); (b) take full account of suggestions and responses made by respondents and, where possible, to modify the account; (c) in the case of disagreement between researchers and respondents, promise to publish respondents' comments and criticisms alongside the researchers' report.

Sturman (1997) places on a set of continua the nature of data collection, data types and data-analysis techniques in case study research. These are presented in summary form in Table 19.1.

At one pole are unstructured, typically qualitative data, whilst at the other are structured, typically quantitative data. Researchers using case study approaches will need to decide which methods of data collection, which type of data and techniques of analysis to employ, all on the basis of fitness for purpose.

In planning a case study Thomas (2011) makes an important distinction between the *subject* and *object* of a case study. The subject is the example, the focus (e.g. an education system, a school, a group of students), whereas the object is that which has to be explained – the *explanandum* – for instance, the structures, management effectiveness and levels of achievement respectively. Selecting the subject – the focus – of the case is a matter of sampling, and we discuss sampling below (e.g. critical cases, extreme cases, typical cases). Taking into account Thomas's distinction of *subject* and *object*, in planning the study the researcher will need to consider:

- the most appropriate *subject* (focus) of the study in order to address the purpose, for example, a group of students, a particular child, a group of teachers, a curriculum innovation etc. (e.g. derived from local knowledge, key cases or outlier cases);
- the *object* of the study: what it is that has to be explained in which the researcher is interested, the analytical issue that the researcher is exploring, the *explanandum*;
- the *purpose* of the study (e.g. intrinsic, instrumental, evaluative, exploratory), addressing fitness for purpose;
- the *approach* to be used, for example, theory-testing, theory-building, illustrative/descriptive;
- the *process* to be used, for example, single (retrospective, snapshot, diachronic) or multiple (nested, parallel, sequential);
- the *sample* (e.g. a critical case, an extreme case, a typical case, a representative case).

For example, the researcher might be interested in why upper secondary school male students outperform female students in science subjects. This is the *explanandum*, that which is to be explained, i.e. the *object* of the researcher: 'what is this a case of' (Thomas, 2011, p. 515). The researcher decides that the most suitable focus here is Form 5 and Form 6 male and female students' results; this is the *subject* of the research. The researcher decides the most effective kind of case study (e.g. an exploratory case study) and approach to be used (e.g. theory-building). Then the researcher decides on the sampling strategy, and she adopts a 'typical case' sampling, involving those males and females who do and do not decide to follow sciences in post-school study or employment, those who are following discipline-specific science (physics, chemistry, biology) and General Science in Forms 5 and 6, the careers guidance teachers and science teachers in the school, and the parents of the students in question.

TABLE 19.1 CONTINUA OF DATA COLLECTION, TYPES AND ANALYSIS IN CASE STUDY RESEARCH

	Data Collection	
Unstructured (field notes)	⟷ (interviews – open to closed)	Structured (survey, census data)
	Data Types	
Narrative (field notes)	⟷ (coded qualitative data and non-parametric statistics)	Numeric (ratio scale data)
	Data Analysis	
Journalistic (impressionistic)	⟷ (content analysis)	Statistical (inferential statistics)

Source: Adapted from Sturman (1997)

Hamilton and Corbett-Whittier (2013, pp. 51–62) identify six 'key decisions' in approaching the planning of a case study:

i 'self-reflection' (where you actually are) (p. 53);
ii 'research questions' (where you wish to go) (p. 55);
iii 'defending your methodological approach' (p. 57);
iv 'strategic approaches' ('who will do what, when and with whom') (p. 59);
v 'getting organized' ('what will go where, when') (p. 60);
vi 'presenting the findings' (p. 61).

Stake (2005) argues that the qualitative case study should include (pp. 459–60):

- setting the boundaries of the case and conceptualizing the object of study;
- selecting appropriate phenomena, issues or themes for study, which might be framed in the research questions;
- seeking patterns in the data in order to develop the issues of focus;
- triangulation of key observations in order to support interpretations;
- identifying alternative interpretations for further study;
- developing generalizations or assertions from the case.

19.7 Case study design and methodology

Yin (2009, pp. 46ff.) identifies four main case study designs:

i The *single-case design* can focus on a critical case, an extreme case, a unique case, a representative or typical case, a revelatory case (an opportunity to research a case heretofore unresearched, e.g. Whyte's *Street Corner Society*, see Chapter 15), a longitudinal case.
ii The *embedded single-case design*, in which more than one 'unit of analysis' is incorporated into the design, for example, a case study of a whole school might also use sub-units of classes, teachers, students, parents, and each of these might require different data-collection instruments, for example, a survey questionnaire, interviews, observations etc.
iii The *multiple-case design*, for example, comparative case studies within an overall piece of research, or replication case studies. Campbell (1975, p. 180) suggests that having two case studies, for comparative purposes, is more than worth having double the amount of data on a single case study! For example, educationists may want to see the effects of a new innovation, let us say in mathematics teaching, in three circumstances (conditions): one where teachers are given in-house staff development for the new mathematics, one where they attend externally provided courses on the new mathematics, and another where the teachers receive both kinds of staff development; here the case studies might compare the effects in the schools concerned (cf. Yin, 2009, pp. 54–5).
iv The *embedded multiple-case design*, in which different sub-units may be involved in each of the different cases and a range of instruments (e.g. a survey questionnaire, interviews, observations, archival records etc.) might be used for each sub-unit, and each is kept separate to each case.

A single case may be part of a multiple case-study design, and, by contrast, a particular data-collection instrument (e.g. a survey) may be part of a cross-site case study. In considering multiple case studies, it is important to decide how many are required; typically, the more subtle is the issue under investigation, the more cases are required (Yin, 2009, p. 58) in order to be able to rule out rival explanations. Yin also notes that a single-case design can overlook the possible benefits of multiples cases, for example, replication, thereby avoiding the criticism of being a unique, single case in which the researcher is 'putting all the eggs in one basket', which may be risky: an 'all-or-nothing' risk.

A key issue in case study research is the selection of information. Though it is frequently useful to record typical, representative occurrences, the researcher need not always adhere to criteria of representativeness. For example, it may be that infrequent, unrepresentative but critical incidents or events occur that are crucial to the understanding of the case. A subject might only demonstrate a particular behaviour once, but it is so important as not to be ruled out simply because it occurred once; sometimes a single event might occur which sheds a hugely important insight into a person or situation (see the discussion of critical incidents in Chapter 33); it can be a key to understanding a situation (Flanagan, 1949; Tripp, 1993).

For example, it may be that a psychological case study might happen upon a single instance of child abuse earlier in a person's life, but the effects of this are so profound as to constitute a turning point in understanding that adult. A child might suddenly pass a single comment that indicates complete frustration with

or complete fear of a teacher, yet it is too important to overlook. Case studies, in not having to seek frequencies of occurrences, can replace quantity with quality and intensity, separating the significant few from the insignificant many instances of behaviour. Significance rather than frequency is a hallmark of case studies, offering the researcher an insight into the real dynamics of situations and people.

In designing a case study, Yin (2009, p. 27) indicates five components to address:

- the case study's questions (it was suggested earlier that case study is particularly powerful in answering the 'how' and 'why' type of questions, and Yin (p. 29) argues that the more specific are the questions that the case study should answer, the stronger is the likelihood of the case study staying on track and within limits);
- the case study's propositions (if there are any) (e.g. a hypothesis to be tested);
- the case study's 'unit(s) of analysis' (this relates to the key issue in case study, which is defining what constitutes the case, e.g. an individual, a group, a community, an organization, a programme, a piece of innovation, a decision and its ramifications, an industry, an economy etc.). What constitutes the case should be clear from the research questions being asked (p. 30), as these should specify the unit of analysis. Yin (p. 32) suggests that the unit of analysis should be concrete (a real-life phenomenon) rather than abstract (e.g. an argument or topic). Identifying the unit of analysis can be used to identify the tricky question of what constitutes a case;
- the logic that links the data gathered to the propositions set out in the case study (i.e. how the data will be analysed, e.g. by looking for patterns, explanations, analysis of events as they unravel over time, cross-site and cross-case analysis) (p. 34);
- the 'criteria for interpreting the findings' from the case study (which includes a clear indication of how the interpretation given is better than rival explanations of the data).

Yin (p. 35) also adds that theory generation should be included in the research design phase of the case study, as this assists in focusing the case study; such theories might be of the behaviour of individuals, groups, organizations, communities, societies, i.e. there are several levels of theory.

Unlike the experimenter who manipulates variables to determine their causal significance or the survey researchers who ask standardized questions of large, representative samples of individuals, the case study researcher typically observes the characteristics of an individual unit – a child, a clique, a class, a group, a school or a community. The purpose of such observation is to probe deeply and to analyse intensively the multi-stranded phenomena that constitute the life of the unit, possibly with a view to generalizing to the wider population to which that unit belongs.

Observation in case study

Case studies are methodologically eclectic (i.e. embedded within them may be more than one kind of research such as ethnography, experiment, action research, survey, illuminative research, observational research, documentary research); they can use a range of methods of data collection, data types (quantitative and qualitative) and ways of analysing data (statistically and through qualitative tools), and they can be short term or long term. In short, case study is a hybrid (cf. Verschuren, 2003, p. 125). That said, at the heart of many case studies lies observation.

Case studies vary in their degree of structure, for example, 'natural' (e.g. ethnographies) to artificial (e.g. a counselling situation, the Stanford Prison Experiment and the Milgram studies of obedience (see Chapter 30)); structured (e.g. structured non-participant observations) to unstructured (e.g. ethnographic observation); interventionist (e.g. a case study of an individual undergoing therapy) to non-interventionist (e.g. a child study).

There are two principal types of observation: participant observation and non-participant observation. In the former, observers engage in the very activities they set out to observe. Often their 'cover' is so complete that as far as the other participants are concerned, they are simply one of the group. In the case of Patrick, for example, born and bred in Glasgow, his researcher role remained hidden from the members of the Glasgow gang in whose activities he participated for four months (Patrick, 1973). Such complete anonymity is not always possible, however. Thus in Parker's study of downtown Liverpool adolescents, it was generally known that the researcher was waiting to take up a post at the university. In the meantime, 'knocking around' during the day with the lads and frequenting their pub at night rapidly established that he was 'OK'. The researcher was, in his own terms, 'a drinker, a hanger-arounder' who could be relied on to keep quiet on illegal matters (Parker, 1974).

Cover is not necessarily a prerequisite of participant observation. In a study of a small group of working-class boys during their last two years at school and their first months in employment, Willis (1977) attended all the different subject classes at school – 'not as a

teacher, but as a member of the class' – and worked alongside each boy in industry for a short period.

Non-participant observers, on the other hand, stand aloof from the group activities they are investigating and eschew group membership. For example, the non-participant observer role is where the researcher sits at the back of a classroom writing notes or coding up the verbal exchanges between teacher and students onto structured observational categories.

Bailey (1994, p. 247) explains that it is hard for a researcher who wishes to undertake covert research not to act as a participant in a natural setting, as, if the researcher does not appear to be participating, then why is he/she there? Hence, in many natural settings the researchers are participants. This is in contrast to laboratory or artificial settings, in which non-participant observation (e.g. through video recording) may take place.

The unstructured, ethnographic account of teachers' work is a typical method of observation in the natural surroundings of a setting, for example, a school in which the study is conducted. Similarly, structured observations may be a common approach in a more artificial setting, for example, a counsellor's office.

The natural scientist, Schutz (1962) points out, explores a field that means nothing to the molecules, atoms and electrons therein. By contrast, the subject matter of the world in which the educational researcher is interested is composed of people and is essentially meaningful to them. That world is subjectively structured, possessing particular meanings for its inhabitants. The task of the educational investigator is often to explain the means by which an orderly social world is established and maintained in terms of its shared meanings. How do participant observation techniques assist the researcher in this task? Bailey (1994, pp. 243–4) identifies some inherent advantages in the participant observation approach:

1. Observation studies are superior to experiments and surveys when data are being collected on non-verbal behaviour.
2. In observation studies, investigators are able to discern ongoing behaviour as it occurs and are able to make appropriate notes about its salient features.
3. Because case study observations take place over an extended period of time, researchers can develop more intimate and informal relationships with those they are observing, generally in more natural environments than those in which experiments and surveys are conducted.
4. Case study observations in natural settings are less reactive than other types of data-gathering methods. For example, in laboratory-based experiments and surveys that depend upon verbal responses to structured questions, bias can be introduced in the very data that researchers are attempting to study.

Further, direct observation is faithful to the real-life, *in situ* and holistic nature of a case study (Verschuren, 2003, p. 131).

19.8 Sampling in case studies

Sampling has a dual meaning here: the participants in the case study, or the kind of case study to be adopted. With regard to the latter is the decision about purposive sampling: whether to choose a typical case, a representative case, a critical case, an extreme case, a deviant case, an outlier, intensity sampling, maximum variation sampling (e.g. for multiple case studies), homogeneous sampling, reputational case sampling, revelatory case sampling, theoretical sampling, opportunistic sampling etc. We review these in Chapter 12, and we advise readers to go to this chapter. At issue here is the need for the selection of the case to be fit for purpose, relevant to the topic or issue in hand, to include the significant features of the subject and object of the research, to be a suitable instance of the phenomenon under investigation, to be suitably bounded and to be capable of maintaining a holistic view of the case as well as its particular contributing elements.

Having decided the most suitable *kind* of case, the researcher then turns to the most appropriate sampling of *people* or *issues*. Here, again, the researcher can utilize typical case sampling, and case studies often use non-probability, purposive samples (see Chapter 12). Again, the researcher must select the sample for the case study in terms of fitness for purpose.

Often the case study and its participants are chosen as being 'typical cases', critical cases or extreme cases. Robson (2002, pp. 181–2) notes the distinction between a critical case study and an extreme or unique case. In a critical case study, the case in question might possess all, or most, of the characteristics or features that one is investigating, more fully or distinctly than under 'normal' circumstances, for example, a case study of student disruptive behaviour might go to a *very* disruptive class, with students who are very seriously disturbed or challenging, rather than going into a class where the level of disruption is not so marked.

By contrast, Robson argues (2002, p. 182) that the extreme and the unique case can provide a valuable 'test bed'. Extremes include, he argues, the situation in which 'if it can work here it will work anywhere', or choosing an ideal set of circumstances in which to try

out a new approach or project, maybe to gain a fuller insight into how it operates before taking it to a wider audience (e.g. the research and development model).

19.9 Data in case studies

We mentioned earlier that case studies are eclectic in the types of data that are used. Indeed many case studies will rely on mixed methods and a variety of data. Whilst observation and participant observation are often pre-eminent in case studies, they are by no means the only sources of data. For example, Yin (2009, p. 101) identifies:

- *documents* (p. 103), for example, letters, emails, memoranda, agendas, minutes, reports, records, diaries, notes, other studies, newspaper articles, website uploads, etc.;
- *archival records* (p. 105), for example, public records, organizational records and reports, personal (maybe medical or behavioural) and personnel data stored in an organization (with due care to privacy legislation), charts and maps;
- *interviews* (p. 106): in-depth, focused, and formal survey interviews (see Chapter 25);
- *direct observation* (p. 109), i.e. non-participant observation of the natural setting and the target individual(s), groups *in situ*, artefacts, rooms, decor, layout;
- *participant observation* (p. 111), in which the researcher takes on a role in the situation or context featured in the case study;
- *physical artefacts* (p. 113), for example, pictures, furniture, decorations, photographs, ornaments.

Here the multiple sources of evidence can provide convergent and concurrent validity on a case, and they demand of the researcher an ability to handle and synthesize many kinds of data simultaneously. This, in turn, advocates the compilation of a case study database of evidence (Yin, 2009, p. 118) that comprises two main kinds of collection: the actual data gathered, recorded and organized by entry, and the researcher's ongoing analysis, report, comments and narrative on the data.

The diverse data provide the evidence needed for the researcher to draw conclusions, the evidential 'chain of evidence' that gives credibility, reliability and validity to the case study (Yin, 2009, p. 122). When writing the report, the researcher must make direct reference to the actual evidence that supports the point being made, and we turn to the writing of the case study report below.

The researcher can use several computer-assisted software tools (e.g. NVivo) to process the data ready for analysis (see Chapter 32). These can group, retrieve, organize and search single and multiple data sets, and return these ready for analysis and presentation in such forms as (Miles and Huberman, 1984):

- matrices and arrays of data;
- patterns, themes and configurations;
- narratives;
- data displays;
- flowcharts;
- within-site and cross-site analyses;
- cause and effect diagrams and chains (e.g. where an effect becomes a subsequent cause);
- networks of relationships and causes or linked events (i.e. rather than linear models of cause and effect);
- chronologies and causal sequences;
- time series and critical events;
- key issues and subordinate issues;
- explanations;
- tabulations;
- grounded theory.

Yin (2009, p. 143) makes the point that, in analysing data, the researcher has to go back through the data several times to ensure that all the data fit the interpretations given or conclusions drawn, i.e. without unexplained anomalies or contradictions (the constant comparison method), that all the data are accounted for (p. 160), that rival interpretations are considered (p. 160) and that the significant features of the case are highlighted (p. 161). It may be that there are several perspectives and interpretations of the data, as case studies deal in multiple realities rather than a single right answer.

The recording of observations is a frequent source of concern to inexperienced case study researchers. Whilst field notes in ethnographic research are typically copious, how much should be recorded, and in what form? What does one do with the mass of recorded data? We offer several suggestions here with regard to field notes:

- record the notes as quickly as possible during or after observation, since the quantity of information forgotten is very slight over a short period of time but accelerates quickly over time;
- discipline yourself to write notes quickly and reconcile yourself to the fact that recording field notes can take as long as time spent in actual observation, and transcribing interviews can take four or five times

longer than the actual interview, so use transcription sparingly;
- recording and dictating rather than writing may be possible but writing has the advantage of stimulating thought;
- entering field notes onto a secure computer file is preferable to handwriting, as it is easy to store, recover, read, process and manipulate data;
- field notes should be sufficiently full and vivid to make sense after time has passed (e.g. after a month or months).

Field notes are often part of unstructured observation studies. Such notes, confessed Wolcott (1973), helped him fight the acute boredom that he sometimes felt when observing the interminable meetings that were the daily lot of the school principal. Occasionally, however, a series of events would occur so quickly that Wolcott had time only to make cursory notes which he supplemented later with fuller accounts. One useful tip from this experienced ethnographer is worth noting: never resume your observations until the notes from the preceding observation are complete. There is nothing to be gained merely by your presence as an observer. Until your observations and impressions from one visit are a matter of record, there is little point in returning to the classroom or school and reducing the impact of one set of events by superimposing another and more recent set. Indeed, when to record one's data is but one of a number of practical challenges identified by Walker (1980), which are listed in Box 19.3.

19.10 Writing up a case study

Writing up a case study abides by the twin criteria of 'fitness for purpose' and 'fitness for audience'. Robson (2002, pp. 512–13) and Yin (2009, pp. 176–9) suggests six forms of organizing the writing-up of a case study:

1. In the *suspense structure* the author presents the main findings (e.g. an executive summary) in the opening part of the report and then devotes the remainder of the report to providing the evidence, analysis, explanations, justifications (e.g. for what is selected in or out, what conclusions are drawn, what alternative explanations are rejected) and argument that lead to the overall picture or conclusion.
2. In the *narrative report* a prose account is provided, interspersed with relevant figures, tables, emergent issues, analysis and conclusion.
3. In the *comparative structure* the same case is examined through two or more lenses (e.g. explanatory, descriptive, theoretical) in order either to provide a rich, all-round account of the case, or to enable the reader to have sufficient information from which to judge which of the explanations, descriptions or theories best fit(s) the data.
4. In the *chronological structure* a simple sequence or chronology is used as the organizational principle, enabling cause and effect to be addressed and possessing the strength of an ongoing story. The chronology can be sectionalized as appropriate (e.g. key events or key time frames), and can intersperse

BOX 19.3 THE CASE STUDY AND PROBLEMS OF SELECTION

Among the issues confronting the researcher at the outset of his case study are the problems of selection. The following questions indicate some of the obstacles in this respect:

1. How do you get from the initial idea to the working design (from the idea to a specification, to usable data)?
2. What do you lose in the process?
3. What unwanted concerns do you take on board as a result?
4. How do you find a site which provides the best location for the design?
5. How do you locate, identify and approach key informants?
6. How they see you creates a context within which you see them. How can you handle such social complexities?
7. How do you record evidence? When? How much?
8. How do you file and categorize it?
9. How much time do you give to thinking and reflecting about what you are doing?
10. At what points do you show your subject what you are doing?
11. At what points do you give them control over who sees what?
12. Who sees the reports first?

Source: Adapted from Walker (1980)

commentaries on, interpretations of, explanations for, and summaries of emerging issues as events unfold (e.g. akin to 'memoing' in ethnographic research). The chronology becomes an organizing principle, but different kinds of contents are included at each stage of the chronological sequence.

5 In the *theory-generating structure*, the structure follows a set of theoretical constructs or a case that is being made. Here, Robson suggests, each succeeding section of the case study contributes to, or constitutes, an element of a developing 'theoretical formulation', providing a link in the chain of argument, leading eventually to the overall theoretical formulation.

6 In the *unsequenced structures* the sequence, for example, chronological, issue-based, event-based, theory-based, is unimportant. Robson suggests that this approach renders it difficult for the reader to know which areas are important or unimportant, or whether there are any omissions. It risks the caprice of the writer.

Some case studies are of a single situation – a single child, a single social group, a single class, a single school. Here any of the above six approaches may be appropriate. Some case studies require an unfolding of events, others operate under a 'snapshot' approach (e.g. of several schools, or classes, or groups at a particular point in time). In the former it may be important to preserve the chronology, whereas in the latter such a chronology may be irrelevant. Some case studies are divided into two main parts (e.g. Willis, 1977): the data reporting and then the analysis/interpretation/explanation.

A case study report should consider rival explanations of the findings and indicate how the explanation adopted is better than its rivals. Such rival explanations might include, for example (Yin, 2009, pp. 133–5):

- the role of chance/coincidence;
- experimenter effects or situation effects (reactivity);
- researcher bias;
- other influences on the case;
- covariance or the influence of another variable, i.e. a cause other than the intervention or situation reported explains the effects;
- alternative explanations of what the data show;
- the *process* of the intervention, rather than its *contents*, explain the outcome;
- a different theory can explain the findings more fully and fittingly;
- the intervention was part of a much bigger intervention that was already taking place at the time of the case study, so is subsumed by that bigger intervention;
- observed changes might have happened anyway, without the intervention from the case study.

Yin (2009, pp. 185–9) suggests that an 'exemplary' case study must be 'significant', 'complete', take into consideration 'alternative perspectives', be careful to include 'sufficient evidence' and be 'engaging'. These precepts, surely, can provide a useful guide for researchers.

19.11 What makes a good case study researcher?

A case study requires in-depth data, a researcher's ability to gather data that address fitness for purpose, and skills in probing beneath the surface of phenomena. These requirements imply that the researcher must be an effective questioner, listener, prober, able to make informed inferences (to 'read between the lines'; Yin, 2009, p. 70) and adaptable to changing and emerging situations. Given that a case study uses a range of methods for data collection (e.g. observation (participant to non-participant), accounts, interviews, artefacts, documents, archival records, survey), and that it may use different methodologies within it (e.g. action research, experiment, ethnography), the effective case study researcher must be versed in each of these, know how to draw on them at the most appropriate moment, be able to keep a clear sense of direction in the data collection, so that the case study is kept on track and not side-tracked, and have a clear grasp of the issues for which the case study is being conducted (and keep to these). Clarity of focus, issues and direction are important here.

Further, the effective case study researcher will need to possess the ability to collate and synthesize data from different sources, to make inferences and interpretations based on evidence, to know how to test inferences and conclusions (and how to test them against rival explanations) and know how to report multiple perspectives.

The case study researcher is often privy to confidential or sensitive material. Hence he/she must be clear on: the ethics of the research; his/her own stance in respect of disclosing private or sensitive data; how to protect people at risk or vulnerable groups; how to address matters of justified covert research; whether to report people anonymously or to identify them; how to address non-traceability and non-identifiability of participants; non-attributability of particular comments to individuals; and how to incorporate specific, important features into a cross-site analysis.

It is important for the case study researcher to have the subject knowledge and research expertise required to conduct the case study, to be highly prepared, to have a sense of realism about the situation being researched (as case study is a 'real-life' exercise), to be an excellent communicator (which may require training) and to have the appropriate personality characteristics that will enable access, empathy, rapport and trust to be built up with a diversity of participants. Not every researcher has all of these, yet each is vitally important.

Finally, case study researchers, like other educational researchers, are concerned with providing factual information, explanations and theories rather than, for example, the promotion of their own value judgements (Foster *et al*., 2000). Their value judgements do not have any privileged position, taking into account, of course, that intellectual authority and expertise may be important. Of course, factual information may be value-relevant, but that is not the same as making value judgements (pp. 22–3).

19.12 Conclusion

Macpherson *et al*. (2000, pp. 57–8) set out several principles to guide the practice of case study research. With regard to *purpose*, they suggest a collaborative approach between participants and researcher in order to address *contextuality*. With regard to *place*, they suggest *sensitivity* to the place (akin to ecological validity). With regard to both *purpose* and *process*, they suggest *authenticity* (fitness for purpose), *applicability* (thinking large but starting small) and *growth* (ensuring development and social transformation). With regard to *product*, they suggest *communicability* of the findings through networking (which they also apply to *purpose* and *process*).

Case study has had a mixed press. Flyvberg (2006), Yin (2009) and Ulriksen and Dadalauri (2016), for example, note that it has been regarded as a weaker sibling to other methods because of its putative loose structure, limited generalizability, biased case selection which derives from knowledge of the dependent variable, informality and indiscipline, limited empirical legitimacy, subjectivity and subjective conclusions, but Pring (2015, p. 56) argues that this is to falsely assume that there exists a single reality rather than multiple realities.

Thomas (2010) notes that in case study, as in science more widely, which uses induction, rather than expecting permanent universality or generalizability (which is a misplaced hope), 'exemplary knowledge' is more suited to the phronesis of case study and to multiple interpretations and horizons of researchers and readers of case study. Further, Morrison (2009) and Ulriksen and Dadalauri (2016) note that case studies have considerable potential for providing causal explanations (Ulriksen and Dadalauri (2016) develop this in terms of 'process tracing').

The authors referenced in this chapter have powerfully and roundly refuted the putative weaknesses of case study and have accorded it a place alongside and equal to other kinds of research in social science and educational research. We hold to this latter position: case study has a unique and distinctive contribution to make to educational research. Whether to use case study is driven by fitness for purpose.

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Experiments

CHAPTER 20

This chapter discusses key issues in experiments in education, indicating how they might address causality as a main target of much educational research. The chapter includes:

- randomized controlled trials
- designs in educational experiments
- true experimental designs
- quasi-experimental designs
- single-case ABAB design
- procedures in conducting experimental research
- threats to internal and external validity in experiments
- the timing of the pre-test and the post-test
- the design experiment
- Internet-based experiments
- *ex post facto* research

The intention here is to introduce different forms of experiment, to ensure that researchers are aware of key issues to be addressed in their planning and conduct, and what might or might not legitimately be inferred from their results.

20.1 Introduction

Experiments, particularly – indeed sometimes exclusively – randomized controlled trials (RCTs), in educational research seem unstoppable, rapidly achieving hegemonic status (Pearce and Raman, 2014). From being a matter of under-representation in educational research in the early part of the century, their allure now seems irresistible to governments and researchers alike (cf. National Research Council, 2002), and the Campbell Collaboration (the social science equivalent of the Cochrane Collaboration in medicine) provides powerful evidence of this, including the provision of research syntheses and meta-analyses. The literature is replete with examples of experiments, and a cursory Internet search will return thousands of examples.[1]

Experiments make several claims (cf. Denscombe, 2014): scientific credibility, repeatability, precision and causality. The great claim of experimental methods, particularly RCTs, is that they demonstrate causality, i.e. that an outcome has been caused by a specific intervention. The issue of *causality* and, hence, predictability has exercised the minds of researchers (Morrison, 2009), and one response has been in the operation of *control* of variables and settings, and it finds its apotheosis in experimental design. If rival causes or explanations can be eliminated from a study then clear causality can be established; the model can *explain* outcomes causally. The National Research Council (2002), Torgerson and Torgerson (2008), Torgerson (2009) and Morrison (2009) note that the experimental approach concerns itself with causality; this is contestable, as we make clear in Chapter 6.

The essential feature of experimental research is that investigators deliberately control and manipulate the conditions which determine the events in which they are interested, introduce an intervention and measure the difference that it makes. An experiment involves making a change in the value of one variable – the independent variable – and observing the effect of that change on another variable – the dependent variable. Experimental research can be *confirmatory*, seeking to support or not to support a null hypothesis, or *exploratory*, discovering the effects of certain variables. In an experiment the post-test measures the dependent variable, and the independent variables are isolated and controlled carefully.

20.2 Randomized controlled trials

Randomized controlled trials (RCTs), a 'true' experiment (discussed below), have considerable prominence in education; hence we devote much discussion to them in this chapter. Experiments inform policy and practice in education, and, as Torgerson (2009) notes, if they are sufficiently large, can take account of different characteristics of students, the nature and implementation of an intervention, and differences in outcome (p. 314).

The US has the 'What Works Clearinghouse' and the Institute of Education Sciences (IES) which report RCTs. The What Works Clearinghouse enables educationists to interrogate the data of RCTs in education by topic, student characteristics and units of randomization

(individual and cluster). International organizations focus on RCTs (e.g. Bouguen and Gurgand (2012) report national RCTs in Europe), as do educational researchers in the evidence-based movement (e.g. Torgerson and Torgerson, 2001, 2003a, 2013; Moore *et al*., 2003; Gorard and Torgerson, 2006; Hutchison and Styles, 2010; Goldacre, 2013; Hassey, 2015).

In the UK, the Educational Endowment Foundation was established in 2011 (Torgerson and Torgerson, 2013), initiating fifty-nine RCTs involving 2,300 schools; the Behavioural Insights Team opened in 2012; and in 2013 the UK's Department for Education announced two major RCTs on (a) schools' attainment in mathematics and science and (b) child protection. Haynes *et al*. (2012), in a publication issuing from the Cabinet Office of the UK government, declared that '[r]andomised controlled trials (RCTs) are the best way of determining whether a policy is working' (p. 4). This echoes statements elsewhere that RCTs provide 'the best scientific evidence' on policies such as educational technology, class size and school vouchers (Angrist, 2003, p. 1).

In order to increase the explanatory power of RCTs in education – why certain effects are found – they are often accompanied by ethnographic data ('process evaluations').

Key elements of a randomized controlled trial

Imagine that we have been transported to a laboratory to investigate the properties of a new wonder-fertilizer that farmers could use on their cereal crops (and agriculture was an early user of RCTs), let us say wheat (Morrison, 1993, pp. 44–5, based on Fisher, 1966). The scientist would randomly take from a bag of wheat seed a number of seeds and then randomly split them into two equal parts. One part would be grown under normal existing conditions: controlled and measured amounts of soil, warmth, water and light, with other factors excluded. This would be called the control group. The other part would be grown under the same conditions: the same controlled and measured amounts of soil, warmth, water and light as the control group, *and*, additionally, the new wonder-fertilizer. Then, four months later, the two groups are examined and their growth measured. The control group has grown half a metre and each ear of wheat is in place but the seeds are small. The experimental group, by contrast, has grown half a metre as well but has significantly more seeds on each ear, and the seeds are larger, fuller and more robust.

The scientist concludes that, because both groups came into contact with nothing other than measured amounts of soil, warmth, water and light, then it could not have been anything else but the new wonder-fertilizer that caused the experimental group to flourish so well. The key factors in the experiment were:

- the random selection of the seeds from a population of seeds;
- the random allocation of the randomly selected sample of wheat into two matched groups (the control and the experimental group), involving the initial measurement of the size of the wheat to ensure that it was the same for both groups (i.e. the pre-test);
- the identification and isolation of key variables (soil, warmth, water and light);
- the control of the key variables (the same amounts to each group);
- the exclusion of any other variables;
- the giving of the special treatment (the intervention) to the experimental group (i.e. manipulating the independent variable) whilst holding every other variable constant for the two groups;
- ensuring that the two groups are entirely separate throughout the experiment (non-contamination);
- the final measurement of yield and growth to compare the control and experimental groups and to look at differences from the pre-test results (the post-test);
- the comparison of one group with another;
- the stage of generalization – that this new wonder-fertilizer improves yield and growth under a given set of conditions.

In educational research this translates into:

- random sampling of participants from a population;
- random allocation of the sample to control or experimental groups;
- pre-testing the control and experimental groups to ensure parity, i.e. that there are no statistically significant differences or large effect sizes between them;
- identification and isolation of key variables;
- control of the key variables;
- exclusion of any other variables;
- special treatment (the intervention) given to the experimental group (i.e. manipulating the independent variable) whilst holding every other variable constant for the two groups;
- ensuring that the two groups are entirely separate throughout the experiment (non-contamination);
- final measurement of outcomes to compare the control and experimental groups and to look at differences from the pre-test results (the post-test);

- comparison of one group with another, to see the effects of the intervention on the experimental groups and the dependent variable.

The RCT – the 'true' experiment – is represented diagrammatically in Figure 20.1.

So strong is this simple and elegant 'true' experimental design, that all the threats to internal validity identified in Chapter 14 are, according to Campbell and Stanley (1963), controlled in the pre-test–post-test control group design. The term 'control' has been used in two main senses so far: the random allocation of participants to a control or an experimental group and the isolation and control of variables. Whilst the former is self-evident, in the second the researcher isolates key independent variables and controls what happens to these, for example, so that the same amounts of these are given to both the control group and the experimental group, i.e. the control group and experimental groups are matched in their exposure to these independent variables. This involves giving an identical, measured amount of exposure of both groups to these (whether this can actually be achieved in practice is a moot point, but for the purpose of the discussion here we assume it can). By holding the independent variable constant (giving the same amount to both the control group and the experimental group), it is argued that any changes brought about in the experimental group must be attributable to the intervention, the other variables having been held constant (controlled).

The importance of randomization

Schneider *et al*. (2007, p. 13) suggest that Holland's (1986) 'fundamental problem of causal inference' (a person cannot be in both the control and the experimental group simultaneously) comes into being once one accepts that a causal effect is the difference between what would have happened to a person in an experiment if she had been in the experimental group (receiving the intervention) and if the same person had been in the control group. This 'fundamental problem' is addressed through randomization, and a key feature of an RCT is, as its name suggests, randomization:

> Randomization is a key, critical element of the 'true' experiment; random sampling and random allocation to either a control or experimental group is a key way of allowing for the very many additional uncontrolled and, hence, unmeasured, variables that may be part of the make-up of the groups in question.… It is an attempt to overcome the confounding effects of exogenous and endogenous variables: the *ceteris paribus* condition (all other things being equal); it assumes that the distribution of these extraneous variables is more or less even and perhaps of little significance. In short it strives to address Holland's (1986) 'fundamental problem of causal inference', which is that a person may not be in both a control group and an experimental group simultaneously.… [B]ecause random allocation takes into account both observed and unobserved factors, controls on unobserved factors, thereby, are unnecessary.… If students are randomly allocated to control and experimental group and are equivalent in all respects (by randomization) other than one group being exposed to the intervention and the other not being exposed to the intervention, then, it

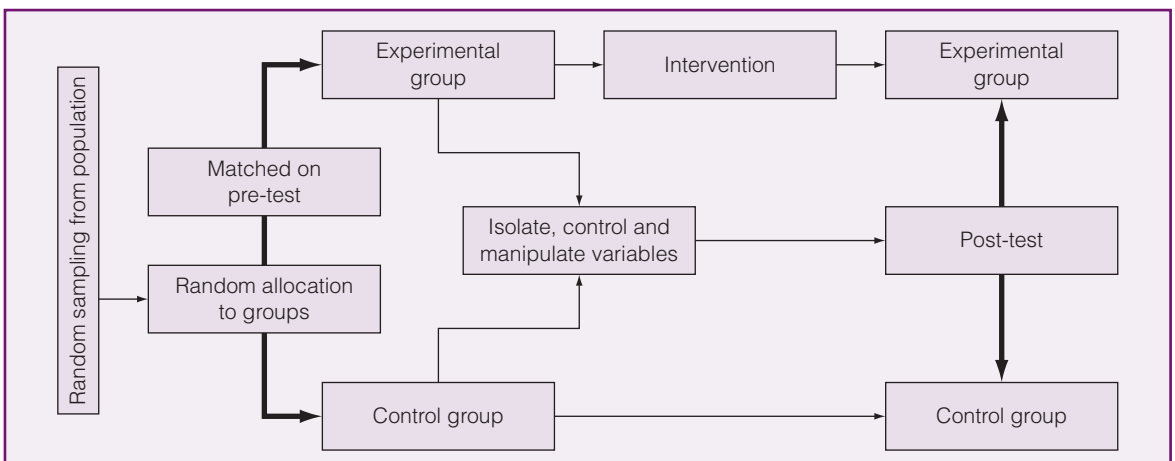

FIGURE 20.1 The 'true' experiment

> is argued, the researcher can attribute any different outcomes between the two groups to the effects of the intervention.
>
> (Morrison, 2009, pp. 143–4)

Kerlinger (1970) observes that, in theory, random assignment to experimental and control groups controls all possible independent variables. In practice, of course, it is only when enough subjects are included in the experiment that the principle of randomization has a chance to operate as a powerful control. However, the effects of randomization even with a small number of subjects is well illustrated in Box 20.1.

Randomization ensures the greater likelihood of equivalence, that is, the equal apportioning out between the experimental and control groups of any other factors or characteristics of the subjects which might conceivably affect the experimental variables in which the researcher is interested (cf. Torgerson and Torgerson, 2003a, 2003b, 2008). If the groups are equivalent, then any 'clouding' effects (other minor variables) should be present in both groups.

Randomization, Smith (1991, p. 215) explains, produces equivalence over a whole range of variables, whereas matching produces equivalence over only a few named variables. Randomization is a way of reducing the effects of allocation bias (Sullivan, 2011), ensuring that baseline features or characteristics, which may not be known to the researcher, are evenly distributed between the control and experimental groups.

Holland (1986, p. 947) suggests a statistical solution to his 'fundamental problem of causal inference' through randomization and the measurement of the *average* results (p. 948). The *average* score on the pre-test and post-test may be useful unless it masks important differences between subsets of the two samples, for example, students with a high IQ and students with a low IQ may perform very differently, but this would be lost in an average, in which case stratification into sub-samples can be adopted. We address problems of averages below.

Schneider *et al*. (2007, pp. 13–15) also make suggestions to address Holland's problem:

- Place the same person in the control group, followed by placing her in the experimental group (which assumes *temporal stability* (cf. Holland 1986, p. 948), i.e. the fact that there are two time periods must make no difference to the results, there being a constancy of response, regardless of time), assuming or demonstrating that the placement of the person in the first group does not affect the person for long enough to contaminate (affect) the person's response to being in the second group (cf. Holland 1986, p. 948) (see below: repeated measures designs).
- Assume that all the participants are identical in every respect (which may be possible in the physical sciences but questionably so in the human sciences, even in studies of twins (Holland, 1986, p. 947)).

Torgerson (2009) notes that, in educational research, randomization may occur at the class or school level rather than the individual person level, as the individuals in a class are not completely independent of each other, i.e. there may be a bias in only working within individuals in a single class or in a single school. Cluster sampling also reduces the risk of contamination (the experimental group influencing the control group and vice versa) which may occur if the trial is contained

BOX 20.1 THE EFFECTS OF RANDOMIZATION

Select twenty cards from a pack, ten red and ten black. Shuffle and deal into two ten-card piles. Now count the number of red cards and black cards in either pile and record the results. Repeat the whole sequence many times, recording the results each time.

You will soon convince yourself that the most likely distribution of reds and blacks in a pile is five in each: the next most likely, six red (or black) and four black (or red); and so on. You will be lucky (or unlucky for the purposes of the demonstration!) to achieve one pile of red and the other entirely of black cards. The probability of this happening is 1 in 92,378! On the other hand, the probability of obtaining a 'mix' of not more than six of one colour and four of the other is about 82 in 100.

If you now imagine the red cards to stand for the 'better' ten children and the black cards for the 'poorer' ten children in a class of twenty, you will conclude that the operation of the laws of chance alone will almost probably give you close equivalent 'mixes' of 'better' and 'poorer' children in the experimental and control groups.

Source: Adapted from Pilliner (1973)

within a single school. Cluster sampling means that the number of individuals in the sample increases significantly in order to ensure statistical power (see Chapter 39), as each class or school becomes just one cluster – one unit – which, in turn, comprises individuals (p. 316).

For example, Torgerson and Torgerson (2008, p. 100) suggest that a new curriculum is implemented at the whole school level, rather than an individual person level. Hence the unit of randomization is the school, so the researcher would have to randomly sample, from the population of schools, several schools to be the control group and several other schools to be the experimental group. This might present problems in finding sufficient schools, as it increases the sample size, each school counting as only one unit (Tymms (2012) reports the example of using 120 schools in one project that used cluster sampling). Torgerson (2009) suggests that it is preferable to use many small schools, each with a small number of students, rather than a smaller number of schools with large numbers of students in each. This echoes the comment of Lindquist (1940) that 'the *unit* of sampling in educational research' may be the class or the school, or indeed the community, rather than the student (p. 24).

Cluster sampling, however, reduces the chance of finding a difference between the control and experimental groups. It may 'dilute any intervention effects' (Torgerson and Torgerson, 2008, p. 100) and it may risk bias in choosing the individual people from a cluster. The authors note also that statistical treatment in cluster samples may be more sophisticated, as it may use multilevel modelling (though Gorard (2013, p. 107) argues against this). Further, cluster sampling runs the risk that, since the unit of analysis is the school and not the individual, as individuals come and go in any one school, it may be that the post-test is conducted on students who were not included in the pre-test. This problem can be attenuated by ensuring that random sampling of individuals takes place at the pre-test and post-test stages. For further analysis of cluster-level analysis we refer the reader to Torgerson and Torgerson (2008) and Bland (2010).

Full randomization (i.e. random *sampling*: selection from a total population) in much educational research may be impracticable, even impossible (Lindquist, 1940, pp. 24–5), but random *allocation* may be possible (e.g. within a school), and, as Lindquist notes, this may suffice for adherence to sampling theory.

Concerns about randomized controlled trials

Powerful advocacy of RCTs for planning and evaluation is provided by Boruch (1997), Torgerson and Torgerson (2008) and Goldacre (2013). Indeed Boruch argues (1997, p. 69) that the problem of poor experimental controls has led to highly questionable claims being made about the success of programmes.

RCTs in education have their protagonists and antagonists. On the one hand, RCTs claim to provide evidence of 'what works', which is preferable to introducing or using untested interventions in education. RCTs can meet a rigorous standard of evidence and can upset long-held, false myths about education, and can suggest probabilistic causation. Small-scale RCTs acting as pilots can also reduce risk.

On the other hand, RCTs have been criticized on many counts. For example, the irreducible complexity and multiplicity of purposes, contexts and changing dynamics of participants in a specific context (Brooks *et al*., 2014, p. 71), intended outcomes and contents of education frustrate the simplicity of RCTs. Concerns have also been raised about the questionable ethics of randomization (e.g. denying control groups access to potentially positive interventions). Further, randomization in educational RCTs might be difficult, and the solution may not necessarily be provided by cluster randomization (Torgerson, 2009).

The many challenges facing RCTs in education have also been well aired.[2] For example, classical experimental methods, abiding by the need for replicability and predictability, may not be particularly fruitful since, in complex phenomena, results are never clearly replicable or predictable: we never step into the same river twice. Further, in linear thinking, small causes bring small effects and large causes bring large effects, but, as in complexity and chaos theory, small causes can bring huge effects and huge causes may have little or no effect. Moreover, to atomize phenomena into measurable variables and then to focus only on certain ones of these is to miss synergy and the spirit of the whole. Measurement, however acute, may tell us little of value about a phenomenon; I can measure every physical variable of a person but the nature of the person, what makes that person who she or he is, eludes atomization and measurement. RCTs, in this sense, have to answer the sometimes discredited view of science as positivism.

The RCT, premised on notions of randomization, isolation and control of variables in order to establish causality, may be appropriate for a laboratory, though whether, in fact, a social situation either ever *could*

become the antiseptic, artificial world of the laboratory or *should become* such a world are empirical and moral questions respectively. Indeed, the discussion of the 'design experiment' later in this chapter notes that its early advocate (Brown, 1992) had moved away from laboratory experiments to naturalistic settings in order to catch the true interaction of myriad variables in the real world. Further, the ethical dilemmas of treating humans as manipulable, controllable and inanimate are considerable (see Chapter 7).

Whilst we address ethical concerns in Chapter 7, it is important here to note the common reservation that is voiced about the two-group experiment (e.g. Gorard, 2001b, p. 146), which questions how ethical it is to deny a control group access to a treatment or intervention in order to suit the researcher (to which the counter-argument is, as in medicine, that (a) the researcher does not know whether the intervention, e.g. the new drug, will work or whether it will bring harmful results, and indeed the purpose of the experiment is to discover this (Goldacre, 2013), and (b) if an intervention works, then it can be offered to the control group at a later date once the trial has finished).

Hage and Meeker (1988, p. 55) suggest that the experimental approach may be fundamentally flawed in assuming that a single cause produces an effect. Further, it may be that the setting effects are acting causally, rather than the intervention itself, i.e. where the results are largely a function of their context (see Maxwell, 2004), for instance in the Milgram studies of obedience and the Stanford Prison Experiment reported in Chapter 30 and Zimbardo (2007a, 2007b).

Morrison (2001, p. 69) argues that RCTs in education on their own operate from a restricted view of causality and predictability; understate the value of other data sources and types; display unrealistic reductionism, simplification and atomization of a complex whole; understate the importance of multiple perspective in judging 'what works'; fail to catch the dynamics of non-linear phenomena; are silent on the processes (and causal processes) that take place in experiments (the black box approach); and neglect the significance of context. In other words, undifferentiated RCTs alone cannot tell the whole story of efficacy, generalizability and effectiveness.

Whilst randomization, harking back to Fisher, is designed to overcome myriad within-group and between-group differences, focusing on average results of control and experimental groups, this might be all well and good for the agricultural model in *The Design of Experiments* (1966), but humans, for example, students in school, are infinitely more complex and less passive than seeds which are affected by soil, heat, light, weather, location and water. An educational intervention is not like putting a fertilizer onto a patch of soil; a fertilizer may have only one effect whereas education may have many, and, whereas fertilizers look for average effects, education concerns the benefits to individuals. Further, in education, one intervention may cause a multiplicity of outcomes and may vary according to the characteristics of the students. Indeed Tymms (1996) notes that the same treatment with the same class may produce different results.

The National Research Council (2002) notes that RCTs may be expensive, may lack generalizability and, anyway, 'cannot test complex causal hypotheses' (p. 125) (see also Cartwright and Hardie, 2012). On the other hand, Torgerson (2009) contends that RCTs are 'particularly well-suited to areas where there is considerable complexity in terms of causal pathways and mechanisms of action' (p. 314), as they override specific causal pathways, control out alternative explanations and concern themselves with an input and an outcome. Maxwell (2004) and Camburn *et al*. (2015) note that a significant shortcoming of an RCT is its failure to provide a causal basis for deciding *how* something works (p. 24) and how far it is generalizable.

One problem that has been identified with an RCT is the interaction effect of testing. Good (1963) explains that whereas the various threats to the validity of the experiments listed in Chapter 14 can be thought of as main effects, manifesting themselves in mean differences independently of the presence of other variables, interaction effects, as their name implies, are joint effects and may occur even when no main effects are present. For example, an interaction effect may occur as a result of the pre-test measure sensitizing the subjects to the experimental variable. Interaction effects can be controlled by adding to the pre-test–post-test control group design two more groups that do not experience the pre-test measures. The result is a four-group design, as suggested by Solomon (discussed below).

The RCT is the 'gold standard' of many educational researchers, as it purports to establish controllability, causality and generalizability (Coe *et al*., 2000; Curriculum, Evaluation and Management Centre, 2000). How far this is true is contested (Morrison, 2001). For example, complexity theory replaces simple causality with an emphasis on networks, linkages, holism, feedback, relationships and interactivity in context (Cohen and Stewart, 1995), emergence, dynamical systems, self-organization and an open system, rather than the closed world of the experimental laboratory (Morrison, 2012). Even if we could conduct an experiment, its applicability to ongoing, emerging, interactive, relational, changing, open situations, in practice, may be

limited (Morrison, 2001, 2012). It is misconceived to hold variables constant in a dynamical, evolving, fluid, open situation.

We also question whether the complexity of education lends itself to RCTs and we suggest that pragmatic, 'real-world' RCTs are more useful than laboratory-like trials, and in fact non-laboratory experiments are likely to be the only options in educational research. Indeed Campbell, a towering figure in experimental research in education, was an advocate of quasi-experiments and field experiments (Shadish *et al*., 2002; Pearce and Raman, 2014).

Some RCTs may have limited external validity (generalizability), and findings in one context may not work in another context (Cartwright and Hardie, 2012). Further, blind and double-blind experiments may not be feasible in education. An experiment may fail to catch, or may ignore, the complexity and significance of teacher–student interactions, and education comprises an ongoing, dynamic interplay of systems, contexts and people that may not be captured in a single RCT, i.e. RCTs over-simplify the 'real world' (cf. Hammersley, 2015b). Indeed Sullivan (2011) notes that contextual factors may trump the findings from RCTs, i.e. it may not be clear whether a result is due to the context or to the intervention, and this is particularly so if the intervention is 'fairly dilute' (p. 285).

Smith (2013) notes that it is difficult to operate RCTs in education because outcomes are not easy to predefine and, even if we could identify such outcomes in education, measuring them is challenging and surrogates and proxies may be problematic (a matter of construct validity, see Chapter 14).

What happens in the hermetically sealed world of the laboratory is unlike what happens in the 'real world' in which contamination and the Hawthorne effect may occur. An RCT might suggest whether something 'works', but not why or how, and these are what educationists need to know (Morrison, 2001; Pawson, 2013), for example, Camburn *et al*. (2015), studying an experiment on school principal training, found that the experiment 'did not illuminate why or how the program failed to influence principal practice' (p. 2).

There is a case for RCTs in educational research, but they must be rigorous, and whilst RCTs have their place, attention must also be given to: the 'real world' (and we explore field experiments and quasi-experiments later in this chapter); the whole person; context; differentiated sub-groups; differentiation by personal characteristics of participants; the amount, quality, strength, frequency, intensity and duration of an intervention (cf. Camburn *et al*., 2015, pp. 8–9) and the effects of differences in these on participants; recognizing that a person is a complex system which combines and connects very many elements whose interactions and outcomes change over time (with commensurate changes to interventions over time).

Further, whilst RCTs may have their place in educational research, this does not obviate the importance of, or preclude the use of, other research approaches (Marsden, 2007; Menter, 2013; Pring, 2015). Sheffield Hallam University (2016) echoes this:

> RCTs on their own provide limited detail on why an intervention has a positive (or negative) impact, or whether specific aspects of a complex intervention are more (or less) effective than others. Because of this, our RCT evaluation designs incorporate a process evaluation that mixes qualitative and quantitative research approaches.
>
> (Sheffield Hallam University, 2016, p. 1)

Pring (2015, p. 50) notes that Campbell himself, after whom the Campbell Collaboration is named, had reservations about the exclusion of qualitative research in the experimental approach. RCTs are only one source of evidence in educational research, and the argument has been advanced that they should be complemented by qualitative data of many different hues (e.g. Pring, 2015).

Whilst being able to identify whether an intervention 'works' under carefully controlled conditions, RCTs need to take account of 'real-world' settings, and improving RCTs involves sub-group identification and inclusion, in short, careful and detailed stratification and analysis of differential treatment effects. We are not against RCTs at all; the point is that if we wish to use RCTs in education they would benefit from greater rigour than often currently obtains.

The limits of averages

The measures used in RCTs focus on the average, overall results rather than outliers or important sub-sample differences (discussed below). Non-cognitive outcomes may be ignored, and focus is placed on whether a particular intervention brings its designed outcome, regardless of the cost (widely defined). Currently many RCTs in education are content with a single average measure, a single measure of effect size or statistical significance, overlooking intervention-response differences, within-group differences, between-group differences and sub-sample differences (which even factorial designs may not catch). This is an important feature here: if RCTs in education are to be conducted, then they need to be more sophisticated and, at the same time, sensitive to individual and group

differences, to context and to the need to move beyond singular measurements of outcomes such as averages. Average difference conceals within-individual and within-group variation, between-individual and between-group variation and interaction. Whilst stratification attenuates this, it increases the sample size (Chapter 12), for example, in each stratum, in order to retain statistical power.

On the other hand, Goldacre (2013), a protagonist for RCTs in education, remarks that in the world of education

> [e]very child is different, of course, and every patient is different too; but we are all similar enough that research can help find out which intervention will work best overall, and which strategies should be tried first, second or third, to help everyone achieve the best outcome.
>
> (Goldacre, 2013, p. 7)

Variable responses ('heterogeneity of treatment effects') are almost inevitable in heterogeneous individuals and their sub-groups. RCTs often overlook such heterogeneities, leading to claims for results being more broadly applicable than in reality they are. Indeed RCTs may overlook sub-groups, other conditions and interventions operating on the situation in question, and other students or contextual characteristics; this is a warning for educational research which too easily assumes that a single intervention will have a single effect; a blunt instrument with a blunt measure.

For RCTs in educational research, benefits come from the sophisticated sub-sampling and sub-group targeted treatments with varied outcomes, researched in suitably differentiated trials in the 'real world'. This is far from the relatively crude, undifferentiated input–output RCTs that appear in educational literature which typically report statistical significance and a single, overall effect size. Further, attention has to be given not only to the magnitude and nature of the effect but how this varies for individuals and sub-groups, arguing perhaps for factorial research designs in RCTs. Averages conceal such differences, and we argue here that RCTs have to be sensitive to variability in individuals and groups. Currently in education this is largely not the case.

Measures of central tendency in RCTs, typically by using averages, may be their strongest point or their Achilles heel, depending on the purpose of the research. Whereas RCTs may seek to establish the best intervention for the average student, and ignore outliers, education has a duty to attend to outliers, as students, be they average or outliers, may or may not benefit equally from the treatment. One should not assume population or response homogeneity, and it is all too easy to dismiss outliers, regardless of the levels at which they are defined: 1 per cent, 5 cent, 10 per cent, or whatever. In education, the more difficult, extreme and small in number is the sub-group, the more it risks being overlooked or even removed from the data analysis, yet it may be the outliers who benefit most from an intervention.

Many RCTs in education seem to take a largely undifferentiated approach to diagnosing who might and might not benefit from an intervention, and then proceed to a relatively crude RCT that is targeted at a relatively undifferentiated group. One lesson here is that educational RCTs may benefit from being differentiated to targeted groups, based on careful diagnosis; the other lesson is that interventions will need to take account of the whole person, not just a few variables.

Given the problems of using averages in RCTs, we suggest the benefits of supplementing the findings from RCTs with evidence from other methodologies and data, because excluding and including variables, i.e. focusing on a single variable of interest in an artificial setting, risks overlooking broader contexts and applicability. Similarly, focusing on one putative homogeneous group may misrepresent the nature of that group.

How do you know if the experiment has 'worked'?

It is often difficult to find an experiment (e.g. an RCT) in education that states in advance the level of success that it requires in order to be judged efficacious or effective and how it will address contingencies and responses to interventions. Many experiments have no clearly specified targets for effectiveness and efficacy, though some may indicate an *overall* effect size sought in order to ensure statistical power (cf. Ellis, 2010). Indeed it is difficult to find RCTs in education which state their prognoses, targeted improved benefit (for whom, how much and about what), predicted benefit or its lack (and for whom), predicted risk and its mitigation (though ethics committees are supposed to act here), and important details of the intervention.

Researchers want to know if their experiment has 'worked'. How can they be assured of this? There are several answers to this question. One approach is to use null hypothesis significance testing; another is to consider effect size; another is to address the statistical power of a test; another is to adopt the subtraction approach; another is to consider rival explanations of the findings; another is more complex, to recognize that unequivocal measures may not tell researchers all that they wish to know, and that they may wish to know the

contingencies and conditions under which their experiment did and did not work: the contingency approach (Pawson, 2013). Further, since experiments may have differing outcomes for different participants, this injects an ethical dimension into the experimental outcomes. We consider all these points below.

Null hypothesis significance testing

Null hypothesis significance testing (NHST), as we discuss in Chapter 39, strives to determine whether results found, for example, whether an intervention makes a difference, and is or is not by chance. It does not and cannot tell the researcher how much difference an intervention makes, and most researchers want to know this: the magnitude of an effect. In Chapter 39 we note the limits of NHST: it is silent on what many researchers and users of research want or need to know, i.e. how much of an effect an intervention has and on whom (which groups and sub-groups), under what conditions and contingencies, with how much 'treatment' (e.g. quantity, quality, intensity, strength, frequency, duration) and at what cost. Indeed we raise concerns about the assumptions on which NHST is built, for example, the assumption of the null hypothesis (Chapter 39).

Fisher's (1966) comment that randomization, linked to the importance of averages and intended to overcome a range of individual differences, 'will suffice to guarantee the validity of the test of significance, by which the result of the experiment is to be judged' (p. 21) is questionable, as significance testing has limited value, telling the researcher only about the likelihood of the result occurring by chance (and indeed this is questionable, see Chapter 39) rather than which students might or might not benefit, and by how much; one cannot read off from a general result or a significance test what will be the result for an individual.

Effect size

Effect size (e.g. Cohen's *d*) is a widely used measure of difference. Effect size is usually measured in standard deviation units, with different measures used for different numbers of groups (e.g. a two-group design; a design with more than two groups). Here researchers should specify in advance of the research what effect size they require in order to judge whether their experiment has 'worked', for example, whether they will be content with a low or medium effect size, or whether they really need a large effect size to warrant their judgement of success. We address effect size in Chapter 39.

Statistical power

Whether an experiment has 'worked' depends on the statistical power of the test, its ability to detect an effect if there is one, avoiding a Type I error – a false positive – and a Type II error – a false negative. In other words, statistical power suggests how much confidence we can place in the results. Researchers should specify what statistical power they wish, as this affects sample size, and this must be set before the research testing takes place. Too often researchers do not indicate the statistical power of the test, and often their sample size is so small that the statistical power is weak, and the results could be simply by chance. We address statistical power in Chapter 39.

The subtraction approach

In the subtraction approach the putative causal effect of an intervention is calculated thus:

Step 1: Subtract the pre-test score of the experimental group from the post-test score of the experimental group to yield score (1).
Step 2: Subtract the pre-test score of the control group from the post-test score of the control group to yield score (2).
Step 3: Subtract score (2) from score (1).

If the result is negative then the causal effect is negative. Though this approach is straightforward, it is difficult to interpret the results, as the criterion for judging success has to be made clear and has to be judged with reference to the scale being used. For example, if I follow the three steps outlined above and I find a difference of, say, 10 points, is this large or small? The answer to this depends on the scale being used: if the scale runs from 0 to 20 then the difference of 10 points is proportionally large; if the scale runs from 0 to 100 then the difference of 10 points is proportionally much smaller. The researcher will need to decide the appropriate level (e.g. proportion of difference) for judging whether the experiment has 'worked'. Further, though this approach is intended to show the average causal effect, a figure on its own does not determine causality; rather it is the design of the experiment itself that may affect any inferences of probabilistic causality.

Considering rival explanations

Like statistical power, this approach is designed to enable the researcher to know how much confidence can be placed in the results obtained. Here the researcher has to consider alternative, rival explanations for the findings, and then defend the claim that these rival explanations are not as persuasive as the

interpretation proffered, for example, that the intervention has not only caused the observed finding, rather than other factors, but has also caused the magnitude of the observed finding. This depends in part on the warrants being brought forward to support the conclusion reached (see Chapter 11), and in part on the power of the evidence brought forward.

The contingency approach

In this approach researchers want more than a simple metric of how much difference an intervention has made, whether this was by chance and how much confidence they can place in the result. Rather, the researcher wishes to know under what circumstances and conditions (contingencies) it works or does not work, for whom and in what terms and under what criteria. Pearce and Raman (2014), commenting on the relation between RCTs and policy making, suggest that advocates of RCTs can help institutions more by putting 'the evidence from trials in its proper context, clarify[ing] the conditions under which interventions work or do not work and why' (p. 398). Such concerns about RCTs resonate with Pawson's (2013) comment that an intervention would be well advised to 'better implement it through A, B, C … better to target it at D, E, F … and better beware of the pitfalls of G, H, I' (p. 190). In other words, in addition to needing to know 'how much' effect a treatment has, and on whom, educational researchers also need to know something that RCTs generally do not indicate, which is *why* some students do or do not respond to an intervention, why others have an excessive response and why others experience side effects or adverse effects, i.e. why there is such variability in effects (Morrison, 2001).

The ethical dimension

Whilst we address ethical aspects of experiments later in this chapter, at this point we suggest that, in order to judge whether an experiment has or has not 'worked', and for whom, it is important to consider the possible fallout from them. Here, for an experiment to 'work' in ethical terms, it should ensure that it has brought no negative or harmful (e.g. psychological, physical, social, emotional) direct or indirect side effects. For example, an experiment to improve student performance in mathematics may succeed in raising performance levels, but at the cost of demotivating students, putting them under immense pressure and turning them off mathematics for life. This is a problem encountered in the 'shadow side' of school (Bray and Lykins, 2012), where students attend private tutorial centres and work with private tutors to improve their test scores in highly competitive systems of schooling; their performance might increase, but so might their dislike of the subject and their anxiety and stress levels.

In approaching any conclusion that the experiment has 'worked', researchers will need to demonstrate that:

- design protocols have been followed;
- randomization has been used appropriately;
- the sample size is suitable;
- the statistical power of the test is appropriate;
- suitable controls have been in place in the experiment;
- extraneous factors have been excluded;
- threats to internal and external validity have been addressed;
- reliability has been addressed;
- appropriate pre-tests and post-tests have been applied, for example, not too easy, not too difficult and with suitable item discriminability (see Chapter 27);
- appropriate proxy measures have been used;
- the correct units of analysis have been used (e.g. individual or cluster analysis);
- appropriate metrics have been used;
- appropriate statistics have been used;
- appropriate criteria for judging 'effectiveness' have been used;
- ethical issues have been addressed.

In noting the affinity between RCTs in education and clinical trials (cf. Torgerson, 2009), responding to the need for recognizing the importance of detail, contingencies and contexts, we suggest that educational research could benefit from the rigour attached to RCTs in medicine, as pharmacopeias indicate: whether a medicine is freely available or a controlled drug; dosage strengths, frequency, quantities and outcomes (dose-response testing); patient screening and diagnosis; security, safety and misuse; indications; contraindications; side effects and adverse effects; delayed effects; register of providers and users; treatment regimens; cautions; patients at risk (e.g. by age, abnormality, special features); presence of other illnesses and other medicines (comorbidities); and methods of treatment. The equivalence of these in RCTs in education is currently difficult to see in their planning, design, conduct, analysis and reporting.

Interventions in experiments in education must take account of a host of factors, contexts and systems in which they exist; rather than trying to control out such factors, contexts and systems, they occupy a central position. In educational research, RCTs have an important place, but theirs is not the entire story of 'what works' when considering the whole system of people, contingencies, changes, contexts, education systems and policy making (cf. Pearce and Raman, 2014) which

obtain in a dynamic, non-linear, interconnected system such as education (Morrison, 2012). Supplementary and complementary methods and data may be useful here.

20.3 Designs in educational experiments

There are several different kinds of experimental design, such as (e.g. Denscombe, 2014):

- the controlled experiment in laboratory conditions (the 'true' experiment): two or more groups;
- the randomized controlled trial;
- the field or quasi-experiment (in the natural setting rather than the laboratory, but where variables are isolated, controlled and manipulated);
- the natural experiment (in which it is not possible to isolate and control variables);
- the retrospective experiment (where the researcher moves from an observed effect and tests to find the likely cause (*ex post facto* research)).

The laboratory experiment (the classic 'true' experiment) is conducted in a specially contrived, artificial environment, so that variables can be isolated, controlled and manipulated (as in the example of the wheat seeds earlier). However, schools and classrooms are not the antiseptic, reductionist, analysed-out or analysable-out world of the laboratory. Indeed the successionist conceptualization of causality (Harré, 1972), wherein researchers make inferences about causality on the basis of observation, must admit its limitations. It is dangerous to infer causes from effects or multiple causes from multiple effects. Generalizability from the laboratory to the classroom is dangerous, yet with field experiments, with their loss of control of variables, generalizability might be equally dangerous.

Sometimes it is not possible, desirable or ethical to set up a laboratory or field experiment. For example, let us imagine that we wanted to investigate the trauma effects on people in road traffic accidents. We could not require a participant to run under a bus, or another to stand in the way of a moving lorry, or another to be hit by a bicycle, and so on. Instead we might examine hospital records to see the trauma effects of victims of bus accidents, lorry accidents and bicycle accidents, and see which group seems to have sustained the greatest traumas. It may be that the lorry accident victims had the greatest trauma, followed by the bus victims, followed by the bicycle victims. Now, although it is not possible to say with 100 per cent certainty what caused the trauma, one could make an intelligent guess that those involved in lorry accidents suffer the worst injuries. Here we look at the outcomes and work backwards to examine possible causes, i.e. we can come to some likely defensible conclusions.

Frequently in experiments on learning in classroom settings the independent variable is a stimulus of some kind, for example, a new method in arithmetical computation, and the dependent variable is a response, for example, the time taken to do twenty sums using the new method. Most empirical studies in educational settings, however, are quasi-experimental rather than experimental. Important differences between the quasi-experiment and the true experiment are that the randomization and controls operating in the true experiment are only partially present, or indeed completely absent, in the quasi-experiment, for example, the groups in the experiment may have been constituted by means other than random selection, or some of the isolation and control of variables may be impossible. In this chapter we identify the essential features of true experimental and quasi-experimental designs, our intention being to introduce the reader to the meaning and purpose of control in educational experimentation.

In experiments, researchers can remain relatively aloof from the participants, bringing a degree of objectivity to the research (Robson, 2002, p. 98). Observer effects can distort the experiment: for example, researchers may record inconsistently, or inaccurately or selectively, or, less consciously, they may be having an effect on the experiment (the problem of bias, deliberate or unconscious). Further, participant effects might distort the experiment (see the discussion of the Hawthorne effect in Chapter 14); the fact of simply being in an experiment, rather than what the experiment is doing, might be sufficient to alter participants' behaviour.

In medical experiments these twin concerns are addressed by having experiments which are blind or double blind and by giving placebos to certain participants, to monitor any changes. In blind experiments, participants are not told whether they are in a control group or an experimental group, though which they are is known to the researcher. In a double-blind experiment not even the researcher knows whether a participant is in the control or experimental group; that knowledge resides with a third party. These are intended to reduce the subtle effects of participants knowing whether they are in a control or experimental group. In educational research it is easier to conduct a blind experiment than a double-blind experiment, and it is even possible not to tell participants that they are in an experiment at all, or to tell them that the experiment is about X when, in fact, it is about Y, i.e. to 'put them off the scent'. This form of deception needs to be justified; a common justification is that it enables the

experiment to be conducted under more natural conditions, without participants altering their everyday behaviour.

In the outline of research designs that follows, we use symbols and conventions from Campbell and Stanley (1963):

- *X* represents the exposure of a group to an experimental variable or event, the effects of which are to be measured;
- *O* refers to the process of observation or measurement;
- *X*s and *O*s in a given row are applied to the same persons;
- left to right order indicates temporal sequence;
- *X*s and *O*s vertical to one another are simultaneous;
- *R* indicates random assignment to separate treatment groups;
- parallel rows unseparated by dashes represent comparison groups equated by randomization, while those separated by a dashed line represent groups not equated by random assignment.

20.4 True experimental designs

There are several variants of the 'true' experimental design, and we consider many of these below:

- the pre-test–post-test control and experimental group design;
- the two control groups and one experimental group pre-test–post-test design;
- the post-test control and experimental group design;
- the post-test two experimental groups design;
- the pre-test–post-test two treatment design;
- the matched pairs design;
- the factorial design;
- the parametric design;
- repeated measures designs.

The laboratory experiment typically has to identify and control a large number of variables, and this may not be possible in education. Further, the laboratory environment itself can have an effect on the experiment, or it may take some time for a particular intervention to manifest its effects (e.g. a particular reading intervention may have little immediate effect but may have a delayed effect in promoting a liking for reading in adult life, or may have a cumulative effect over time).

A 'true' experiment includes several key features:

- one or more control groups;
- one or more experimental groups;
- random sampling from a population;
- random allocation to control and experimental groups;
- pre-test of the groups to ensure parity;
- one or more interventions to the experimental group(s);
- isolation, control and manipulation of independent variables;
- post-test of the groups to see the effects on the dependent variable;
- post-test of the groups to see the effects on the groups;
- non-contamination between the control and experimental groups.

If an experiment does not possess all of these features then it is a quasi-experiment: it may look *as if* it is an experiment ('quasi' means 'as if') but it is not a true experiment, only a variant on it.

An alternative to the laboratory experiment is the quasi-experiment or field experiment, including:

- the one-group pre-test–post-test;
- the non-equivalent control group design;
- the time series design.

We consider these below. Field experiments have less control over experimental conditions or extraneous variables than a laboratory experiment, and, hence, inferring causality is more contestable, but they have the attraction of taking place in a natural setting. Extraneous variables may include:

- participant factors (they may differ on important characteristics between the control and experimental groups);
- intervention factors (the intervention may not be exactly the same for all participants, varying, for example, in sequence, duration, degree of intervention and assistance, and other practices and contents);
- situational factors (the experimental conditions may differ).

These can lead to experimental error, in which the results may not be due to the independent variables in question. Ary *et al*. (2006) and Shadish *et al*. (2002) provide a useful overview of true and quasi experiments.

The pre-test–post-test control and experimental group design

A complete exposition of experimental designs is beyond the scope of this chapter. In the brief outline

that follows, we have selected one design from the comprehensive treatment of the subject by Campbell and Stanley (1963) in order to identify the essential features of what they term a 'true experimental' and what Kerlinger (1970) refers to as a 'good' design. Along with its variants, the chosen design is commonly used in educational experimentation (e.g. Schellenberg, 2004).

The pre-test–post-test control group design can be represented as:

Experimental	RO_1	X	O_2
Control	RO_3		O_4

The two control groups and one experimental group pre-test–post-test design

This is the Solomon design, intended to identify the interaction effect that may occur if the subject deduces the desired result from looking at the pre-test and the post-test. It is the same as the RCT above, except that there are two control groups instead of one. In the standard RCT, any change in the experimental group can be due to the intervention or the pre-test, and any change in the control group can be due to the pre-test. In the Solomon variant the second control group receives the intervention but no pre-test. This can be modelled thus:

Experimental	RO_1	X	O_2
$Control_1$	RO_3		O_4
$Control_2$		X	O_5

Thus any change in this second control group can only be due to the intervention. A variant of the Solomon three-group design is the Solomon four-group design (with one experimental group and three control groups). We refer readers to Bailey (1994, pp. 231–4), Ary *et al*. (2009) and Shadish *et al*. (2002) for a full explication of this technique and its variants.

The post-test control and experimental group design

Here participants are randomly assigned to a control group and an experimental group, but there is no pre-test. The experimental group receives the intervention and the two groups are given only a post-test. The design is:

Experimental	R_1	X	O_1
Control	R_2		O_2

The post-test two experimental groups design

Here participants are randomly assigned to each of two experimental groups. Experimental group 1 receives intervention 1 and experimental group 2 receives intervention 2. Only post-tests are conducted on the two groups. The design is:

$Experimental_1$	R_1	X_1	O_1
$Experimental_2$	R_2	X_2	O_2

The pre-test–post-test two treatment design

Here participants are randomly allocated to each of two experimental groups. Experimental group 1 receives intervention 1 and experimental group 2 receives intervention 2. Pre-tests and post-tests are conducted to measure changes in individuals in the two groups. The design is:

$Experimental_1$	RO_1	X_1	O_2
$Experimental_2$	RO_3	X_2	O_4

The true experiment can also be conducted with one control group and two or more experimental groups. So, for example, the design might be:

$Experimental_1$	RO_1	X_1	O_2
$Experimental_2$	RO_3	X_2	O_4
Control	RO_5		O_6

This can be extended to the post-test control and experimental group design and the post-test two experimental groups design, and the pre-test–post-test two treatment design.

The matched pairs design

As the name suggests, here participants are allocated to control and experimental groups randomly, but the basis of the allocation is that one member of the control group is matched to a member of the experimental group on the several independent variables considered important for the study (e.g. those independent variables that are considered to have an influence on the dependent variable, such as sex, age, ability). So, first, pairs of participants are selected who are matched in terms of the independent variable under consideration (e.g. whose scores on a particular measure are the same or similar), and then each one of the pair is randomly assigned to the control or experimental group. Randomization takes place at the pair rather than the group level. Though, as its name suggests, this ensures

effective matching of control and experimental groups, in practice it may not be easy to find sufficiently close matching, particularly in a field experiment, though finding such a close match in a field experiment may increase the control of the experiment considerably. Matched pairs designs are useful if the researcher cannot be certain that individual differences will not obscure treatment effects, as it enables these individual differences to be controlled.

Borg and Gall (1979, p. 547) set out a useful series of steps in the planning and conduct of a matched pairs experiment:

Step 1: Carry out a measure of the dependent variable.
Step 2: Assign participants to matched pairs, based on the scores and measures established from Step 1.
Step 3: Randomly assign one person from each pair to the control group and the other to the experimental group.
Step 4: Administer the experimental treatment/intervention to the experimental group and, if appropriate, a placebo to the control group. Ensure that the control group is not subject to the intervention.
Step 5: Carry out a measure of the dependent variable with both groups and compare/measure them in order to determine the effect and its size on the dependent variable.

Borg and Gall indicate that difficulties arise in the close matching of the sample of the control and experimental groups. This involves careful identification of the variables on which the matching must take place. They suggest (p. 547) that matching on a number of variables that correlate with the dependent variable is more likely to reduce errors than matching on a single variable. The problem is that the greater the number of variables that have to be matched, the harder it is actually to find the sample of people who are matched. Hence the balance must be struck between having too few variables such that error can occur, and having so many variables that it is impossible to draw a sample. Instead of matched pairs, random allocation is possible, and this is discussed below.

Mitchell and Jolley (1988, p. 103) pose three important questions that researchers need to consider when comparing two groups:

- Are the two groups equal at the commencement of the experiment?
- Would the two groups have grown apart naturally, regardless of the intervention?
- To what extent has initial measurement error of the two groups been a contributory factor in differences between scores?

Borg and Gall (1979) draw attention to the need to specify the degree of exactitude (or variance) of the match. For example, if the subjects were to be matched on, say, linguistic ability as measured in a standardized test, it is important to define the limits of variability that will be used to define the matching (e.g. ±3 points). As before, the greater the degree of precision in the matching here, the closer will be the match, but the greater the degree of precision the harder it will be to find an exactly matched sample.

One way of addressing precision is to place all the subjects in rank order on the basis of the scores or measures of the dependent variable. Then the first two subjects become one matched pair (in which one is allocated to the control group and one to the experimental group randomly, e.g. by tossing a coin), subjects three and four become the next matched pair, subjects five and six become the next matched pair, and so on until the sample is drawn. Here the loss of precision is counterbalanced by the avoidance of the loss of subjects.

The alternative to matching that has been discussed earlier in the chapter is randomization. Smith (1991, p. 215) suggests that matching is most widely used in quasi-experimental and non-experimental research, and is a far inferior means of ruling out alternative causal explanations than randomization.

The factorial design

In an experiment there may be two or more independent variables acting on the dependent variable. For example, performance in an examination may be a consequence of availability of resources (independent variable one: limited availability, moderate availability, high availability) and motivation for the subject studied (independent variable two: little motivation, moderate motivation, high motivation). Each independent variable is studied at each of its levels (in the example here it is three levels for each independent variable). Participants are randomly assigned to groups that cover all the possible combinations of levels of each independent variable, for example:

Independent variable	*Level 1*	*Level 2*	*Level 3*
Availability of resources	limited availability (1)	moderate availability (2)	high availability (3)
Motivation for the subject studied	little motivation (4)	moderate motivation (5)	high motivation (6)

Here the possible combinations are: 1+4, 1+5, 1+6, 2+4, 2+5, 2+6, 3+4, 3+5 and 3+6. This yields

nine groups (3 × 3 combinations). Pre-tests and post-tests or post-tests only can be conducted. It might show, for example, that limited availability of resources and little motivation had a large influence on examination performance, whereas moderate and high availability of resources did not, or that high availability and high motivation had a large effect on performance, whereas high motivation and limited availability did not, and so on.

This example assumes that there are the same numbers of levels for each independent variable; however, this may not be the case. One variable may have, say, two levels, another three levels and another four levels. Here the possible combinations are $2 \times 3 \times 4 = 24$ levels and, therefore, 24 experimental groups. One can see that factorial designs quickly generate several groups of participants. A common example is a 2 × 2 design, in which two independent variables each have two values (i.e. four groups). Here experimental group 1 receives the intervention with independent variable 1 at level 1 and independent variable 2 at level 1; experimental group 2 receives the intervention with independent variable 1 at level 1 and independent variable 2 at level 2; experimental group 3 receives the intervention with independent variable 1 at level 2 and independent variable 2 at level 1; experimental group 4 receives the intervention with independent variable 1 at level 2 and independent variable 2 at level 2.

Factorial designs also have to take account of the interaction of the independent variables. For example one factor (independent variable) may be 'sex' and the other 'age' (Figure 20.2). The researcher may be investigating their effects on motivation for learning mathematics.

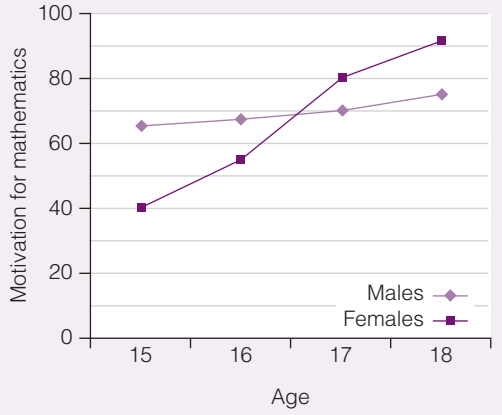

FIGURE 20.2 Interaction effects in an experiment

In Figure 20.2 the difference in motivation for mathematics is not constant between males and females; it varies according to the age of the participants. There is an interaction effect between age and sex, such that the effect of sex depends on age. A factorial design is useful for examining interaction effects.

At their simplest, factorial designs may have two levels of an independent variable, for example, its presence or absence, but, as has been seen here, it can quickly become more complex. That complexity is bought at the price of increasing exponentially the number of groups required.

The parametric design

Here participants are randomly assigned to groups whose parameters are fixed in terms of the levels of the independent variable that each receives. For example, let us imagine that an experiment is conducted to improve the reading abilities of poor, average, good and outstanding readers (four levels of the independent variable 'reading ability'). Four experimental groups are set up to receive the intervention, thus: experimental group 1 (poor readers); experimental group 2 (average readers), experimental group 3 (good readers) and experimental group 4 (outstanding readers). The control group (group 5) would receive no intervention. The researcher could chart the differential effects of the intervention on the groups, and thus have a more sensitive indication of its effects than if there was only one experimental group containing a wide range of reading abilities; the researcher would know which group was most and least affected by the intervention. Parametric designs are useful if an independent variable is considered to have different levels or a range of values which may have a bearing on the outcome (confirmatory research) or if the researcher wishes to discover whether different levels of an independent variable have an effect on the outcome (exploratory research).

Repeated measures designs

Here participants in the experimental groups are tested under two or more experimental conditions. So, for example, a member of the experimental group may receive more than one 'intervention', which may or may not include a control condition. This offers considerable potential for control, as it is exactly the same person receiving different interventions. Order effects raise their heads here: the order in which the interventions are sequenced may have an effect on the outcome; the first intervention may have an influence – a carry-over effect – on the second, and the second intervention may have an influence on the third, and so on. Further, early interventions may have a greater effect than later

interventions. To overcome this it is possible to randomize the order of the interventions and assign participants randomly to different sequences, though this may not ensure a balanced sequence. Rather, a deliberate ordering may have to be planned, for example, in a three-intervention experiment:

Group 1 receives intervention 1 followed by intervention 2, followed by intervention 3;
Group 2 receives intervention 2 followed by intervention 3, followed by intervention 1;
Group 3 receives intervention 3 followed by intervention 1, followed by intervention 2;
Group 4 receives intervention 1 followed by intervention 3, followed by intervention 2;
Group 5 receives intervention 2 followed by intervention 1, followed by intervention 3;
Group 6 receives intervention 3 followed by intervention 2, followed by intervention 1.

Repeated measures designs are useful if it is considered that order effects are either unimportant or unlikely (see Figure 20.3), or if the researcher cannot be certain that individual differences will not obscure treatment effects, as it enables these individual differences to be controlled.

20.5 Quasi-experimental designs

Often in educational research, it is simply not possible for investigators to undertake true experiments, for example, random selection and random assignment of participants to control or experimental groups. Quasi-experiments are the stuff of field experimentation, i.e. outside the laboratory. At best, they may be able to employ something approaching a true experimental design in which they have control over what Campbell and Stanley (1963) refer to as 'the who and to whom of measurement', but lack control over 'the when and to whom of exposure' or the randomization of exposures – essential if true experimentation is to take place. These situations are quasi-experimental and the methodologies employed by researchers are termed quasi-experimental designs. (Kerlinger (1970) refers to quasi-experimental situations as 'compromise designs', an apt description when applied to much educational research where the random selection or random assignment of schools and classrooms is quite impracticable.)

Quasi-experiments come in several forms, for example:

- pre-experimental designs: the one-group pre-test–post-test design; the one-group post-tests only design; the non-equivalent post-test only design;
- pre-test–post-test non-equivalent group design;
- one-group time series.

We consider these below.

A pre-experimental design: the one-group pre-test–post-test

A pre-experimental design is so named because it offers little or even no control over extraneous variables (Ary *et al*., 2009). Very often, reports about the value of a new teaching method or interest aroused by a curriculum innovation reveal that a researcher has measured a group on a dependent variable (O_1), for example, attitudes towards minority groups, and then introduced an

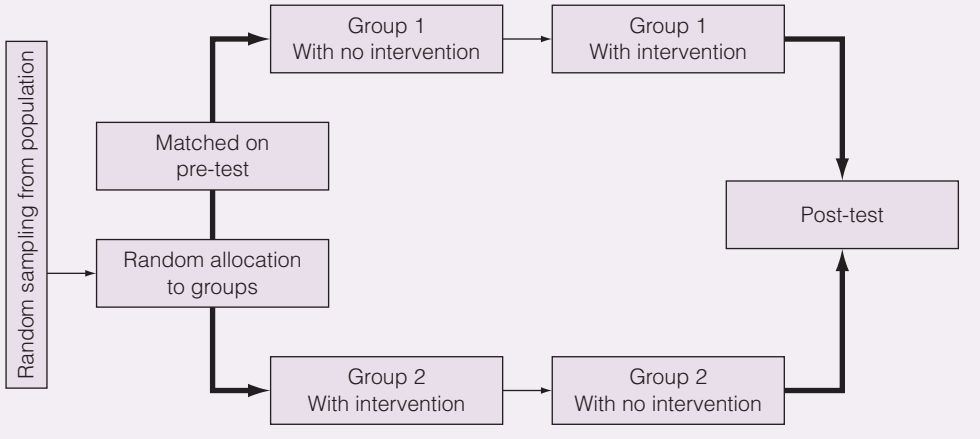

FIGURE 20.3 Two groups receiving both conditions (repeated measures)

experimental manipulation (X), perhaps a ten-week curriculum project designed to increase tolerance of ethnic minorities. Following the experimental treatment, the researcher has again measured group attitudes (O_2) and proceeded to account for differences between pre-test and post-test scores by reference to the effects of X.

The one-group pre-test–post-test design can be represented as:

Experimental	O_1	X	O_2

Suppose that just such a project has been undertaken and that the researcher finds that O_2 scores indicate greater tolerance of ethnic minorities than O_1 scores. How justified is she in attributing the cause of such differences to the experimental treatment (X), that is, the term's project work? At first glance the assumption of causality seems reasonable enough. The situation is not that simple, however. Compare for a moment the circumstances represented in our hypothetical educational example with those which typically obtain in experiments in the physical sciences. A physicist who applies heat to a metal bar can confidently attribute the observed expansion to the rise in temperature that she has introduced because within the confines of her laboratory she has excluded (i.e. controlled) all other extraneous sources of variation. The same degree of control can never be attained in educational experimentation. At this point readers may care to reflect upon some possible influences other than the ten-week curriculum project that might account for the differences in our hypothetical educational example.

They may conclude that factors to do with the pupils, the teacher, the school, the classroom organization, the curriculum materials and their presentation, how the subjects' attitudes were measured, to say nothing of the thousand and one other events that occurred in and about the school during the course of the term's work, might all have exerted some influence upon the observed differences in attitude. These kinds of extraneous variables which are outside the experimenter's control in one-group pre-test–post-test designs threaten to invalidate their research efforts. We later identify a number of such threats to the validity of educational experimentation.

A pre-experimental design: the one-group post-tests only design

Here an experimental group receives the intervention and then takes the post-test. Though this has some features of an experiment (an intervention and a post-test), the lack of a pre-test, of a control group, of random allocation and of controls renders this a flawed methodology.

A pre-experimental design: the post-tests only non-equivalent groups design

Again, though this appears to be akin to an experiment, the lack of a pre-test, of matched groups, of random allocation and of controls renders this a flawed methodology.

A quasi-experimental design: the pre-test–post-test non-equivalent group design

One of the most commonly used quasi-experimental designs in educational research can be represented as:

Experimental	O_1	X	O_2
Control	O_3		O_4

The dashed line separating the parallel rows in the diagram of the non-equivalent control group indicates that the experimental and control groups have not been equated by randomization – hence the term 'non-equivalent'. The addition of a control group makes the present design a decided improvement over the one-group pre-test–post-test design, as, to the degree that experimenters can make experimental and control groups as equivalent as possible, they can avoid the equivocality of interpretations that plague the pre-experimental design discussed earlier. The equivalence of groups can be strengthened by matching, followed by random assignment to experimental and control treatments.

Where matching is not possible, the researcher is advised to use samples from the same population or samples that are as alike as possible (Kerlinger, 1970). Where intact groups differ substantially, however, matching is unsatisfactory due to regression effects which lead to different group means on post-test measures.

The one-group time series

Here the one group is the experimental group, and it is given more than one pre-test and more than one post-test. The time series uses repeated tests or observations both before and after the treatment, which, in effect, enables the participants to become their own controls, which reduces the effects of reactivity. Time series allow for trends to be observed, and avoids reliance on only one single pre-testing and post-testing data-collection point. This enables trends to be observed such as: no effect at all (e.g. continuing an existing upward, downward or even trend), a clear effect (e.g. a sustained rise or drop in performance), delayed effects (e.g. some time after the intervention has occurred). Time series studies have the potential to increase reliability.

20.6 Single-case ABAB design

At the beginning of Chapter 19, we described case study researchers as typically engaged in observing the characteristics of an individual unit, be it a child, a classroom, a school, or a whole community. We went on to contrast case study researchers with experimenters whom we described as typically concerned with the manipulation of variables in order to determine their causal significance. That distinction, as we shall see, is only partly true.

Increasingly, in recent years, single-case research as an experimental methodology has extended to such diverse fields as clinical psychology, medicine, education, social work, psychiatry and counselling. Most of the single-case studies carried out in these (and other) areas share the following characteristics:

- they involve the continuous assessment of some aspect of human behaviour over a period of time, requiring on the part of the researcher the administration of measures on multiple occasions within separate phases of a study;
- they involve 'intervention effects' which are replicated in the same subject(s) over time.

Continuous assessment measures are used as a basis for drawing inferences about the effectiveness of intervention procedures.

The characteristics of single-case research studies are discussed by Kazdin (1982) and Ary *et al*. (2002) in terms of ABAB designs, the basic experimental format in most single-case research. ABAB designs consist of a family of procedures in which observations of performance are made over time for a given client or group of clients. Over the course of the investigation, changes are made in the experimental conditions to which the client is exposed. The basic rationale of the ABAB design is illustrated in Figure 20.4. What it does is this. It examines the effects of an intervention by alternating the baseline condition (the A phase), when no intervention is in effect, with the intervention condition (the B phase). The A and B phases are then repeated to complete the four phases. As Kazdin and Ary *et al*. note, the effects of the intervention are clear if performance improves during the first intervention phase, reverts to or approaches original baseline levels of performance when the treatment is withdrawn, and improves again when treatment is recommenced in the second intervention phase.

An example of the application of the ABAB design in an educational setting is provided by Dietz (1977), whose single-case study sought to measure the effect that a teacher could have upon the disruptive behaviour of an adolescent boy whose persistent talking disturbed his fellow classmates in a special education class.

In order to decrease the unwelcome behaviour, a reinforcement programme was devised in which the boy could earn extra time with the teacher by decreasing the number of times he called out. The boy was told that when he made three (or fewer) interruptions during

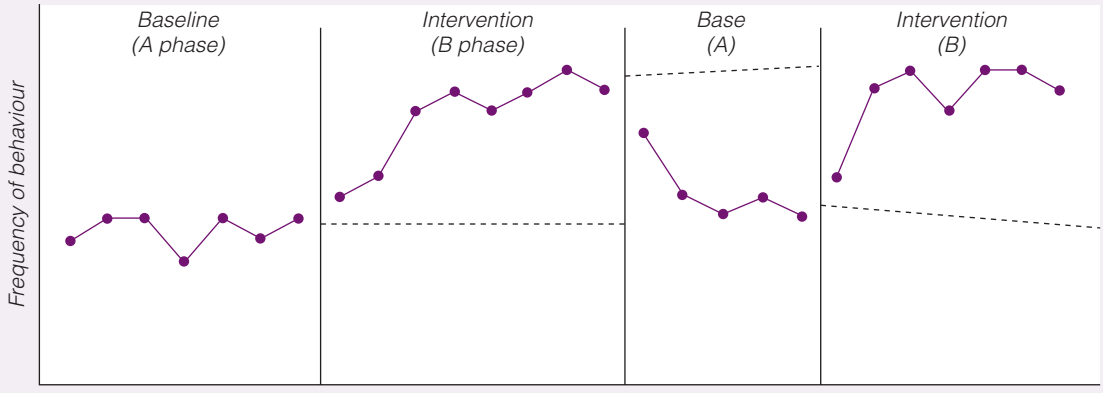

FIGURE 20.4 The ABAB design
Source: Adapted from Kazdin (1982)

any fifty-five-minute class period, the teacher would spend extra time working with him. In the technical language of behaviour modification theory, the pupil would receive reinforcing consequences when he was able to show a low rate of disruptive behaviour (in Figure 20.5 this is referred to as 'differential reinforcement of low rates' or DRL).

When the boy was able to desist from talking aloud on fewer than three occasions during any timetabled period, he was rewarded by the teacher spending fifteen minutes with him helping him with his learning tasks. The pattern of results displayed in Figure 20.5 shows the considerable changes that occurred in the boy's behaviour when the intervention procedures were carried out and the substantial increases in disruptions towards baseline levels when the teacher's rewarding strategies were withdrawn. Finally, when the intervention was reinstated, the boy's behaviour is seen to improve again.

Ary *et al*. (2002) provide an example of an ABAB design with a single case of an eight-year-old boy who was developmentally disabled. There is also the famous example of the 'still face experiment' with young babies(e.g.www.youtube.com/watch?v=apzXGEbZht0) in which a mother interacts positively with the baby for some time, then adopts an expressionless, unresponsive 'still face', and repeats this sequence, and we are able to observe the baby's increasingly frantic attempts to attract the mother's attention.

The single-case research design is uniquely able to provide an experimental technique for evaluating interventions for the individual subject. Moreover, such interventions can be directed towards the particular subject or group and replicated over time or across behaviours, situations or persons. Single-case research offers an alternative strategy to the more usual methodologies based on between-group designs. There are, however, a number of problems that arise in connection with the use of single-case designs having to do with ambiguities introduced by trends and variations in baseline phase data and with the generalizability of results from single-case research.

20.7 Procedures in conducting experimental research

An experimental investigation must follow a set of logical procedures. Those that we now enumerate, however, should be treated with some circumspection. It is extraordinarily difficult (and foolhardy) to lay down clear-cut rules as guides to experimental research. At best, we can identify an ideal route to be followed, mindful that educational research rarely proceeds in such a systematic fashion.

First, the researcher must identify and define the research problem as precisely as possible, always supposing that the problem is amenable to experimental methods.

Second, she must formulate hypotheses that she wishes to test. This involves making predictions about relationships between specific variables and at the same time making decisions about other variables that are to

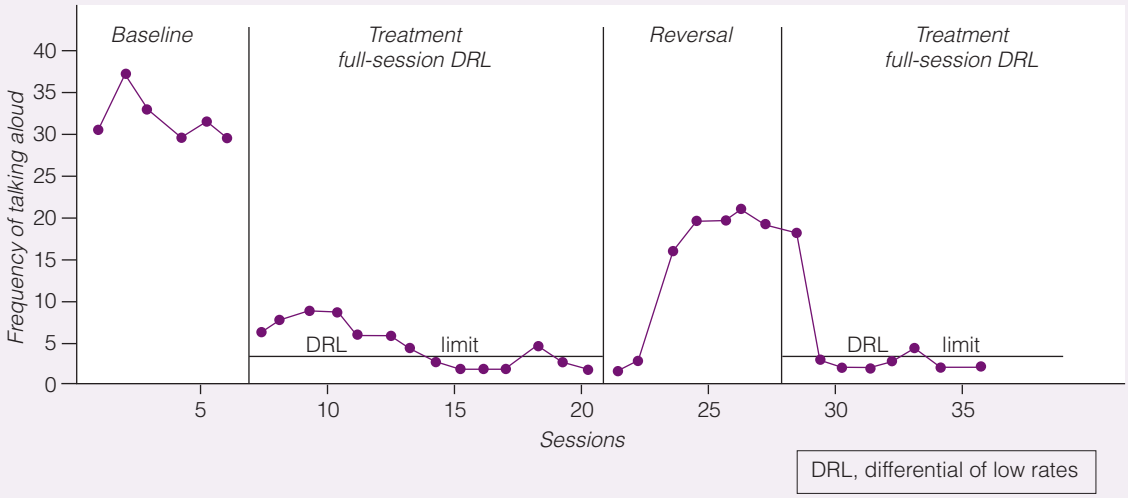

FIGURE 20.5 An ABAB design in an educational setting
Source: Kazdin (1982)

be excluded from the experiment by means of controls. Variables, remember, must have two properties. First, they must be measurable. Physical fitness, for example, is not directly measurable until it has been operationally defined. Making the variable 'physical fitness' operational means simply defining it by letting something else that is measurable stand for it – a gymnastics test, perhaps (a proxy variable). Second, the proxy variable must be a valid indicator of the hypothetical variable in which one is interested. That is to say, a gymnastics test probably is a reasonable proxy for physical fitness; height, on the other hand, most certainly is not. Excluding variables from the experiment is inevitable, given constraints of time and money. It follows therefore that one must set up priorities among the variables in which one is interested so that the most important of them can be varied experimentally whilst others are held constant.

Third, the researcher must select appropriate levels at which to test the independent variables. By way of example, suppose an educational psychologist wishes to find out whether longer or shorter periods of reading make for reading attainment in school settings (see Simon, 1978). She will hardly select five-hour and five-minute periods as appropriate levels; rather, she is more likely to choose thirty-minute and sixty-minute levels, in order to compare with the usual timetabled periods of forty-five minutes' duration. In other words, the experimenter will vary the stimuli at such levels as are of practical interest in the real-life situation. Pursuing the example of reading attainment further, our hypothetical experimenter will be wise to vary the stimuli in large enough intervals so as to obtain measurable results. Comparing reading periods of forty-four minutes or forty-six minutes with timetabled reading lessons of forty-five minutes is scarcely likely to result in observable differences in attainment.

Similarly Torgerson and Torgerson (2008) alert researchers to 'ceiling and floor effects' (pp. 147–8). A 'ceiling effect' is where a test is too easy for the participants, whilst a 'floor effect' is where it is too difficult. This rehearses the need not only to pilot the test but to ensure that item discriminability and appropriate scaling have been addressed (see Chapter 27 of the present volume). The authors note that if there is a ceiling or floor effect then it may lead to the false conclusion that an intervention has not worked.

Fourth, the researcher must decide which kind of experiment she will adopt, perhaps from the varieties set out in this chapter.

Fifth, in planning the design of the experiment, the researcher must take account of the population to which she wishes to generalize her results. This involves her in decisions over sample sizes, sampling methods and contextual matters. Sampling decisions may include questions of funds, staffing and the amount of time available for experimentation. However, one general rule of thumb is to try to make the sample as large as possible so that even small effects can reveal themselves which might otherwise be lost with small samples, even though the trade-off here is that, with large samples, it is easier to achieve statistical significance (i.e. it is easier to find a statistically significant difference between the control group and the experimental group) than it is with a small sample (statistical significance being, in part, a function of sample size) (cf. Torgerson and Torgerson, 2008, p. 128), though measures of effect size overcome this problem. Further, it is important, where possible, to use a random, probability sample, as this not only permits a greater range of statistics to be used (e.g. t-tests and Analysis of Variance (ANOVA), both of which are important in experiments, see Chapter 41), but it also enables the findings to have greater generalizability (external validity), i.e. to represent the wider population. Contextual similarity also has to be considered in addressing generalizability, as results in one context or culture, regardless of statistical significance and effect size, may not travel well to a very different context or culture (Cartwright and Hardie, 2012).

Sixth, with problems of validity in mind, the researcher must select instruments, choose tests and decide upon appropriate methods of analysis (typically t-tests and measures of effect size are used to determine whether there are any statistically significant or sizeable differences that are worthy of note, respectively, between the control and experimental groups).

Seventh, before embarking upon the actual experiment, the researcher must pilot the experimental procedures and measures to identify possible problems in connection with any aspect of the investigation. This is of crucial importance.

Eighth, during the experiment itself, the researcher must endeavour to follow tested and agreed-on procedures to the letter (standard protocols). The standardization of instructions and adherence to them, the exact timing of experimental sequences and the meticulous recording and checking of observations are all the hallmark of the competent researcher.

With her data collected, the researcher faces the most important part of the whole enterprise. Processing data, analysing results and drafting reports are all demanding activities, both in intellectual effort and time. Often this last part of the experimental research is given too little time in the overall planning of the investigation. Experienced researchers rarely make such a

mistake; unanticipated disasters teach the hard lesson of leaving ample time for the analysis and interpretation of experimental findings.

We suggest a ten-step model for the conduct of the experiment:

Step 1: Identify the purpose of the experiment.
Step 2: Select the relevant variables.
Step 3: Specify the level(s) of the intervention (e.g. low, medium, high intervention).
Step 4: Isolate and control the experimental conditions and environment.
Step 5: Select the appropriate experimental design.
Step 6: Administer the pre-test.
Step 7: Sample the relevant population and assign the participants to the groups.
Step 8: Conduct the intervention.
Step 9: Conduct the post-test.
Step 10: Analyse the results.

The sequence of steps 6 and 7 can be reversed; the intention in putting them in the present sequence is to ensure that the two groups are randomly selected, allocated and matched. In calculating differences or similarity between groups at the stages of the pre-test and the post-test, the t-test for independent samples or ANOVA are often used.

20.8 Threats to internal and external validity in experiments

Chapter 14 indicated several threats to the internal and external validity of experiments, and we refer the reader to this chapter. In that chapter threats to internal validity (the validity of the research design, process, instrumentation and measurement) were seen to reside in:

- history
- maturation
- statistical regression
- testing
- instrumentation
- selection
- experimental mortality
- instrument reactivity
- selection–maturation interaction
- Type I and Type II errors.

To this, Hammersley (2008, p. 4) adds the point that not all the confounding variables may be properly controlled in the randomization process.

In Chapter 14, too, threats to external validity (wider generalizability) were seen to reside in:

- failure to describe independent variables explicitly;
- lack of representativeness of available and target populations;
- the Hawthorne effect;
- inadequate operationalizing of dependent variables;
- sensitization/reactivity to experimental/research conditions;
- interaction effects of extraneous factors and experimental/research treatments;
- invalidity or unreliability of instruments;
- ecological validity;
- multiple treatment validity.

To this, Hammersley (2008, p. 4) adds the point that, in principle, a laboratory trial, in which variables are controlled, misrepresents the 'real' world of the classroom or school in which the variables are far less controlled, i.e. the findings may not be transferable to wider conditions and situations. Further, Torgerson (2009) notes that, unlike crops in agriculture (the origin of Fisher's (1966) experimental model), humans do not always act as the experimenter would like or in ways in which the experimenter has predicted (p. 315) (see also Camburn *et al*., 2015, p. 8).

One can add to these factors the matter that statistical significance can be found comparatively easily if sample sizes are large (Kline, 2004) (hence the need to consider placing greater reliance on effect size rather than statistical significance, discussed in Chapter 39). Further, Torgerson and Torgerson (2003a, 2008) draw attention to the limits of small samples in experimental research, as small samples can fail to spot small effects, thereby risking a Type II error (failing to find an effect when, in fact, it exists: a false negative). As they remark, in a time of evidence-based education and discussions of 'what works', small effects can be useful (Torgerson and Torgerson, 2003a, p. 70), and they give the example where, if a small change in 'delivering' the curriculum leads to improved examination passes of one only child in each class in public examinations, then this could scale up to between 20,000 and 30,000 students across the UK.

Torgerson and Torgerson (2003b, 2008) and Torgerson (2009) also identify several sources of bias in randomized controlled trials, for example:

- use of a *very selective sample* (they give the example of an exclusive girls-only boarding school) and then seeking to generalize the results to a much wider population, for example, an inner-city mixed sex comprehensive (non-selective) school (Torgerson and Torgerson, 2003b, p. 37);

- a *selection bias* (i.e. a non-random selection), if the researcher allocates the students on preference: a non-blind random allocation (Torgerson, 2009, p. 316);
- a *selection bias*, where the experimental group possesses a variable that is related to the outcome variable but which is not included in the intervention (Torgerson and Torgerson, 2003b, pp. 37–8);
- a *dilution bias*, where the control group, not being exposed to the intervention, deliberately seeks out a 'compensating treatment' (p. 38). For example, there may be an experiment to test the effects of increased attention to mathematics in the classroom on mathematics results in public examinations; the control group, not being exposed to what they see as a useful intervention (given that there has to be informed consent), may take private mathematics lessons in order to compensate, thereby disturbing or diluting the findings of the experiment;
- *chance effects*: Torgerson and Torgerson (2003b) give an example of a group of forty children learning spellings, in which four of them were dyslexic, and in which the likelihood of them being randomly allocated to the control group and experimental group evenly (two in each group) was very small, indeed all four could be in one group (either the experimental group or the control group). The researchers argue that this can be addressed through 'minimisation' (p. 40), deliberately ensuring an even split of such students into both groups (e.g. matched pairs allocation);
- *'subversion bias'*, where researchers deliberately breach the requirements of random allocation (hence the need for double-blind experiments or where the researcher is not involved in the randomized allocation);
- *attrition bias*: where some students drop out of the experimental group. (Torgerson and Torgerson (2003b) give the example of students who attend voluntary Saturday morning 'booster classes' and then drop out of the class.) Here, if the researchers had only focused on the results of those students who remained in the Saturday morning classes, then they would have obtained very different results from those which might have been found if the dropouts had not dropped out (e.g. in terms of measured motivation levels and, hence, achievement). There is a risk of 'attrition bias' here (p. 75);
- *reporting or detection bias*: where different researchers or reporters for the control and experimental groups report with differing degrees of detail or inclusion of relevant observations (Torgerson and Torgerson, 2003b, p. 42);
- *exclusion bias*, where members of the experimental group, for reasons other than attrition, do not actually take part in the experiment;
- *marker bias*, if post-tests are marked by researchers who are not blinded with regard to the allocation of participants (Torgerson, 2009, p. 316).

20.9 The timing of the pre-test and the post-test

Experiments often suffer from the problem of only having two time points for measurement: the pre-test and the post-test. It is essential that the researcher plans the timing of the pre-test and the post-test appropriately. Morrison (2009, p. 168) writes that 'experimental procedures are prone to problems of timing – too soon and the effect may not be noticed; too late and the effect might have gone or been submerged by other matters'. The pre-test should be conducted as close to the start of the intervention as possible, to avoid the influence of confounding effects between the pre-test and the start of the intervention; that is quite straightforward.

More difficult is the issue of the timing of the post-test. On the one hand, the argument is strong that it should be as close as possible to the end of the intervention, as this will reduce the possibility of the influence of confounding effects. On the other hand, if it is as close as possible to the end of the intervention it might lead to a false positive, i.e. finding an effect which is transitory or only immediate, i.e. an effect which is not sustained to any worthwhile degree over time. A standard example of this is where an end-of course examination is administered at the last session of the course, or within a week of its completion, and, unsurprisingly perhaps, given the 'recency effect' (in which most recently studied items are more easily recalled than items studied a long time previously), many students score well. However, let us imagine that the post-test (the examination) had been conducted one month later, in which case the students might well have bleached the subject matter from their minds. Or, more problematic in this instance is the familiar case of students revising hard before the post-test (the examination) is administered and they score well, but this time it is not a consequence of the intervention but a rehearsal, practice or revision effect.

It may well be that the effects of a particular intervention may not reveal themselves immediately, but much later. For example, a student may study Shakespeare at age fifteen and, on an outcome measure, may use it to say that she strongly dislikes English literature, but, years later, she may point back to her study of

Shakespeare as sowing the seed for her eventual love of Shakespeare that only developed after she had left school.

On the one hand, too soon the post-test and that effect is lost, it goes unmeasured (and this is a serious problem for the 'what works' movement, which often concerns itself with short-term payback). On the other hand, too long a time lapse and it becomes impossible to determine whether it was a particular independent variable that caused a particular effect, or whether other factors have intervened since the intervention to produce the effect.

One way in which the researcher can overcome the difficulty of the timing of the post-test is to have more than one post-test (e.g. an 'equivalent form' of the post-test, see Chapter 14), with the post-test administered soon after the intervention has ended, and its equivalent form administered after a longer period of time – to determine more long-lasting effects.

20.10 The design experiment

The design experiment can be considered as a special case of a field experiment; it has its roots in experimental research, both in 'true' and quasi-experiments, and is intended to provide formative feedback on, for example, practical problems in, say, teaching and learning, and to bridge the potential gap between research and practice (Brown, 1992, p. 143; Reinking and Bradley, 2008; Bradley and Reinking, 2011; Engeström, 2011; Seel, 2011, p. 925; Anderson and Shattuck, 2012; Laurillard, 2012), in other words, to enhance the external validity of an experiment. The design experiment strives to avoid the artificial world of the laboratory and the lack of applicability to 'real-world problems' that follows from this artificial condition (Bradley and Reinking, 2011; Reinking and Bradley, 2008; Seel, 2011; Laurillard, 2012), and to have direct practical relevance to the complex world of teaching, learning and classrooms. Given their intended direct relevance to classrooms and the field nature – the diverse, complex, 'real world' of an actual classroom – design experiments may not be able to fulfil the requirements of a true experiment, for example, in randomization or in the application of controls. In these respects, design experiments are similar to action research (cf. Anderson and Shattuck, 2012).

Bradley and Reinking (2011), commenting on design experiments in early childhood education, note that they are intended to identify factors within classrooms which promote or inhibit effective teaching and learning and then seek to accentuate the positives and eliminate the negatives. The authors note seven features of design experiments (pp. 312–13):

- they focus on interventions in authentic, real-world settings;
- the role of theory is important in providing a rationale for the intervention, indeed testing the theory is a key purpose of design experiments;
- they have the improvement of practice as their goal, for example, how to improve teaching and learning in authentic settings;
- they are iterative in their data collection, gathering data as the intervention evolves over time and across sites;
- contextual factors influence – both positively and negatively – what happens at the sites of interventions and, hence, the design experiment;
- data collection employs multiple methods;
- they are rooted in pragmatism.

The authors raise six questions that design experiments address:

1. What is the pedagogical goal to be investigated; why is that goal valued and important and what theory and practice and previous empirical work speaks to accomplishing that goal instructionally?
2. What instructional intervention, consistent with a guiding theory, has the potential to achieve the pedagogical goal and why?
3. What factors enhance or inhibit the effectiveness, efficiency and appeal of the instructional intervention in regard to achieving the educational goal?
4. How can the instructional intervention be adapted to achieve the pedagogical goal more effectively and efficiently and in a way that is appealing and engaging to all stakeholders?
5. What unanticipated positive and negative effects does the instructional intervention produce?
6. Has the instructional environment changed as a result of the intervention?

(Bradley and Reinking, 2011, pp. 314–15)

Similarly, Anderson and Shattuck (2012) note that design-based research is a mixed methods approach which: (a) focuses on interventions in real-world, authentic educational contexts; (b) involve multiple iterations as events evolve; (c) focus on improvements in practice; and (d) seek to test a theory and theoretical relationships (pp. 16–18).

Key principles of design studies in education (The Design-Based Research Collective, 2003, p. 5), for example in developing learning environments, are:

1. They intertwine theory, models and practice.
2. Research and development occur in cycles of refinement, testing and feedback ('design, enactment and analysis'; The Design-Based Research Collective, 2003, p. 6).
3. The findings must be communicated and shared with all parties, including the users.
4. The research and the outcomes must be tested and used in authentic, real-world settings respectively.
5. Reporting and development go together in developing a useable outcome.

Shavelson *et al*. (2003, p. 26) suggest that the key principles of design studies are that they are: (a) 'iterative'; (b) 'process focused'; (c) 'interventionist'; (d) 'collaborative'; (e) 'multileveled'; (f) 'utility oriented'; and (g) 'theory driven'. Cobb *et al*. (2003, p. 9) suggest that theory generation is a key feature of design experiments; they are 'crucibles for the generation and testing of theory' (p. 9), their purpose is to generate theories of teaching and learning (p. 10), and this involves development, intervention and reflection. In having 'pragmatic roots' (p. 10), Cobb *et al*. point us to suggesting the affinity between design experiments and mixed methods research (see Chapter 2; see also Gorard *et al*., 2004, pp. 579, 593). Similarly, Bradley and Reinking (2011) comment that a hallmark of a design experiment is its iterative nature and that this supports the importance accorded to teacher development (p. 307).

The design experiment is perhaps more fittingly termed a 'design study', as it frequently does not conform to the requirements of an experiment (e.g. it does not have the hallmarks of a randomized controlled trial), as set out in the earlier part of this chapter. It is included here because of its nomenclature rather than its affinity to experiments as described in this chapter, though, like an experiment, it involves a deliberate and planned intervention. Anderson and Shattuck (2012) note the increasing interest and growth in design experiments globally, particularly in the US, the Netherlands, the UK and Singapore, and particularly focused on learning interventions, instructional technology and for school-age students.

It is more useful to focus on the word 'design' rather than 'experiment' here, as a design study owes some of its pedigree to engineering and science rather than to an experiment which has control and experimental groups. Brown (1992, p. 141) suggests that design studies attempt to 'engineer innovative educational environments and simultaneously conduct experimental studies of those innovations'. Take the example of engineering: here the designer develops a product and then tests it in real conditions (Gorard *et al*., 2004, p. 576), noting, during the testing (the experiment), what are the problems with the design, what needs to be improved, where there are faults and failures, and so on, gathering data from other participants and users. Then the engineer redesigns the product to address the faults found, refines the product and re-tests the improved product, noting faults, problems or failures; the engineer reworks the product to address these problems and tests it out again, and so on. We can observe here (e.g. Bradley and Reinking, 2011) that:

- the process is iterative; it has many cycles, trials, improvements and refinements over time;
- it focuses on the processes involved in the workings of the product;
- it communicates with different parties (theoreticians, designers, practitioners) about the design and development of the product (the designers, the engineers, the users), akin to a research-and-development model;
- the product has to work in the 'real world' (an example of 'what works') and in non-laboratory conditions and contexts;
- it is data-driven – the next cycle of refinement is based on data (e.g. observational data, measurement data, notes and records) derived from the previous round.

Bradley and Reinking (2011) note that, in addition to the engineering metaphor, the design experiment also emphasizes the ecology metaphor (p. 316), as each classroom has its own ecological character that has to feature in the design experiment. The design experiment has not only to take account of the classroom ecology but must work with it.

The inception of design studies is often attributed to Brown (1992), whose autobiographical account of her years of research charts a movement away from the laboratory and into the classroom, in order to catch the authenticity of the real world in research and development. She recognizes that this is bought at the price of tidiness, and she justifies this in terms of the real world being 'rarely isolatable' in terms of its components, and in which 'the whole really is more than the sum of its parts' (p. 166). For Brown and her successors, interventions are based on theoretical claims (e.g. about teaching and learning) and are inextricably linked to practices that improve the situation (e.g. of teaching and learning); they respond to 'emergent features' of the situation in which they are operating (The Design-Based Research Collective, 2003, p. 6). Practitioners, researchers and developers work together to produce a useful intervention and innovation.

A design-based study focuses on changing practice, instead of the static, 'frozen' input–output model of an intervention that one sees in much experimental and educational research (The Design-Based Research Collective, 2003, p. 7); in a design study the 'product' changes over time, as refinements are made in response to feedback from all parties.

However, unlike an engineering product, a design-based study does not end with the perfecting of a particular product. Rather, as Brown (1992) indicates, it affects theory, for example, of learning, of teaching. The design-based study can address and generate many kinds of knowledge (The Design-Based Research Collective, 2003, p. 8):

- investigating possibilities for new and innovative teaching environments;
- developing theories of teaching and learning that are rooted in real-world contexts;
- developing cumulative knowledge of design;
- increasing capacity in humans for innovation.

To this Shavelson *et al*. (2003, p. 28) suggest that design studies can address research that asks 'what is happening?', 'is there a systematic effect?' and 'why or how is it happening?'

The attraction of the approach is that it takes account of the complex, real, multivariate world of learning, teaching and education; as such, design studies are 'messier' than conventional experiments, as they take account of many variables and contexts, and the intervention develops and changes over time and involves several parties and strives to ensure that what works at the design stage really works in practice (Gorard *et al*., 2004, pp. 578, 582). The design study develops a profile of multiple variables rather than testing a sole hypothesis (Lobato, 2003, p. 19).

On the other hand, Shavelson *et al*. (2003) argue that design studies are not exempted from the usual warrants of research, for example, the epistemological basis and warrants in the research (p. 25), particularly if there are many possible confounding variables at work (p. 27), how generalizable the results can be, as they are so rooted in specific contexts (p. 27), and how alternative explanations of the outcomes have been considered (p. 27). To answer these questions, McCandliss *et al*. (2003, p. 15) also add that video-recording can provide useful data over time, and Shavelson *et al*. (2003) suggest that longitudinal narrative data are particularly useful as they can track developments and causal developments over time in a way that catches the complexity and contextualization of the intervention which inheres in its very principles. However, narrative accounts risk circularity, and there need to be external checks and balances, controls and warrants, in validating the knowledge claims (p. 27).

Further, Sloane and Gorard (2003) and Anderson and Shattuck (2012) indicate some difficulties that design studies have to address, including measurement problems, external validity, the lack of controls and control groups, the problem of insider research (e.g. bias), the lack of failure criteria (and they argue that engineers include failure criteria as essential features of their research and development) and the need for appropriate modelling of causality at both the alpha stages (the designers) and the beta stages (the users). Hence researchers using a design study have to be clear on its purposes, intended contribution to theory generation, participants and communication processes between them, processes of intervention and debriefing/feedback, understanding of the local context of the intervention (Cobb *et al*., 2003, p. 12) and 'testable conjectures' that can be revised iteratively (p. 11).

20.11 Internet-based experiments

A growing field in educational and psychological research is the use of the Internet for experiments. Internet-based experiments adhere to the same principles as 'true' and field experiments, with attention to independent variables, controls and manipulation of the key variable. Hewson *et al*. (2003) and Johnson and Christensen (2010) note that Internet-based experiments have the attractions of: ease of access to diverse and dispersed populations; ease of access by the participants (i.e. they do not have to come to the researcher); high statistical power because of large samples; the opportunity for many participants to be involved simultaneously; access at any time of the day/week; high-speed, real-time access and involvement (and the ability for the researcher to control timing); freedom from experimenter bias (as the researcher is not present); anonymity of the participants; and cost savings.

On the other hand, the researcher has less experimental control; no control over possible multiple, repeated submissions by participants; problems of self-selection (e.g. a non-representative volunteer sample); no control over the experimental conditions and environment in which the involvement takes place; hacking; no control over whether the participants are being honest about themselves and their characteristics; no control over whether the participants are completing the experiment alone or with others; technical problems (e.g. connectivity, compatible software); misunderstandings or lack of understanding of aspects of the experiment by the participants; and dropout. (Indeed it

may be impossible for respondents who withdraw partway through an experiment to have their data withdrawn, as their particular data may not be identifiable (Brooks *et al*., 2014, pp. 72–3). This problem is not exclusive to Internet experiments; it may be the same for other forms of research in which individuals are not required to identify themselves, in the interests of anonymity and non-traceability.) Further, asking young persons to interact with an unknown researcher online may violate the ethical issue of advice given to young people to avoid talking to strangers (p. 94).

Hewson *et al*. (2003, p. 48) classify Internet experiments into four principal types: (i) those using printed materials; (ii) those using non-printed materials such as audio or video; (iii) online reaction-time experiments; and (iv) experiments which require interpersonal interaction.

The first kind of experiment is akin to a survey in that it sends formulated material to respondents (e.g. graphically presented material) by email or by web page, and the intervention will be to send different groups different materials. Here all the cautions and comments that were made about Internet surveys apply (Chapter 18), particularly the problems of download times and different browsers and platforms. However, the matter of download time applies more strongly to the second type of Internet-based experiments that use video clips or sound, and some software packages will reproduce higher quality than others, even though the original that is transmitted is the same for everyone. This can be addressed by ensuring that the material runs at its optimum even on the slowest computer (Hewson *et al*., 2003, p. 49) or by stating the minimum hardware required for the experiment to be run successfully.

Reaction-time experiments, those that require very precise timing (e.g. to milliseconds), are difficult in remote situations, as different platforms and Internet connection speeds and congestion on the Internet through having multiple users at busy times can render standardization virtually impossible. One solution to this is to have the experiment downloaded and then run offline before loading it back onto the computer and sending it.

The fourth type involves interaction, and is akin to Internet interviewing (discussed below), facilitated by chat rooms. However, this is solely a written medium and so intonation, inflection, hesitancies, non-verbal cues, extra-linguistic and paralinguistic factors are ruled out of this medium. It is, in a sense, incomplete, though the use of screen-top video cameras mitigates this. Indeed this latter development renders observational studies an increasing possibility in the Internet age.

Reips (2002a) reports that in comparison to laboratory experiments, Internet-based experiments experienced greater problems of dropout, the dropout rate in an Internet experiment was very varied (from 1 per cent to 87 per cent) and dropout could be reduced by offering incentives, for example, payments or lottery tickets, bringing a difference of as much as 31 per cent to dropout rates. Dropout on Internet-based research was due to a range of factors (e.g. motivation, how interesting the experiment was), not least of which was the non-compulsory nature of the experiment (in contrast, for example, to the compulsory nature of experiments undertaken by university student participants as part of their degree studies). The discussion of the 'high-hurdle technique' (Chapter 18) is applicable to experiments. Reips (2002b, pp. 245–6) also reports that greater variance in results is likely in an Internet-based experiment than in a conventional experiment due to technical matters (e.g. network connection speed, computer speed, multiple software running in parallel). He also reports (Reips, 2009, p. 381) that Internet experiments suffer from reducing the controls that the experimenter can place on the participant and the problems of a biased, volunteer-only sample (p. 382) or recruitment biases.

On the other hand, Reips (2002b, p. 247) also reports that Internet-based experiments have an attraction over laboratory and conventional experiments in that they:

- have greater generalizability because of their wider sampling;
- demonstrate greater ecological validity as typically they are conducted in settings which are familiar to the participants and at times suitable to the participant ('the experiment comes to the participant, not vice versa'), though, of course, the obverse of this is that the researcher has no control over the experimental setting (p. 250);
- they have a high degree of voluntariness, such that more authentic behaviours can be observed.

How correct these claims are is an empirical matter. For example, some software packages can reduce experimenter control as these packages may interact with other programming languages. Indeed Schwarz and Reips (2001) report that the use of Javascript led to a 13 per cent higher dropout rate in an experiment compared to an identical experiment that did not use Javascript. Further, multiple returns by a single participant could confound reliability (see also Chapter 18).

Reips (2002a, 2002b) provides a series of 'dos' and 'don'ts' in Internet experimenting. In terms of 'dos' he gives five main points:

1. Use dropout as a dependent variable.
2. Use dropout to detect motivational confounding (i.e. to identify boredom and motivation levels in experiments).
3. Place questions for personal information at the beginning of the Internet study. Reips (2002b) suggests that asking for personal information may assist in keeping participants in an experiment, and that this is part of the 'high-hurdle' technique, where dropouts self-select out of the study, rather than dropping out during the study.
4. Use techniques that help ensure quality in data collection over the Internet (e.g. the 'high-hurdle' and 'warm-up' techniques discussed earlier, subsampling to detect and ensure consistency of results, using single passwords to ensure data integrity, providing contact information, reducing dropout).
5. Use Internet-based tools and services to develop and announce your study (using commercially produced software to ensure that technical and presentational problems are overcome). Some websites (e.g. the American Psychological Society) also announce experiments.

In terms of 'don'ts' he gives five main points:

1. Do not allow external access to unprotected directories. This can violate ethical and legal requirements, as it provides access to confidential data. It also might allow the participants to have access to the structure of the experiment, thereby contaminating the experiment.
2. Do not allow public display of confidential participant data through URLs (a problem as these can be found easily), as this again violates ethical codes.
3. Do not accidentally reveal the experiment's structure (as this could affect participant behaviour). This might be done through including the experiment's details on a related file or a file in the same directory.
4. Do not ignore the technical variance inherent in the Internet (configuration details, browsers, platforms, bandwidth and software might all distort the experiment, as discussed above).
5. Do not bias results through improper use of form elements (i.e. measurement errors, where omitting particular categories (e.g. 'neutral', 'do not want to respond', 'neither agree nor disagree') could distort the results).

The points made in connection with Internet surveys and questionnaires (Chapters 18 and 24) apply equally to Internet experiments, and we advise readers to review these.

Reips (2002b) points out that it is a misconception to regard an Internet-based experiment as the same as a laboratory experiment, as: (a) Internet participants can choose to leave the experiment at any time; (b) they can conduct the experiment at any time and in their own settings; (c) they are often conducted with larger samples than conventional experiments; (d) they rely on technical matters, network connections and the computer competence of the participants; and (e) they are more public than most conventional experiments. On the other hand, he also cautions against regarding the Internet-based experiment as completely different from the laboratory experiment, as: (a) many laboratory experiments also rely on computers; (b) fundamental ideas are the same for laboratory and Internet-based surveys; (c) similar results have been produced by both means. He suggests several issues in conducting Internet-based experiments:

- consider a web-based software tool to develop the experimental materials;
- pilot the experiment on different platforms for clarity of instructions and availability on different platforms;
- decide the level of sophistication of HMTL scripting and whether to use HTML or non-HTML;
- check the experiments for configuration errors and variance on different computers;
- place the experiment on several websites and services;
- run the experiment online and offline to make comparisons;
- use the 'warm-up' and 'high-hurdle' techniques, asking filter questions (e.g. about the seriousness of the participant, their background and expertise, language skills);
- use dropout to ascertain whether there is motivational confounding;
- check for obvious naming of files and conditions (to reduce the possibility of unwanted access to files);
- consider using passwords and procedures (e.g. consistency checks) to reduce the possibility of multiple submissions;
- keep an experimental log of data for any subsequent analysis and verification of results;
- analyse and report dropout;
- keep the experimental details on the Internet, to give a positive impression of the experiment.

Reips (2009, p. 375) also writes that the success of Internet-based experimentation depends in part on the 'cues transmitted', the 'bandwidth', 'cost constraints', 'level and type of anonymity' and 'synchronicity and exclusivity'.

Given the rise of evidence-based practice in education, and the advocacy of randomized controlled trials in education, this form of experimentation has become more widely used in education. We also refer readers to Birnbaum (2009) and Joinson *et al*. (2009).

20.12 *Ex post facto* research

Ex post facto studies start with groups that are already different with regard to certain characteristics or observations; here the researcher goes in reverse, searching back for likely factors that brought about those differences.

In *ex post facto* experiments, it is not possible to control variables in advance of the experiment or during the experiment, the data being already in existence before the experiment has commenced. However, in this case, the controls can be applied at the stage of data analysis, where the researcher can manipulate the independent variables to hold them constant, i.e. to control for the relative effects of these. For an example of this, we refer the reader to Chapter 6 on causation, and to Chapter 40 for an indication on how controls can be placed statistically, for example, partial correlations and crosstabulations.

In introducing *ex post facto* research here, we focus on its key features and how to conduct such a project, including:

- co-relational and criterion groups designs;
- characteristics of *ex post facto* research;
- occasions when appropriate;
- advantages and disadvantages of *ex post facto* research;
- designing an *ex post facto* investigation;
- procedures in *ex post facto* research.

In *ex post facto* research the researcher takes the effect (or dependent variable) and examines the data retrospectively to establish causes, relationships or associations, and their meanings.

Introduction

When translated literally, *ex post facto* means 'after the fact'; it signifies 'from what is done afterwards', 'from after the event' or 'from what has happened'. In the context of social and educational research, the phrase means 'retrospectively' and refers to those studies which investigate possible cause-and-effect relationships by observing an existing condition or state of affairs and searching back in time for plausible causal factors. In terms of Chapter 6 (on causation), this is examining the causes of effects, and we advise readers to refer to that chapter. Here researchers ask themselves what factors seem to be associated with certain occurrences, conditions or aspects of behaviour. As they have happened already, the researcher has to hypothesize possible causes and then test them against the evidence, for example, by holding factors constant and by controlling and matching the samples.

Ex post facto research is a method of teasing out possible antecedents of events that have happened and cannot, therefore, be controlled, engineered or manipulated by the investigator (Cooper and Schindler, 2001, p. 136). Researchers can only report what has happened or what is happening, by trying to hold factors constant by careful attention to sampling. Independent variables cannot be manipulated as in true experiments, as they have already happened. Hence the researcher is in the realms of probabilistic causation, inferring causes tentatively rather than being able to demonstrate causality unequivocally.

Ex post facto research can be used to study groups which are similar and which have had the same experience with the exception of one condition, and here the effect of the one differing condition on the dependent variable can be assessed. *Ex post facto* research, then, is a form of experiment, but without the stringent controls of a true experiment; there are control and experimental groups (the latter where a particular condition has been applied), but, since there is little or no rigorous manipulation of the independent variables or conditions, and since there is no random allocation of subjects to groups, any inferences of causation are tentative.

The following example will illustrate the basic idea. Let us return to the example introduced earlier in this chapter. Imagine a situation in which there has been a dramatic increase in the number of fatal road accidents in a particular locality. An expert is called in to investigate. Naturally, there is no way in which she can set the actual accidents because they have already happened; nor can she turn to technology for a video replay of the incidents; nor can she require a participant to run under a bus or a lorry, or to stand in the way of a speeding bicycle, in order to discover the effects. What she can do, however, is to study hospital records to see which groups have experienced the greatest trauma – bus, lorry or bicycle impact victims. Or she can attempt a reconstruction by studying the statistics, examining the accident spots and taking note of the statements given by victims and witnesses. In this way the expert will be in a position to identify possible determinants of the accidents, looking at the outcomes and working backwards to examine possible causes. These may include excessive speed, poor road conditions, careless driving,

frustration, inefficient vehicles, effects of drugs or alcohol and so on. On the basis of her examination, she can formulate hypotheses as to the likely causes and submit them to the appropriate authority in the form of recommendations. These may include improving road conditions, or lowering the speed limit, or increasing police surveillance, for instance. The point of interest to us is that in identifying the causes retrospectively, the expert adopts an *ex post facto* perspective.

Ex post facto research is a method that can also be used instead of an experiment, to test hypotheses about cause and effect in situations where it is impossible, impractical or unethical to control or manipulate the dependent variable or, indeed, the independent variables. For example, let us say that we wish to test the hypothesis that family violence causes poor school performance. Here, ethically speaking, we should not expose a student to family violence. However, one could put students into two groups, matched carefully on a range of factors, with one group comprising those who have experienced family violence and the other comprising those who have not. If the hypothesis is supportable then the researcher should be able to discover a difference in school performance between the two groups when the other variables are matched or held as constant as possible.

Kerlinger (1970) has defined *ex post facto* research as that in which the independent variable or variables have already occurred and in which the researcher starts with the observation of a dependent variable or variables. She then studies the independent variable or variables in retrospect for their possible relationship to, and effects on, the dependent variable or variables. The researcher is thus examining retrospectively the effects of a naturally occurring event on a subsequent outcome with a view to establishing a causal link between them. The key to establishing the causes is the careful identification of those that are possible, testing each against the evidence, and then eliminating the ones that do not stand up to the test, ensuring that attention is paid to careful sampling and to controls – holding fixed some variables.

Some instances of *ex post facto* designs correspond to experimental research in reverse, for instead of taking groups that are equivalent and subjecting them to different treatments so as to bring about differences in the dependent variables to be measured, an *ex post facto* experiment begins with groups that are already different in some respect and searches in retrospect for the factor that brought about the difference. An *ex post facto* experiment, then, is a form of quasi-experiment.

One can discern two approaches to *ex post facto* research. In the first approach one commences with subjects who differ on an *independent* variable, for example, their years of study in mathematics, and then studies how they differ on the dependent variable, for example, a mathematics test. In a second approach, one can commence with subjects who differ on the *dependent* variable (e.g. their performance in a mathematics test) and discover how they differ on a range of independent variables, for example, their years of study, their liking for the subject, the amount of homework they do in mathematics. The *ex post facto* research here seeks to discover the causes of a particular outcome (mathematics test performance) by comparing those students in whom the outcome is high (high marks on the mathematics test) with students whose outcome is low (low marks on the mathematics test), after the independent variable has occurred.

Ary *et al*. (2006, p. 335) discuss 'proactive' and 'retroactive' *ex post facto* research designs. In the former, the subjects are grouped on the basis of the presence or absence of an independent variable, and then the researcher compares the groups in terms of the outcomes – the dependent variable. In the latter, the dependent variable is constant, and the researcher seeks to discover the independent variables that might have contributed to the outcome, hypothesizing about these independent variables and then testing them against the evidence. Figure 20.6 indicates these two main types of *ex post facto research* designs.

Here is an example of an *ex post facto* piece of research. It has been observed that staff at a very large secondary school have been absent on days when they teach difficult classes. An *ex post facto* piece of research was conducted to try to establish the causes of this. Staff absences on days when teaching difficult secondary classes were noted, thus:

	Days when teaching difficult secondary classes	
Absences	Yes	No
High	26	30
Low	22	50
Total	48	80
Overall total: 128		

Here the question of time was important: were the staff absent only on days when they were teaching difficult classes or at other times? Were there other variables that could be factored into the study, for example, age groups? Hence the study was refined further, collecting more data:

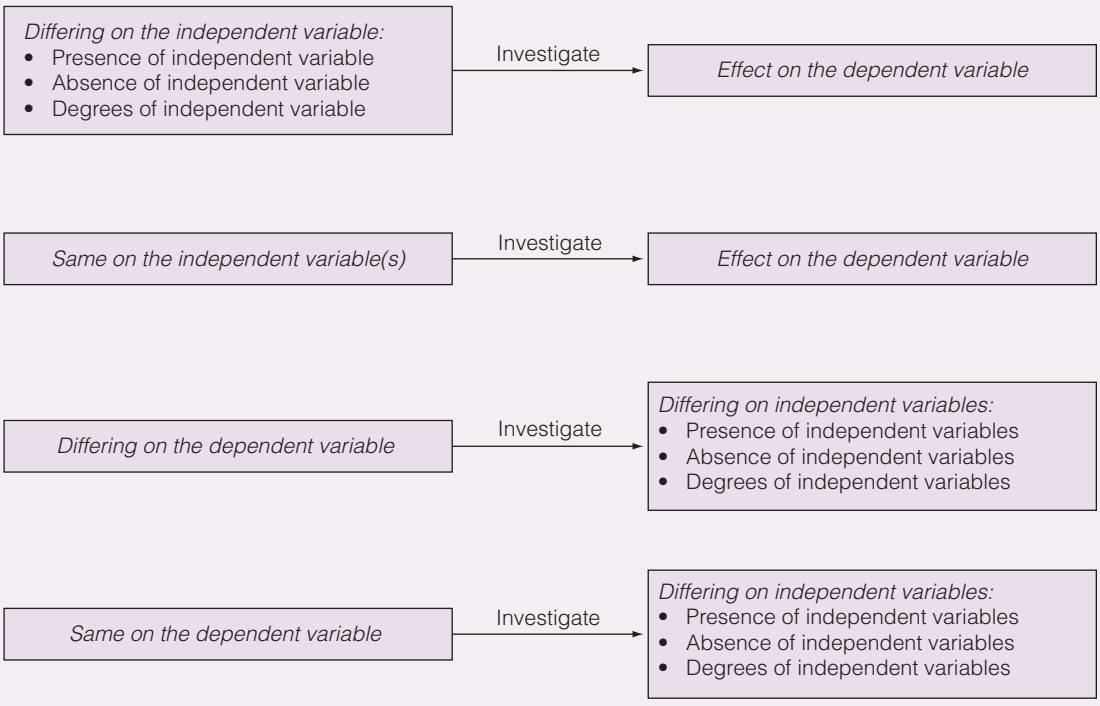

FIGURE 20.6 Four types of *ex post facto* research

Age	*Days when teaching difficult secondary classes*		*Days when not teaching difficult secondary classes*	
	High absence	*Low absence*	*High absence*	*Low absence*
<30 years old	30	6	16	10
30–50 years old	4	4	4	20
>50 years old	2	2	2	28
Total	36	12	22	58
Overall total: 128				

This shows that age was also a factor as well as days when teaching difficult secondary classes: younger people were more likely to be absent. Most teachers who were absent were under thirty years of age. Within age groups, it is also clear that young teachers had a higher incidence of excessive absence when teaching difficult secondary classes than teachers of the same (young) age group when they were not teaching difficult secondary classes.

Of course, a further check here would be to compare the absence rates of the same teachers when they did and did not teach difficult classes, and conduct difference tests (e.g. t-tests, ANOVA: see Chapter 41) to examine differences between the two sets of scores (days when difficult classes were taught and days when they were not taught; differences between age groups in respect of the days when difficult classes were and were not taught).

Co-relational and criterion groups designs

Two kinds of design may be identified in *ex post facto* research – the co-relational study and the criterion group study. The former is sometimes termed 'causal research' and the latter, 'causal-comparative research'. A co-relational (or causal) study is concerned with identifying the antecedents of a present condition. As its name suggests, it involves the collection of two sets of data, one of which will be retrospective, with a view to determining the relationship between them. The basic design of such an experiment can be represented thus (using the symbols from Campbell and Stanley (1963), where X = the independent variable and O = the dependent variable, discussed below):

$$X \rightarrow O$$

A study by Borkowsky (l970) was based upon this kind of design. He attempted to show a relationship between the quality of a music teacher's undergraduate training (*X*) and his subsequent effectiveness as a teacher of his subject (*O*). Measures of the quality of a music teacher's college training included grades in specific courses, overall grade average and self-ratings, etc. Teacher effectiveness was assessed by indices of pupil performance, pupil knowledge, pupil attitudes and judgement of experts, etc. Correlations between all measures were obtained to determine the relationship. At most, this study could show that a relationship existed, after the fact, between the quality of teacher preparation and subsequent teacher effectiveness. Where a strong relationship is found between the independent and dependent variables, three possible interpretations are open to the researcher:

1. that the variable *X* has caused *O*;
2. that the variable *O* has caused *X*; or
3. that some third unidentified, and therefore unmeasured, variable has caused *X* and *O*.

It is often the case that a researcher cannot tell which of these is correct. This raises the issue of the direction of causality: it is difficult in an *ex post facto* experiment to determine what causes what: whether A causes B or B causes A.

The value of co-relational or causal studies lies chiefly in their exploratory or suggestive character, for while they are not always adequate in themselves for establishing causal relationships among variables, they are a useful first step in this direction in that they do yield measures of association.

In the criterion-group (or causal-comparative) approach, the investigator sets out to discover possible causes of a phenomenon being studied, by comparing the subjects in which the variable is present with similar subjects in whom it is absent, i.e. noting the circumstances in which a given effect occurs and does not occur (Lord, 1973, p. 3). The basic design in this kind of study may be represented thus:

	O_1
X	
	O_2

If, for example, a researcher chose such a design to investigate factors contributing to teacher effectiveness, the criterion group O_1, the effective teachers, and its counterpart O_2, a group *not* showing the characteristics of the criterion group, are identified by measuring the differential effects of the groups on classes of children. The researcher may then examine *X*, some variable or event, such as the background, training, skills and personality of the groups, to discover what might 'cause' only some teachers to be effective.

Morrison (2009, p. 181) gives an example of a criterion-group piece of *ex post facto* research. He writes thus:

> Let us imagine, for example, that the researcher is seeking to establish the cause of effective teaching, and hypothesizes that one cause is collegial curriculum planning with other members of the department. The research could be designed as in Figure 20.7.
>
> Here there are two criterion groups: (a) the presence of collegial curriculum planning; and (b) the absence of collegial curriculum planning. By examining the difference in teaching effectiveness between those teachers (however one wished to measure 'effective teaching') who did and did not plan their curriculum with colleagues (collegial curriculum planning) one could infer a possible causal difference. But one has to be cautious: at most this is a correlational study and causation is not the same as correlation. Indeed … a third cause may be influencing both the effective/ineffective teaching and the presence/absence of collegial curriculum planning, e.g. staff sociability.
>
> (Morrison, 2009, p. 181)

The causal-comparative design is different from a historical design, in that the former is concerned with present events, whereas the latter traces the history of past events (Lord, 1973, p. 4).

Criterion-group or causal-comparative studies may be seen as bridging the gap between descriptive research methods on the one hand and true experimental research on the other.

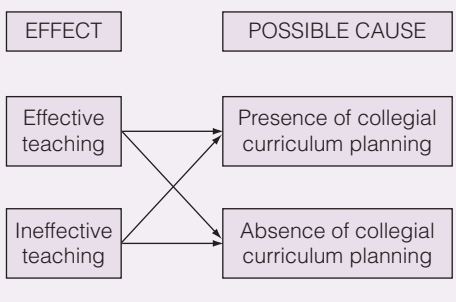

FIGURE 20.7 Two causes and two effects

Controls and causality

Other characteristics of *ex post facto* research become apparent when it is contrasted with true experimental research. Kerlinger (1970) describes the modus operandi of the experimental researcher. ('If *x*, then *y*' in Kerlinger's usage. We have substituted *X* for *x* and *O* for *y* to fit in with Campbell and Stanley's (1963) conventions throughout the chapter.) Kerlinger hypothesizes: if *X*, then *O*; if frustration, then aggression. Depending on circumstances and his own predilections in research design, he uses some method to manipulate *X*. He then observes *O* to see if concomitant variation, the variation expected or predicted from the variation in *X*, occurs (see also Chapter 6). If it does, this is evidence for the validity of the proposition 'if *X*, then *O*'. Note that the scientist here predicts from a controlled *X* to *O*. To help him achieve control, he can use the principle of randomization and active manipulation of *X* and can assume, other things being equal, that *O* is varying as a result of the manipulation of *X*.

In *ex post facto* designs, on the other hand, *O* is observed. Then a retrospective search for *X* ensues. An *X* is found that is plausible and agrees with the hypothesis. Due to lack of control of *X* and other possible *X*s, the truth of the hypothesized relation between *X* and *O* cannot be asserted with the confidence of the experimental researcher. Basically, then, *ex post facto* investigations have, so to speak, a built-in weakness: lack of control of the independent variable or variables. As Spector (1993, p. 43) suggests, it is impossible to isolate and control every possible variable, or to know with absolute certainty which are the most crucial variables.

The most important difference between experimental and *ex post facto* designs is control. In the experimental situation, investigators at least have manipulative control; they have as a minimum one active variable. If an experiment is a 'true' experiment, they can also exercise control by randomization. They can assign subjects to groups randomly; or, at the very least, they can assign treatments to groups at random. In the *ex post facto* research situation, this control of the independent variable is not possible, and, perhaps more important, neither is randomization. Investigators must take things as they are and try to disentangle them, though having said this, they can make use of selected procedures that will give them an element of control in this research. These we shall touch upon shortly.

By their very nature, *ex post facto* experiments can provide support for any number of different, perhaps even contradictory, hypotheses; they are so flexible that it is largely a matter of postulating hypotheses according to one's personal preference. The investigator begins with certain data and looks for an interpretation consistent with them; often, however, a number of interpretations may be at hand. Consider again the hypothetical increase in road accidents in a given town. A retrospective search for causes will disclose half-a-dozen plausible ones.

Experimental studies, by contrast, begin with a specific interpretation and then determine whether it is congruent with externally derived data. Frequently, causal relationships seem to be established on nothing more substantial than the premise that any related event occurring prior to the phenomenon under study is assumed to be its cause – the classical *post hoc, ergo propter hoc* fallacy ('after this, therefore because of this'); just because one variable precedes another in time, it does not follow that the first variable *causes* the second: I may drink coffee and then have a sleepless night, but it does not follow that drinking the coffee *caused* the sleepless night – there may have been other causes. Even when we do find a relationship between two variables, we must recognize the possibility that both are individual results of a common third factor rather than the first being necessarily the cause of the second.

As mentioned earlier, there is also the real possibility of reverse causation, for example, that a heart condition promotes obesity rather than the other way around, or that they encourage each other. The point is that the evidence simply *illustrates* the hypothesis; it does not test it, since hypotheses cannot be tested on the same data from which they were derived. The relationship noted may actually exist, but it is not necessarily the only relationship, or perhaps the crucial one. Before we can accept that smoking is the primary cause of lung cancer, we have to rule out alternative hypotheses.

Further, a researcher may find that playing computer games correlates with poor school performance. Now, it may be there is a causal effect here: playing computer games causes poor school performance; or there may be reverse causality: poor school performance causes students to playing computer games. However, there may be a third explanation: students who, for whatever reason (e.g. ability, motivation), do not do well at school also like playing computer games; it may be the third variable (the independent variable of ability or motivation) that is causing the other two outcomes (playing computer games or poor school performance).

We cannot conclude from what has just been said that *ex post facto* studies are of little value; many important investigations in education and psychology

are *ex post facto* designs. There is often no choice in the matter: an investigator cannot cause one group to become failures, delinquent, suicidal, brain-damaged or dropouts. Research must of necessity rely on existing groups. On the other hand, the inability of *ex post facto* designs to incorporate the basic need for control (e.g. through manipulation or randomization) makes them vulnerable from a scientific point of view and the possibility of their being misleading should be clearly acknowledged. Indeed, *ex post facto* designs are probably better conceived more circumspectly, not as experiments with the greater certainty that these denote, but more as surveys, useful as sources of hypotheses to be tested by more conventional experimental means at a later date.

Occasions when appropriate

Ex post facto designs are appropriate in circumstances where the more powerful experimental method is not possible. These arise when, for example, it is not possible to select, control and manipulate the factors necessary to study cause-and-effect relationships directly; or when the control of all variables except a single independent variable may be unrealistic and artificial, preventing the normal interaction with other influential variables; or when laboratory controls for many research purposes would be impractical, costly or ethically undesirable.

Ex post facto research is particularly suitable in social, educational and psychological contexts where the independent variable or variables lie outside the researcher's control. Examples of the method abound here: the research on cigarette-smoking and lung cancer, for instance; or studies of teacher characteristics; or studies examining the relationship between political and religious affiliation and attitudes; or investigations into the relationship between school achievement and independent variables such as social class, ethnicity, gender and intelligence. Such investigations may be large scale or small scale *ex post facto*.

For educational research, public domain databases and data sets can be used for conducting *ex post facto* educational research, for example, databases and data sets produced by:

- government agencies (e.g. www.gov.uk/government/statistics);
- research agencies (e.g. www.data-archive.ac.uk);
- consortia (e.g. www.socsciresearch.com/r6.html);
- organizations, for example:
  - The OECD: http://stats.oecd.org/index.aspx;
  - UNESCO (Institute for Statistics);
  - The PISA database (www.oecd.org/pisa/pisaproducts; https://nces.ed.gov/surveys/pisa);
  - The World Bank (statistics section);
  - The TIMSS database (http://nces.ed.gov/timss/datafiles.asp).

Advantages and disadvantages of *ex post facto* research

Among the advantages of the approach are the following:

- *ex post facto* research meets an important need of the researcher where the more rigorous experimental approach is not possible;
- the method yields useful information concerning the nature of phenomena – what goes with what and under what conditions. Here *ex post facto* research is a valuable exploratory tool;
- improvements in statistical techniques and general methodology have made *ex post facto* designs more defensible;
- in some ways and in certain situations the method is more useful than the experimental method, especially where the setting up of the latter would introduce a note of artificiality into research proceedings;
- *ex post facto* research is particularly appropriate when simple cause-and-effect relationships are being explored;
- the method can give a sense of direction and provide a fruitful source of hypotheses that can subsequently be tested by the more rigorous experimental method.

Among the limitations and weaknesses of *ex post facto* designs are the following:

- there is the problem of lack of control in that the researcher is unable to manipulate the independent variable or to randomize her subjects;
- one cannot know for certain whether the causative factor has been included or even identified;
- it may be that no single factor is the cause;
- a particular outcome may result from different causes on different occasions;
- when a relationship has been discovered, there is the problem of deciding which is the cause and which the effect; the possibility of reverse causation must be considered;
- the relationship of two factors does not establish cause and effect;
- the *ex post facto* hypothesis is generated after the data have been collected, so it is not possible to disconfirm it (Babbie, 2010, p. 462);

- classifying into dichotomous groups can be problematic;
- there is the difficulty of interpretation and the danger of the *post hoc* assumption being made, that is, believing that because *X* precedes *O*, *X* causes *O*;
- as the researcher attempts to match groups on key variables, this leads to shrinkage of sample (Spector, 1993, p. 43). (Lewis-Beck (1993, p. 43) reports an example of such shrinkage from a sample of 1,194 to 46 after matching had been undertaken);
- it often bases its conclusions on too limited a sample or number of occurrences;
- it frequently fails to single out the really significant factor or factors, and fails to recognize that events have multiple rather than single causes;
- as a method it is regarded by some as too flexible;
- it lacks nullifiability and confirmation.

Designing an *ex post facto* investigation

We earlier referred to the two basic designs embraced by *ex post facto* research – the co-relational (or causal) model and the criterion group (or causal-comparative) model. As we saw, the causal model attempts to identify the antecedent of a present condition and may be represented thus:

Independent variable	*Dependent variable*
X	O

Although one variable in an *ex post facto* study cannot be confidently said to depend upon the other as would be the case in a truly experimental investigation, it is nevertheless usual to designate one of the variables as independent (*X*) and the other as dependent (*O*). The left to right dimension indicates the temporal order, though having established this, we must not overlook the possibility of reverse causality. In a typical investigation of this kind, then, two sets of data relating to the independent and dependent variables respectively are gathered. As indicated earlier, the data on the independent variable (*X*) will be retrospective in character and as such will be prone to the kinds of weakness, limitations and distortions to which all historical evidence is subject.

For example, imagine a secondary school in which it is hypothesized that low staff morale (*O*) has come about as a direct result of school reorganization some two years earlier. A number of key factors distinguishing the new organization from the previous one can be identified. Collectively these could represent or contain the independent variable *X* and data on them could be accumulated retrospectively, for example, curricular innovation, loss of teacher status, decline in student motivation, modifications to the school catchment area or the appointment of a new headteacher. These could then be checked against a measure of prevailing teachers' attitudes (*O*), thus providing the researcher with some leads at least as to possible causes of current discontent.

Here the causal-comparative model may be represented schematically as:

Group	*Independent variable*	*Dependent variable*
E	X	O_1
C		O_2

Using this model, the investigator hypothesizes the independent variable and then compares two groups, an experimental group (*E*) which has been exposed to the presumed independent variable *X* and a control group (*C*) which has not. (The dashed line in the model shows that the comparison groups *E* and *C* are not equated by random assignment.) Alternatively, she may examine two groups that are different in some way or ways and then try to account for the difference or differences by investigating possible antecedents. We refer the reader to Chapter 6 on effect-to-cause investigations.

The basic design of causal-comparative investigations is similar to an experimentally designed study. The chief difference resides in the nature of the independent variable, *X*. In a truly experimental situation, this will be under the control of the investigator and may therefore be described as manipulable. In the causal-comparative model (and also the causal model), however, the independent variable is beyond her control, having already occurred. It may therefore be described in this design as non-manipulable.

Procedures in *ex post facto* research

Ex post facto research is concerned with discovering relationships among variables in one's data; and we have seen how this may be accomplished by using either a causal or causal-comparative model. We now examine the steps involved in implementing a piece of *ex post facto* research. We begin by identifying the problem area to be investigated. This stage will be followed by a clear and precise statement of the hypothesis to be tested or questions to be answered. The next step is to make explicit the assumptions on which the hypothesis and subsequent procedures will be based. A review of the research literature follows. This enables the investigator to ascertain the kinds of issues, problems, obstacles and findings disclosed by previous

studies in the area. There then follows the planning of the actual investigation and this consists of three broad stages – identification of the population and samples; the selection and construction of techniques for collecting data; and the establishment of categories for classifying the data. The final stage involves the description, analysis and interpretation of the findings.

Drawing on Lord (1973, p. 6), we can set out several stages in conducting an *ex post facto* piece of research:

Stage 1: Define the problem and survey the literature.
Stage 2: State the hypotheses and the assumptions or premises on which the hypotheses and research procedures are based.
Stage 3: Select the subjects (sampling) and identify the methods for collecting the data.
Stage 4: Identify the criteria and categories for classifying the data to fit the purposes of the study and which are as unambiguous as possible and which will enable relationships and similarities to be found.
Stage 5: Gather data on those factors which are always present in which the given outcome occurs, and discard the data in which those factors are not always present.
Stage 6: Gather data on those factors which are always present in which the given outcome does not occur.
Stage 7: Compare the two sets of data (i.e. subtract the former (Stage 5) from the latter (Stage 6)), in order to be able to infer the causes that are responsible for the occurrence or non-occurrence of the outcome.
Stage 8: Analyse, interpret and report the findings.

One has to bear in mind that the evidence illustrates rather than tests the hypothesis here (Lord, 1973, p. 7). It was noted earlier that the principal weakness of *ex post facto* research is the absence of control over the independent variable influencing the dependent variable in the case of causal designs or affecting observed differences between dependent variables in the case of causal-comparative designs. Although the *ex post facto* researcher is denied not only this kind of control but also the principle of randomization, she can nevertheless utilize procedures that provide some measure of control in her investigation; it is to some of these that we now turn.

One of the commonest means of introducing control into this type of research is that of matching the subjects in the experimental and control groups where the design is causal-comparative. Matched pair designs are careful to match the participants on important and relevant characteristics that may have a bearing on the research (for an example of this, see Leow, 2009). There are difficulties with this procedure, however, for it assumes that the investigator knows what the relevant factors are, that is, the factors that may be related to the dependent variable. Further, there is the possibility of losing those subjects who cannot be matched, thus reducing one's sample.

As an alternative procedure for introducing a degree of control into *ex post facto* research, the researcher can build the extraneous independent variables into the design and then use an analysis of variance technique. For example, if intelligence is a relevant extraneous variable but it is not possible to control it through matching or other means, then it could be added to the research as another independent variable, with the participants being classified in terms of intelligence levels. Through analysis of variance techniques the dependent variable measures would then be analysed to reveal the main and interaction effects of intelligence, indicating any statistically significant differences or effect sizes between the groups on the dependent variable, even though no causal relationship between intelligence and the dependent variable could be assumed.

Yet another procedure which may be adopted for introducing a measure of control into *ex post facto* design is that of selecting samples that are as homogeneous as possible on a given variable. For example, if intelligence were a relevant extraneous variable, its effects could be controlled by including participants from only one intelligence level. This would disentangle the independent variable from other variables with which it is commonly associated, so that any effects found could be associated justifiably with the independent variable.

Finally, control may be introduced into an *ex post facto* investigation by stating and testing any alternative hypotheses that might be plausible explanations for the empirical outcomes of the study. A researcher has to beware of accepting the first likely explanation of relationships in an *ex post facto* study as necessarily the only or final one. A well-known instance to which reference has already been made is the presumed relationship between cigarette smoking and lung cancer. Health officials were quick to seize on the explanation that smoking causes lung cancer. Tobacco firms, however, put forward an alternative hypothesis – that both smoking and lung cancer were possibly the result of a third factor, i.e. the possibility that both the independent and dependent variables were simply two separate results of a single common cause.

20.13 Conclusion

This chapter has introduced a range of different types of experiment. Starting with the randomized controlled trial, the 'true' experiment', it held this up as the

clearest example of a full experiment, as it abides by all the features of an experiment that is intended to yield evidence of 'what works'. The strengths and limitations of the true experiment and the randomized controlled trial were set out. Further variants of a true experiment were set out. Moving further out of the laboratory and into the 'real world', the chapter then presented a discussion of different types of quasi-experiment, i.e. those kinds of experiment in which not all the requirements of a true experiment were met or, in the case of *ex post facto* experiments or those which could not be justified on ethical or practical grounds, where the requirements of a true experiment were impossible to meet. Rendering an experiment a quasi-experiment rather than a true experiment was seen to lie not only in design matters, but also in issues of sampling and controls. The chapter introduced design experiments, or, as was argued to be more fittingly described, a design study, Internet experiments and their limitations, and a full overview of *ex post facto research*.

Meta-analysis, systematic reviews and research syntheses

CHAPTER 21

Harsh Suri

This chapter will explore:

- meta-analysis and the different stages of research synthesis
- systematic reviews
- methodologically inclusive research syntheses

21.1 Introduction

In contemporary educational research, most issues or interventions tend to be examined in a variety of contexts utilizing a diverse range of methodological approaches. Making sense of such complex domains of literature to inform policy, practice or further research can be challenging for decision makers and practitioners. As evidence-based education gathers pace, research syntheses are increasingly gaining prominence as valid methods for knowledge generation in their own right (Suri, 2014). Most high-ranking educational research journals have become open to publishing quality research syntheses. Many educational research journals also specifically focus on quality research syntheses. These include *Review of Educational Research*, *Australian Education Review*, *Educational Research Review*, *Research Synthesis Methods* and *Review of Education*.

Glass (1976) coined the term 'meta-analysis' to distinguish between three forms of analysis: primary analysis, secondary analysis and meta-analysis (p. 3). Primary research involves collecting and analysing fresh data; secondary analysis involves re-analysing data collected for primary research to answer different questions; and meta-analysis involves rigorous statistical integration of findings reported across a number of primary research studies. Meta-analysts employ explicit protocols to enhance consistency and objectivity through all stages. In the last four decades, popularity of meta-analyses has grown exponentially (Glass, 2006; Cooper and Hedges, 2009).

In popular areas of research, such as the effect of different interventions on student achievement, Hattie *et al*. (2014) note that on average, one primary research report gets published every hour. A number of meta-analyses have been conducted to examine the impact of individual interventions on student achievement. Making rigorous comparisons across the findings of a number of meta-analyses is a complex endeavour for which useful guidelines have been provided (Hattie *et al*., 2014). Hattie's visible learning series, based on the synthesis of more than 800 meta-analyses (Hattie, 2009), has generated significant interest among teachers and policy makers (see visible-learning.org).

While meta-analyses facilitate comparisons across quantitative studies by bringing them on a common metric called effect size, they are not suitable for synthesizing qualitative research. In a seminal research monograph, Noblit and Hare (1988) proposed meta-ethnography as an appropriate method for synthesizing a small number of qualitative research reports selected through the logic of purposeful sampling. Distinguishing features of their approach include an emphasis on being 'interpretive rather than aggregative' (p. 11); being inductive rather than using an a priori conceptual framework; employing purposeful sampling rather than exhaustive sampling for selecting primary research studies; being consciously aware of one's own subjectivity; and paying attention to the target audience's discourse (Noblit and Hare, 1988). The literature on guidelines for rigorous synthesis of qualitative research in education was relatively sparse until the early 2000s. In this century, excellent guidelines have been published by educational researchers for publishing qualitative research (e.g. Major and Savin-Baden, 2010; Suri, 2014).

Following the popularity of systematic reviews of research in medicine, evidence-based education and systematic reviews also became popular in education in the last two decades. In the past two decades, several large-scale centres have been established to support systematic reviews (e.g. Campbell Collaboration, n.d.; EPPI-Centre, n.d.). Early proponents of systematic reviews in education were meta-analysts who used randomized controlled trials as the gold standard for rigour. In recent years a number of systematic reviewers have included qualitative and mixed methods research.

Educational researchers espousing critical and interpretive orientations have made another important contribution to methods of research synthesis by questioning the rhetoric of systematic reviews and aggregative reviews and raising a concern over this rhetoric which undermines the contributions of other forms of conceptual reviews (Hammersley, 2001; Clegg, 2005; Kennedy, 2007).

Research synthesis is an umbrella term which includes a range of styles of bringing together into a single expert review or report several studies and summaries on a particular topic. The evidence, methodological perspectives and techniques employed in a research synthesis can be qualitative, quantitative or a combination of both. The purpose of a research synthesis is to produce new knowledge by making explicit connections and relations between individual reports that were not visible before. It involves purposeful selection, review, analysis and synthesis of previously published reports on a similar topic to draw conclusions that enable recommendations to be made for policy, practice and further research. In a rigorous synthesis, readers are provided with sufficient information about the synthesis process so that they can make informed decisions about the extent to which the synthesis findings may be adapted to their own contexts (Cooper and Hedges, 2009; Suri, 2014).

This chapter introduces key issues in the fields of meta-analysis, systematic reviews and methodologically inclusive research syntheses as part of the push towards evidence-based policy and practice in education.

21.2 Meta-analysis

Early meta-analysts criticized intuitive narrative reviews for not being comprehensive in their coverage; overly relying on significance tests and subjective judgements; being prone to Type II error and inconclusive findings; overlooking the magnitude of the effect sizes; and overlooking contextual variables that potentially moderate effect size (Jackson, 1980; Cook *et al*., 1992).

To reduce unstated subjectivity in aggregating findings from a range of separate and disparate primary research reports examining a similar concept or intervention, meta-analysts recommend an explicit adherence to scientific rigour in each of the following stages of research synthesis (Lipsey and Wilson, 2001; Glass, 2006; Cooper and Hedges, 2009):

- formulating a problem;
- searching for relevant literature;
- extracting relevant information from selected studies;
- integrating findings across studies;
- presenting the findings as a scientific report.

Meta-analysts have systematized the entire process of research synthesis by identifying the main tasks in each phase, highlighting critical decision points within each phase and allowing discussion of the relative merits of different choices at each decision point. They advocate explicit statement and justification of the decisions made at each stage of the research synthesis from hypothesis formulation, data selection, evaluation, analysis and interpretation, to public presentation. There are also several types of sensitivity analyses that can examine the dependence of the findings on the assumptions made about the nature of the data. Over the past three decades, meta-analysts have conducted numerous investigations to examine the robustness of their techniques and have explored ways of refining these techniques, as well as examining many substantive uses in the field of education. Meta-analysis now has become but one (important) method in integrative research synthesis.

Formulating a problem

Meta-analyses seek to discover both consistencies in similar-appearing primary studies and also to account for the variability found between them, leading to generalizations within the limits and contexts of the research studies used (Cooper and Hedges, 2009). The purpose of a meta-analysis is formulated in terms of a clear hypothesis with conceptual and operational definitions of key constructs, independent variables and dependent variables. Keeping in mind the intended audience, the contextual variation covered within the scope of the synthesis is explicitly stated. Meta-analysts note that statistical significance is easier to achieve with large samples than with small samples. Hence, they integrate findings across a number of primary research studies examining a conceptually similar hypothesis, by bringing them to a common metric called an effect size (Lipsey and Wilson, 2001).

In education, for example, a large number of primary research studies examines the effects of specific interventions on student achievement through experimental or quasi-experimental designs. Meta-analyses are particularly suitable for synthesizing effect sizes across a range of contexts reported in different studies examining a similar intervention, to estimate the cumulative effect size, the associated confidence intervals and the potential moderators of the effect size (Hattie *et al*., 2014).

Searching for relevant literature

In a meta-analysis, the criteria for inclusion and exclusion of primary research are explicitly stated. Comprehensive searches are conducted for relevant studies with explicit delineation of search protocols. While some meta-analysts argue that studies with relatively weak study designs ought to be excluded (Slavin, 2008), others insist that all research reports which meet the substantive selection criteria ought to be included in the synthesis, and an empirical examination should then be conducted of how different study design features moderate the effect size (Glass *et al*., 1981).

Meta-analysts have identified a number of publication biases and search biases along with strategies for taking these biases into account. A publication bias exists when the chances of a study being published depends on the nature of its methodological orientation or findings. A search bias exists when certain types of studies are more likely to be retrieved through common search channels, such as key databases. Studies with large sample sizes are more likely to attract research funding, being submitted for publishing and getting published in reputable journals. Research that does not report marked differences between individual groups or sub-groups examined within a study is less likely to be published (Rothstein *et al*., 2004). 'Sub-group reporting bias' exists when several sub-groups are compared but only comparisons with interesting or statistically significant findings get published. Similarly, 'time-lag bias' exists when certain types of studies, such as those with large sample sizes or effect sizes, take less time to get published (Sutton, 2009, p. 448). Unaccounted publication biases and search biases can lead to Type I error, leading to erroneous reporting of a large overall effect.

Extracting relevant information from selected studies

Meta-analysts follow explicit procedures for extracting relevant information from each study by developing protocols for coding contextual and outcome variables. Findings of individual studies are then converted to a common metric called an effect size, typically expressed as the difference of means between the experimental and control groups divided by the standard deviation. Algebraically,

$$(Me - Mc)/SD$$

where *Me* is the mean of the experimental group, *Mc* is the mean of the control group and *SD* is the pooled standard deviation. An effect size of $d=0.0$ is indicative of no change, while an effect size of $d=1.0$ is typically regarded as a blatantly obvious change (Cohen, 1988).

Meta-analytic literature contains sophisticated discussions of different types of effect sizes suitable for different study designs; formulae that allow conversion between different effect size indices; guidelines for estimating an effect size when some information is not reported in the primary research report; and appropriateness of various effect indices for analysing different types of data (Borenstein, 2009; Fleiss and Berlin, 2009).

Integrating findings across studies

Reasoning that findings from studies with large samples are more precise, often meta-analysts compute the composite effect by averaging the relevant d-statistics weighted by the reciprocal of their respective variances. Confidence intervals associated with the cumulative effect are also computed (Hedges and Olkin, 1985).

Within each category of conceptually similar effect sizes, the homogeneity statistic between the studies (Q_B) is estimated by assuming that Q_B has an approximate chi-square distribution with $m-1$ degrees of freedom, where m is the number of studies within each category. In rare cases, when the Q_B value is non-significant (indicating a consistency of outcomes across studies), the composite effect size is taken as a conclusive result representative of the within-category findings. However, often the Q_B value is significant, which indicates a considerable inconsistency across findings. In these cases, the composite effect size does not adequately describe the studies, since the magnitudes and perhaps the directions of the findings are very different from each other. These categories are analysed further to account for the differences in individual outcomes.

At this stage of the analysis, an outlier diagnosis is performed by visually plotting all the conceptually similar effect sizes to identify any effect size that markedly differs from the remaining effect sizes. If the study design of the outlier markedly differs from all the remaining studies, then the outlier is isolated and the difference in study design noted as a potential moderator of the effect size.

The remaining studies are subjected to categorical model testing, which is analogous to analysis of variance (ANOVA), to account for the heterogeneity of outcomes of different studies by identifying potential moderators of the effect. The studies are divided into sub-groups based on a study characteristic. Within each class, composite effect size and the within-group homogeneity statistic, Q_W, is estimated by assuming Q_W to have an approximate chi-square distribution with $k-1$ degrees of freedom, where k is the number of studies within each sub-group. A non-significant Q_W value indicates consistency of outcomes within a class. The

between-group homogeneity statistic (Q_B) is also estimated where a significant Q_B indicates that the study characteristic under consideration significantly moderates the effect size (Hedges and Olkin, 1985).

Meta-analysts sometimes conduct sensitivity analyses to 'assess robustness and bound uncertainty' (Orwin and Vevea, 2009, p. 196). In this procedure, the meta-analyst constructs connected understandings from the same data by making different assumptions about the data, including the missing data. The relative match between these constructed understandings demonstrates the degree to which these understandings are dependent on the initial assumptions made about the data. For instance, meta-analysts often compute inter-rater reliability in terms of multiple measures of inter-rater agreement; isolate outlier cases; isolate variables with low confidence ratings; use different formulae for computing or transforming effect sizes (e.g. Borman *et al*., 2003); and compare generalizations to the study sample based on a fixed effects model with generalizations to a large population based on a random effects model (e.g. Sirin, 2005). Meta-analysts employ various strategies to examine a potential publication bias (Sutton, 2009), such as: funnel plot method of plotting sample sizes of individual studies against their effect sizes; computing a fail-safe *n* (Rosenthal, 1980) to estimate the number of studies with insignificant findings that would have to be added to the analysis to make the cumulative effect size insignificant. Sensitivity analyses facilitate ratification and validation of conclusions geared for consensus and convergence.

There are several useful and cost-effective software programs for meta-analysis which offer many features including user-friendly menus to input information about an individual study's characteristics and data for computing effect sizes; compute and transform individual effect sizes; calculate cumulative effect sizes after appropriately adjusting relevant effect sizes; conduct homogeneity analyses, outlier diagnoses and categorical testing for identifying moderator variables; and conduct sensitivity analyses for comparing results based on different assumptions and analytic paths. See Shadish (n.d.) for a list of commonly used software for meta-analysis.

Presenting the findings as a scientific report

Meta-analysts typically employ the scientific reporting format with an explicit discussion of the critical decision points in the process. It typically has four distinct sections, i.e. Introduction, Methods, Results and Discussion. The meta-analyst begins with an identification and contextualization of the problem; describes their attempts to find the solutions; then they describe their findings using appropriate statistical and visual techniques; and finally they interpret and contextualize their findings (Cooper and Hedges, 2009).

21.3 Systematic reviews

In an age of evidence-based education, systematic reviews are increasingly used methods of investigation, bringing together different studies to provide evidence to inform policy making and planning (Gough *et al*., 2012). Several large centres have been established to support production and dissemination, for example:

- the EPPI-Centre (Evidence for Policy and Practice Information and Co-ordinating Centre) at the University of London (http://eppi.ioe.ac.uk/cms);
- the Social, Psychological, Educational and Criminological Controlled Trials Register (SPECTR) (Milwain, 1998; Milwain *et al*., 1999), later transferred to the Campbell Collaboration (www.campbellcollaboration.org), a parallel to the Cochrane Collaboration in medicine (www.cochrane.org), which undertakes systematic reviews and meta-analyses of, typically, experimental evidence in medicine;
- the Curriculum, Evaluation and Management (CEM) centre at the University of Durham (www.cemcentre.org);
- the What Works Clearinghouse in the US (http://ies.ed.gov/ncee/wwc);
- Centre for Reviews and Dissemination (www.york.ac.uk/crd); and
- Best Evidence Encyclopedia (www.bestevidence.org).

Like meta-analyses, systematic reviews use several techniques to minimize bias. They follow explicit protocols and criteria for searching for relevant primary, usually empirical studies, for example: their inclusion and exclusion; the standards for acceptable methodological rigour; their relevance to the topic in question; the scope of the studies included; team approaches to reviewing in order to reduce bias; the adoption of a consistent and clearly stated approach to combining information from across different studies; drawing careful, relevant conclusions and recommendations (Evans and Benefield, 2001).

In addition, systematic reviewers make noteworthy contributions to the methodology of research by embedding the following features in systematic reviews (Gough *et al*., 2012):

- according a greater agency of control to stakeholders in making decisions about how the synthesis should proceed;

- intention to regularly update their reviews with the new relevant studies in the field;
- intention to reduce duplication through explicit international collaborations;
- providing methodological support to groups interested in conducting systematic reviews;
- development of useful databases of intervention studies and systematic reviews to facilitate their dissemination and access; and
- utilizing technology strategically to update and disseminate relevant information widely.

There are two methodologically distinct perspectives prevalent among systematic reviewers. The first group is dominated by meta-analysts who recommend that ideally a systematic review must hold randomized controlled trials (RCTs) as the gold standard for individual studies (e.g. Campbell Collaboration, n.d.). The second group of systematic reviewers have engaged with various issues associated with including qualitative and mixed methods research in systematic reviews: developing efficient search strategies; appraisal criteria and synthesis techniques for research from different methodological traditions; engaging various stakeholders in formulating and critiquing their reviews' questions, protocols and summary reports; and stressing that systematic reviews must be complemented with other forms of reviews to facilitate informed decision making by different stakeholders (e.g. Petticrew and Roberts, 2006; Pope *et al*., 2007; Gough *et al*., 2012).

Since the mid-1990s, there has been a growing interest in systematic reviews of qualitative studies, especially in the areas of health care and public policy. A variety of methods have been proposed for synthesizing qualitative research from interpretive and critical-realist perspectives which vary along several dimensions (Barnett-Page and Thomas, 2009). Some methods have been developed to facilitate a fuller understanding of a phenomenon (Jensen and Allen, 1996) but others are aimed at generating mid-range theory (Eastabrooks *et al*., 1994; Zimmer, 2006) or 'lines-of-action' (Hannes and Lockwood, 2011a, p. 1633) to inform practical decision making. While some systematic reviewers recommend purposeful sampling for selecting studies, others recommend comprehensive searches and inclusion criteria. Some recommend including epistemologically similar qualitative studies in a synthesis; others recommend including studies from diverse epistemologies. And while many qualitative systematic reviewers recommend a grounded theory-like approach of axial coding for identifying themes emerging across studies, others note that a grounded theory-like approach to synthesizing research can sometimes become very resource-intensive and may not be viable. To improve efficiency, some systematic reviewers recommend starting with an a priori conceptual framework and modifying it as new themes emerge from the data (Carroll *et al*., 2011; Dixon-Woods, 2011).

Some systematic reviewers argue that in preference to quantitative or qualitative research syntheses, often 'mixed methods research syntheses' are more suitable for providing 'more complete, concrete and nuanced answers' to complex synthesis questions (Heyvaert, 2013, p. 671). Particularly noteworthy is Pawson's (2006) method of 'realist synthesis' to develop theory from successful as well as non-successful implementations of a programme. Rather than making global generalizations, realist reviews seek to explain how different aspects of a programme are likely to work in different circumstances. The reviewer begins by identifying the key theories underlying the specific phenomenon to formulate a more refined theory. Then the reviewer applies this theory successively to explain a number of successful and unsuccessful cases. With each application, the reviewer refines the theory. The salient features of Pawson's method include: purposeful sampling; including studies with diverse qualitative and qualitative designs; involvement of stakeholders in identifying the purpose; and tentative findings which inform decision makers of the likely implications of different decisions made in different situations rather than what works (Pawson, 2006).

21.4 Methodologically inclusive research syntheses

Meta-analyses and systematic reviews have made a substantial contribution towards advancing methods of research synthesis and have their own domains of applicability. Nonetheless, many systematic reviewers exclude a large proportion of research on the grounds of poor methodological quality, using evaluation criteria that are biased against certain paradigmatic orientations. Such an unacknowledged bias raises serious questions about the validity and generalizability of review findings (Pawson, 2006). Even in their inclusion of qualitative research, systematic reviewers often include only interpretive qualitative research and seek ideologically neutral evidence. The rhetorical effect of terms like 'evidence-based practice', 'systematic reviews', 'clarity', 'comprehensive', 'reliable', 'objectivity', 'replicable' not only might discredit opposition, but also may have the political impact of favouring post-positivism. Ironically, these key terms that are associated with systematic reviews are operationalized differently by different groups of systematic reviewers.

The problem here is not the subjectivity associated with these terms, but the systematic reviewers' denial of subjectivity itself (Hammersley, 2004).

Many systematic reviewers uncritically value objectivity and transparency of process, a priori protocols and exhaustive searches. Accordingly, advantages of emergent synthesis designs and purposeful sampling are less discussed in this body of literature. In reality, transparency itself is always subjective, partial and purposefully informed, where each way of showing is mirrored by a way of concealing, which may or may not be deliberate. Prescribing a priori rules to enhance objectivity, transparency and clarity could reduce the quality of reviews by discouraging reflection on important process decisions (MacLure, 2005; Kennedy, 2007). Hammersley (2003) observes that the phrase systematic reviews makes the other forms of reviews appear 'unsystematic', which can be misleading. Rather than categorizing reviews as 'systematic/unsystematic', he urges the educational research community to develop an appropriate typology for distinguishing between reviews with different foci (p. 5).

Recognizing the need to move beyond post-positivist reviews that often focus on constructing a coherent understanding of a field, there have been calls for reviews that challenge prevalent understandings, illuminate variations across contexts and highlight the tensions inherent in our understanding about a phenomenon (Eisenhart, 1998); reviews which reflexively interrogate the inequalities associated with educational research and practice (Meacham, 1998); and post-structural reviews that focus on constructing multiple understandings with a critical awareness that any understanding is inherently partial and situated within a particular perspective and time (Lather, 1999).

In critiquing the hegemonic dominance of systematic reviews, critical scholars alert us to several contentious issues, such as the problematics of formalization and systematization of research synthesis processes (e.g. Gallagher, 2004; MacLure, 2005), and power issues influencing how evidence is used (Clegg, 2005, p. 425). Many of these criticisms apply to most formal research synthesis methods and not just systematic reviews.

Suri (2014) draws upon the diverse literature on primary research methods and research synthesis methods to expand possibilities within research synthesis methods from a perspective of methodological inclusivity. Noting that contemporary educational research is marked by diversity, complexity and richness of purposes, methods and perspectives, she illuminates the variety of ways in which we can accommodate and reflect such variety and complexity at the level of synthesizing educational research.

Suri (2014) has identified the following three general guiding principles for a quality research synthesis:

1 informed subjectivity and reflexivity;
2 purposefully informed selective inclusivity;
3 audience-appropriate transparency.

Noting that each guiding principle will be enacted differently depending on the overarching epistemological and teleological orientation of the synthesis, Suri (2014) has clustered key decisions associated with the process of a research synthesis into six phases:

1 identifying an appropriate epistemological orientation;
2 identifying an appropriate purpose;
3 searching for relevant literature;
4 evaluating, interpreting and distilling evidence from selected reports;
5 constructing connected understandings;
6 communicating with an audience.

In the remainder of this chapter, key decisions associated with each of these phases of research synthesis are discussed from a methodologically inclusive perspective.

Phase one: identifying an appropriate epistemological orientation

There is no best-fit orientation for all research syntheses. The overarching orientation of the synthesis ought to be guided by the anticipated utility of the synthesis, the nature of primary research in the field and the synthesist's methodological expertise. The synthesist must attempt to make explicit the reflexive relationship between the synthesis findings and the synthesist's own research disposition. In Table 21.1, an illustrative framework of four epistemological orientations is used to demonstrate how syntheses with different paradigmatic orientations can serve varied, albeit equally useful, purposes.

The first row in Table 21.1 illustrates distinct ontological positions of a synthesis. The second row illustrates different purposes that a synthesis can serve. The third row illustrates potential relationships that a synthesist can have with participants and authors of primary research. Evidence included in a research synthesis is interpreted and represented first by the participants in primary research, then by the authors of primary research and finally by the research synthesist. Both participants and authors of primary research serve as informants for a research synthesist. The fourth row of Table 21.1 illustrates a range of strategies for searching and distilling relevant evidence and constructing
