Ontological position	Objective factual world is out there	World is constructed through meanings that individuals and groups attribute to events	Individuals and groups construct their own world views through participation	Relativistic and transitional world views reflective of dominant power structures
Amenable purposes	Objectively explain, predict or describe in terms of probabilistic, generalizable laws, facts or relations between measurable constructs and variables	Construct deeper and more comprehensive understanding about phenomena as experienced subjectively by different stakeholders	Understand and/or improve ourselves and our local world experientially through critical engagement	Problematize prevalent metanarratives to deconstruct and/or transform dominant discourses
Informant–synthesist relationship	Objective distancing of an unbiased expert	Sensitive and reflective understanding with minimal power imbalance	Critical, selective and creative understanding, emphasizing realistic transferability to inform local practice	Self-doubting and reflexive understandings of perspectives represented in, and missing from, primary research literature
Common strategies	Exhaustive sampling; a priori protocol and coding sheets; statistical variable-oriented analysis	Purposive sampling; emergent design; holistic case-oriented analysis; summary sheets, meta-matrices, reciprocal translations, etc.	Purposive sampling; emergent design; eclectic data analysis; emphasis on practical and experiential knowledge	Openly ideological, dialogic, dialectic selection and analysis of evidence, emphasis on historical and structural insights
Quality criteria	Validity and reliability	Deep and authentic understanding	Empower participants to improve locally	Catalytic validity or crystallization
Suitable genres	Scientific reporting format	Comprehensive narrative with thick descriptions	Interactive reporting	Nuanced texts celebrating intertextuality

connected understandings from the distilled evidence. The fifth row illustrates various quality criteria suitable for evaluating syntheses. The last row illustrates common genres that synthesists could employ to communicate with their audiences.

The four columns of Table 21.1 illustrate distinctions between research syntheses aligned with four distinct epistemological orientations: post-positivist syntheses; interpretive syntheses; participatory syntheses; critical syntheses. Boundaries between different orientations are blurred and rigid adherence to any single perspective is neither prescribed nor recommended. Nonetheless, synthesists should be critically aware of the implications of the choices they make, where some of these choices are likely to involve drawing from more than one paradigm.

Post-positivist syntheses: Often post-positivist synthesists, like meta-analysts, seek to synthesize research objectively with minimal researcher bias, by designing a priori synthesis protocols to minimize biases introduced by the synthesist's subjective preferences; defining conceptually and operationally all key constructs in behavioural terms at the outset; and employing exhaustive sampling in order to be representative of the entire population of studies. Sometimes post-positivist synthesists blind primary research reports to reduce biases introduced in judging the quality of individual reports by preconceived notions about the source of the publication or the author of the individual primary research report. Also, they measure inter-rater reliability to judge the degree of objectivity and reliability associated with the key decisions in the synthesis process

(Lipsey and Wilson, 2001; Orwin and Vevea, 2009; Wilson, 2009).

Post-positivist synthesists commonly employ variable-oriented statistical analyses to reduce Type II error and to enhance objectivity in the process of analysis and synthesis; target global decision makers and researchers as their audience; utilize the scientific reporting format; and adapt Cook and Campbell's (1979) constructs of validity and reliability to address issues of rigour in research synthesis. Sophisticated discussions have been published about ways of reducing threats to internal validity, external validity, internal reliability and external reliability within post-positivist syntheses (e.g. Petticrew and Roberts, 2006; Matt and Cook, 2009; see also Chapter 14 of the present volume).

Interpretive syntheses: In the last two decades, interpretive syntheses have been discussed under various names, such as meta-ethnography (Noblit and Hare, 1988), exploratory case-study oriented review of multivocal literatures (Ogawa and Malen, 1991), cross-case analysis (Miles and Huberman, 1994), aggregated analysis (Eastabrooks *et al*., 1994), meta-analysis of qualitative research (Jensen and Allen, 1994), qualitative meta-synthesis (Zimmer, 2006), interpretivist-oriented reviews (Eisenhart, 1998), meta-synthesis (Bair, 1999), meta-study (Paterson *et al*., 2001), thematic synthesis (Thomas and Harden, 2008) and framework synthesis (Carroll *et al*., 2011).

Contesting an objective reality that is out there, interpretive synthesists hold that the world is socially constructed in terms of the meanings we attribute to events. Typical questions addressed by an interpretive synthesist include: How do different stakeholders in different contexts experience a phenomenon? How do the contextual particularities interact with the perceptions of different groups and individuals? How do individual primary research reports on a topic reinforce, contradict or augment each other?

Interpretive synthesists begin by acknowledging the tacit knowledge, values and experiences that they bring to the synthesis process. They recognize that each primary research report is the author's interpretation of the research participants' interpretation of the phenomenon being studied. By engaging in iterative negotiations between multiple meanings constructed at each layer of interpretation and representation, they try to reveal the multiple perspectives of different stakeholders with a sensitive understanding. They seek evidence that contests, reinforces or augments their emerging understanding of the phenomenon. Refraining from the tendency to construct one coherent grand metanarrative, they remain open to constructing multiple understandings of the phenomenon (Paterson *et al*., 2001).

Participatory syntheses: Participatory synthesists encourage critical thinking through engaged participation with those whose practices and experiences are being researched. A complementary collaborative model, where the distinct skill sets and expertise of individual collaborators are valued, is suitable for encouraging participation of different stakeholders in a research synthesis, without burdening them with a heavier workload (Ritchie and Rigano, 2007; Yu, 2011). Rather than ironing out the differences, a participatory synthesis involves paying careful attention to learning opportunities that arise from the differences in language, perspectives and experiences of individual co-synthesists (Paugh and Robinson, 2011). A participatory synthesis can become a site for teachers where they collaboratively reflect on their own practice using published research as a mirror to develop 'actionable knowledge' about their own practice (Torrance, 2004, p. 198).

Participatory synthesists value practical experience, local knowledge and serendipitous leaps of intuitive understanding. Such participants could be: the authors of the primary research reports being synthesized; members of stakeholder groups who participated in those studies; or stakeholders wishing to engage critically with the literature to inform their own decisions. Academic synthesists collaborate with these participants in order to co-synthesize the relevant body of research through a process of reciprocal learning and co-constructing connected understandings. A participatory synthesis of action research reports authored by teacher-researchers or reflexive practitioners, on how they effected changes within their contextual constraints, can provide useful information to policy makers and other practitioners. Identifying patterns across these individual reports can provide useful input from this group of action researchers towards theory-building.

A participatory synthesis can involve: cycles of reflection to formulate synthesis purpose; conducting the research synthesis; implementing changes as suggested by the implications of the synthesis; evaluating the implemented change and comparing these evaluations with the relevant research literature. Using emergent, pragmatic and eclectic designs, participatory synthesists can employ purposeful sampling strategies for selecting studies which illuminate aspects of a phenomenon that are of immediate interest to the participant co-synthesists. They can use the delphi-technique for collecting, analysing and building collective understandings of research to involve a homogeneous or heterogeneous group of participants with a common interest in the research topic. Participatory synthesists can construct critical, selective and creative understandings with

realistic transferability to inform practice in local contexts of the participants. They can employ an interactive reporting format to encourage a participative audience. The synthesis can be evaluated in terms of the progress in thinking and transformation of the contexts of the individuals and the communities of those engaged in the synthesis process (see also Chapter 3 of the present volume). A practical example of some of these ideas can be seen in the work of Bassett and McGibbon (2012), who designed a critical, participatory and collaborative method for scoping literature with individuals who had been actively drawing attention to barriers to health and well-being in rural, Aboriginal and African Canadian communities in Canada.

Critical syntheses: Critical synthesists can reveal how certain forms of knowledge get privileged and regulate the norms within discussions of policy, practice and research in a field (Aronowitz and Giroux, 1991; Clegg, 2005; see also Chapter 3 of the present volume). By paying attention to the presence and absence of various issues in the primary research reports, critical synthesists can disrupt conventional thinking to construct spaces for new ways of talking about policy, practice and research (Eisenhart, 1998; Segall, 2001; Kress, 2011). A good example of a critical synthesis is Windschitl's theoretical analysis of research to illuminate the uncertainties and tensions experienced by teachers along with the compromises they make as they implement a constructivist pedagogy in practice (Windschitl, 2002, p. 131).

Through critical interrogation of the very text being synthesized and by constantly questioning the assumptions we make in constructing our understanding, critical synthesists could open new ways of thinking about a phenomenon. They can challenge the prevalent understanding by revealing the errors and elements of ignorance underpinning the prevalent understanding of a phenomenon. Rather than forcibly constructing a single coherent understanding of a phenomenon, critical synthesists could illuminate multiple understandings of a phenomenon to expand possibilities for practitioners (Sholle, 1992). Postmodern synthesists, as a sub-group of critical synthesists, could disrupt and problematize the metanarratives in a research domain in order to enhance multiple discourses that celebrate diversity and inclusivity by refusing to provide simplistic explanations for complex phenomena (Lather, 1993).

Examples of questions addressed by critical synthesists could include the following: What are the gaps in our understanding of a phenomenon? What methodologies or theoretical perspectives are likely and/or unlikely to be employed by primary researchers in the field? In the published literature, whose questions are prioritized? Whose questions have received little attention from primary researchers? How are the answers to such questions intertwined?

Critical synthesists could construct self-doubting and reflexive understandings of not only the perspectives represented in the primary research literature but also those missing from the published primary research to illuminate how some groups have become invisible in the field with little representation. Critical synthesists can also collaborate with the groups who have been relatively silenced in the primary research in order to identify how the body of primary research has failed to adequately represent their interests (see, e.g., Warschauer and Matuchniak, 2010). Rather than deferring to the *authority of the author*, postmodernist critical synthesists would recognize an author as someone who is in the process of making sense, a sense which is partial and temporal (Lather, 1999; Richardson, 2001).

Phase two: identifying an appropriate purpose

An emphasis on purposefully informed selective inclusivity necessitates that synthesists carefully identify a purpose that takes into account:

- potential stakeholders and collaborations;
- the nature of the substantive area;
- the intended audience and utility;
- pragmatic constraints;
- ethical considerations.

All these factors might influence, and be influenced by, the synthesist's contextual positioning and the overarching epistemological, theoretical and political orientations of the synthesis.

A number of groups can differentially influence or be affected by a research synthesis, including the following: learners, families of learners, educators and educational institutions, primary researchers in the substantive area, policy makers, the wider community, commercial and political groups with an interest in the topic. Funding agencies, editorial boards and communities, and professional synthesists can also feature in these groups.

Stakeholders in a synthesis are often anticipatory rather than retrospective. Synthesists can purposefully collaborate with diverse stakeholders to achieve some of the following objectives:

- encourage syntheses that address the concerns of a wide range of stakeholders;
- facilitate syntheses informed by the perspectives of different groups;

- empower members of different groups by facilitating their participation in syntheses which may be of interest to them;
- enhance the impact of a synthesis by promoting participation of the agents of change who are crucial in implementing the recommendations made by the synthesis;
- contribute to wider dissemination of research syntheses;
- deepen academic synthesists' understandings of the collaborating stakeholders' concerns and understandings.

Different collaborators have the potential to enrich the synthesis by bringing in their own particular expertise. Each form of collaboration also introduces issues of power and varied interests that can add complexity to the synthesis process (Yu, 2011). In a collaborative synthesis, synthesists must carefully negotiate issues arising from different perceptions of roles, responsibility, collaboration, authority and authorship (Baldwin and Austin, 1995).

When seeking input from stakeholders, synthesists should sensitively clarify the nature of input being sought and what can or cannot be negotiated; address power imbalances between different stakeholders; recognize heterogeneity within stakeholder groups; and ensure that less powerful groups do not feel further disempowered with the perception that their views are not being paid adequate attention (Petticrew and Roberts, 2006; Rees and Oliver, 2012).

Often, research synthesists begin by reading previous research reviews in the field. Previous reviews, along with their bibliographic references, can provide useful information for developing a broad overview of primary research and research syntheses reported in the field. In formulating an appropriate synthesis purpose, synthesists often consider: the topicality of the field; the nature of predominant methodologies employed in the primary research studies; the general relationship between individual studies; and the volume and scope of the relevant primary research. Paying careful attention to ethical issues of representation and non-representation, synthesists should formulate the purpose for an intended audience and synthesis goal.

Phase three: searching for relevant literature

Research synthesists draw their evidence from the primary research, secondary research and previous research syntheses reported in a field. Research syntheses on the same topic conducted for different purposes can have different sampling strategies, each being equally legitimate but tailored to serve different purposes. Synthesists must search strategically for the relevant evidence to meet the synthesis purpose efficiently within the available resources and pragmatic constraints.

Several publication biases and search biases can influence funding, publishing and visibility of certain types of primary research as well as research synthesis (Petticrew and Roberts, 2006). Funding bias, methodological bias, outcome bias and confirmatory bias are examples of publication bias. Database bias, citation bias, availability bias, language bias, country bias, familiarity bias and multiple publication bias are examples of search bias that must be considered in planning appropriate search techniques. Through a careful cost–benefit analysis, synthesists make decisions related to inclusion or exclusion of unpublished reports.

The terms 'exhaustive' and 'expansive' are sometimes used to distinguish between two approaches to searching for suitable studies in recent literature on qualitative evidence synthesis in health care (Finfgeld-Connett and Johnson, 2012). Exhaustive searches are more suitable for integrative syntheses aimed at producing generalizable findings. They are typically employed by meta-analysts and systematic reviewers. Expansive searches with purposeful sampling strategies are more suitable for syntheses with emergent designs, where the search criteria evolve as the synthesis progresses, and are aimed at facilitating understanding, participation, emancipation or deconstruction (Suri, 2011).

A clear set of inclusion criteria defines the scope of the synthesis. The level of specificity associated with the inclusion criteria at different stages of the synthesis may vary in accordance with the synthesis purpose. The synthesist must strategically choose and sequence the use of appropriate search channels in a way that is aligned with the sampling logic and which yields the most relevant, trustworthy and comprehensive evidence within the available resources.

Phase four: evaluating, interpreting and distilling evidence from selected studies

While some synthesists argue that all research reports which meet the substantive selection criteria ought to be included in the synthesis (e.g. Jensen and Allen, 1996; Glass, 2000), others insist that studies which have relatively weak study designs ought to be excluded (e.g. Eastabrooks *et al*., 1994; Slavin, 2008). All synthesists agree that findings from primary research that have stronger study designs should be given more weight in constructing collective understandings. Rather than asking 'Is this a perfect study?',

a synthesist ought to ask 'How do methodological features of this study impact upon the trustworthiness of its findings in ways that are relevant to my synthesis purpose?' Synthesists must examine each report closely for a coherence between its theoretical background, intended purpose, context and/or nature of intervention being studied, methods for collecting, analysing and interpreting evidence, results and conclusions. Equally important is the relevance of the report for the synthesis purpose (Dixon-Woods *et al*., 2006; Major and Savin-Baden, 2010).

In a rigorous synthesis, the set of evaluation criteria for individual studies is essentially guided by the overarching teleological and theoretical orientation of the synthesis. For example, studies with representative samples are suitable for generating generalizations. However, issues of how the views and voices of different stakeholders are represented become particularly important in an emancipatory synthesis. Useful discussions have been published for evaluating the quality of primary research reports stemming from different traditions, such as those for post-positivist research (e.g. Centre for Reviews and Dissemination, 2009; Valentine, 2009), interpretive research (Hannes *et al*., 2010), participatory research (Heron and Reason, 1997) and critically oriented research (Lather, 1986).

Ongoing reflexive engagement with the selected studies is crucial to reduce unaccounted or unacknowledged biases. While coding information from individual studies, synthesists can assign 'confidence ratings' to findings or insights that require higher levels of interpretation (Stock, 1994, p. 128). One approach to coding can be to assign each finding one of the following three codes based on the degree to which the finding is supported by reported evidence: compelling, credible and unsupported (Major and Savin-Baden, 2010). Decisions in relation to dealing with missing data or biased findings should be consistent, substantiated and disclosed.

To minimize unstated subjective biases, meta-analysts and systematic reviewers try to maintain consistency and transparency by adhering to a priori protocols. Research synthesists espousing critical orientations, on the other hand, stress that synthesists should reflexively respond to change, rather than rigidly follow an a priori protocol (Zhao, 1991; Pawson *et al*., 2005). A reflexive stance involves constantly reflecting critically on how the synthesist's own dispositions and perspectives are dialectically influencing, and being influenced by, the synthesis process and findings (MacLure, 2005).

Several authors recommend that the complexity of a research synthesis process requires collaborative efforts to ensure a certain level of trustworthiness: to minimize subjective judgements and biases by maximizing inter-coder reliability (Stock, 1994) or by deliberately critiquing and contesting each other's emerging understandings (Ogawa and Malen, 1991); as a form of triangulation to improve rigour (Eastabrooks *et al*., 1994); or for co-constructing collective interpretations through dialogic discussions (Wideen *et al*., 1998, p. 135; Paterson *et al*., 2001, p. 47).

Phase five: constructing connected understandings

While some research synthesis methods focus on variable-oriented connections, others focus on study-oriented connections. In variable-oriented connections, the variations in the effects, implementations, manifestations, meanings, understandings or conceptions of a phenomenon are the prime focus of a synthesis. Each account is examined to the extent that it contributes to explaining the relationships between the target variables. When several individual studies examine a particular intervention, concept or phenomenon using similar methodologies, the findings may be aggregated to increase size and variations of the overall sample. These findings can then be used to make generalizations, provide plausible explanations and predict patterns of human behaviour as in a meta-analysis or an aggregated analysis (Eastabrooks *et al*., 1994). Comparative techniques such as content analysis, statistical techniques and visual displays are commonly employed for constructing variable-oriented connections.

Study-oriented connections are amenable for constructing holistic and complex understandings with an attempt to retain the contextual integrity of individual accounts, as in Noblit and Hare's (1988) meta-ethnography. The focus here is on understanding the dynamics of individual accounts as the synthesist attempts to reconcile the dynamics of each study with those of the other studies. The synthesist tries to determine the relations and tensions between individual accounts through a dialectical process of comparing key constructs, phrases and themes used in each study as interpreted by each co-synthesist (Noblit and Hare, 1988).

When individual reports are addressing similar issues, they are amenable to a reciprocal translational synthesis to construct a collective understanding that captures the essence of all the included studies (Jensen and Allen, 1996; Paterson *et al*., 2001). The findings of each report are tested for their abilities to translate the findings of the other reports. Those terms or findings are selected which can more succinctly describe the findings of all the reports within the subset. When the synthesist has limited resources, the synthesist can

select an exemplary study and examine other studies for the extent to which they demonstrate or add to the description of the phenomenon in the exemplar study (Miles and Huberman, 1994).

When individual reports give conflicting representations of the same phenomenon, they lend themselves to a 'refutational synthesis' (Noblit and Hare, 1988, p. 47) where the relationships between individual studies and the refutations become the focus of the synthesis process. The contradictions between individual reports may be explicit or implicit. The implicit refutations are made explicit using an interpretive approach. This is followed by an attempt to explain the refutation.

If individual reports examine different aspects of the same phenomenon, a 'lines-of-argument' synthesis could be used to make inferences (Noblit and Hare, 1988). In this method, findings from individual reports are used as pixels to get a fuller picture of the phenomenon at hand. It involves a grounded theory-like approach for open-coding and identifying the categories emerging from the data. The key categories that are more powerful in representing the entire data set are identified by constant comparisons between individual accounts. These categories are then linked interpretively to create a holistic account of the phenomenon.

When synthesizing methodologically diverse reports, a synthesist can begin by constructing collective understandings from clusters of studies with similar designs and then synthesize collective understandings across clusters (Suri, 1999; Greenhalgh *et al*., 2005).

Study-oriented connections can also be implemented, as in Pawson's realist synthesis, by inferring theory from each study and examining its transferability to other cases to refine the initial theory. In a realist synthesis, this process is repeated with every study of successful and unsuccessful implementation to develop a more sophisticated and comprehensive theory that can explain many cases (Pawson *et al*., 2005).

Strategies for enhancing plausibility, authenticity, utility, robustness and validity of synthesis findings include:

- reflexivity;
- collaborative sense-making;
- eliciting feedback from key stakeholders;
- identifying disconfirming cases and exploring rival connections;
- sensitivity analyses and using multiple lenses to identify the dependence of a synthesis finding on underlying assumptions or the frame of reference.

Phase six: communicating with an audience

It is crucial that synthesists carefully select the content, representational style, medium, genre and techniques in alignment with the impact they wish to make on their target audience. They must share the process and the product of their sense-making skilfully and in a way that is credible, trustworthy and useful to the intended audience. A range of interesting, engaging and effective possibilities for communication can arise by embedding various representational tools within diverse structural genres expressed through varied media. As educational reviews are often seen to represent wider power relations, synthesists should be critically conscious of how a review may preferentially normalize certain representations or practices over the others (Baker, 1999).

Many synthesists, especially meta-analysts, employ the scientific reporting format with four distinct sections, i.e. Introduction, Methods, Results, Discussion. Many others use coherent thematic narratives to share their synthetic understandings with an audience. They construct their narrative by organizing into a coherent logical structure the main themes which contextualize and describe the synthesis process and product. These themes, headings and subheadings may vary purposefully according to: intervention types; methodological designs; contextual features (e.g. Engberg, 2004); types of descriptive commentaries such as retrospective, prospective or critical (e.g. Bransford and Schwartz, 1999); or the aspect of the synthesis process being described such as introduction, methods, results and discussion.

For each idea, theme or finding, synthesists should identify pertinent techniques for a rich, succinct and audience-friendly representation. Given the vast nature of evidence in research syntheses, descriptive statistics, abridged quotes and visual displays can be particularly useful tools. Synthesists can also choose from a range of narrative techniques and artistic devices.

Quality research synthesis reports generally share the following characteristics: conceptually substantiated and well-bound coverage of the substantive topic; rigorous critique of previous reviews; identification of common assumptions, theories, methods and findings emerging from extant research; critical analyses of extant research; coherent structuring of the report along meaningful themes; a unique conceptual framework or perspective to think about the topic, future research, practice and policy; clear implications for researchers, practitioners and policy makers; and a discussion of any caveats associated with synthesis findings to clarify its domain of applicability (Suri, 2014).

21.5 Conclusion

This chapter has discussed many of the key issues in carrying out meta-analysis, systematic review and methodologically inclusive research syntheses as an educational researcher. The chapter's central focus settles on the many critical decisions associated with each of six phases of a research synthesis, and these are discussed from a methodologically inclusive perspective. The strengths, complexities, domains of applicability and caveats of the different approaches have been discussed so that researchers can make their own informed choices about the kind of research approach they wish to adopt for a given project.

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Action research

CHAPTER 22

Action research is a widely used approach to research, as evidenced in the numerous journals whose titles bear the phrase 'action research'. The main aim of action research, as one of its key proponents, Elliott (1991), states, is 'to improve practice' (p. 49). It is a methodology for researchers (often teachers) to understand and generate knowledge about educational practices and their complexity (McAteer, 2013, p. 21).

In action research, typically teachers and other parties research their own institutions, staff development facilitators bring about change and groups and communities undertake research. This chapter introduces key issues in the planning, conduct and reporting of action research, including:

- defining action research
- principles and characteristics of action research
- participatory action research
- action research as critical praxis
- action research and complexity theory
- procedures for action research
- reporting action research
- reflexivity in action research
- ethical issues in action research
- some practical and theoretical matters

The chapter draws links between action research and critical theory, in particular in respect of participatory action research. It also notes the connections between action research and complexity theory.

22.1 Introduction

Action research is a useful tool for change and improvement at the local level. Indeed Kurt Lewin's own work (one of action research's founding fathers) was deliberately intended to change the life chances of disadvantaged groups in terms of housing, employment, prejudice, socialization and training. Its combination of *action* and *research* has contributed to its attraction to researchers, teachers and the academic and educational community, breaking the culture of 'spectator research' (Cain, 2011, p. 3) and 'ivory tower' research (Munn-Giddings, 2012, p. 71). Action research, as one of its leading proponents, Stephen Kemmis (2009) notes, seeks to change and transform 'practitioners' *practices*, their *understandings* of their practices, and the *conditions* in which they practice' (p. 463). It is a '*practice-changing practice*' (p. 464; italics in original; see also Kemmis *et al*., 2014). McAteer (2013) adds to this the point that, by being a collaborative process, it aims to become both a 'democratic and democratising process' (p. 17). Cain (2011) argues that action research moves beyond positivist, interpretive and critical research, being self-reflexive, collaborative, political and suitable for dissemination, for example, to other teachers (pp. 13–14). McNiff (2010) advises researchers to

> take action to improve something; make sure you understand what you have done; use understanding (knowledge) to give explanations for how and why you have improved it (in academic terms, this means that you generate new theory – the word 'theory' means explanation).
>
> (McNiff, 2010, p. 16)

Action research, she observes, is 'practice-based' (p. 33), concerns learning and the creation of knowledge, is 'values laden', 'educational', 'collaborative', 'critical and risky' and 'always political' (pp. 33–4), and she provides plentiful advice for researchers working in this mode.

Action research can be used in almost any setting where a problem involving people, tasks and procedures needs a solution, or where some change of feature results in a more desirable outcome. It embraces both problem posing and problem solving. It need not focus solely on problems; it can also embrace areas of interest for development (McNiff, 2010). It can be undertaken by the individual teacher, a group of teachers working cooperatively within one school or a teacher or teachers working alongside a researcher or researchers in a sustained relationship, possibly with other interested parties like advisers and university departments (Holly and Whitehead, 1986). Ferrance (2000)

identifies different levels of action research: individual teacher research, collaborative action research, school-wide action research and district-wide actions research (p. 6).

Action research can be used in a variety of areas, for example:

- *teaching methods*: replacing a traditional method by a discovery method;
- *learning strategies*: adopting an integrated approach to learning in preference to a single-subject style of teaching and learning;
- *evaluative procedures*: improving one's methods of continuous assessment;
- *attitudes and values*: encouraging more positive attitudes to work, or modifying pupils' value systems with regard to some aspect of life;
- *continuing professional development of teachers*: improving teaching skills, developing new methods of learning, increasing powers of analysis of heightening self-awareness;
- *management and control*: the gradual introduction of different techniques of class management;
- *administration*: increasing the efficiency of some aspect of the administrative side of school life.

It can be used to foster democratic institutions, encourage change, empower individuals and groups, encourage reflective practice and be a test-bed for new ideas and practices (Creswell, 2012, p. 578).

These examples do not mean, however, that action research can be typified straightforwardly; that is to distort its complex and multifaceted nature. Indeed Kemmis (2010) suggests that there are several schools of action research. That said, what unites different conceptions of action research is the desire for improvement to practice, based on a rigorous evidential trail of data and research.

Ferrance (2000, p. 1), echoing Watts (1985), argues that a powerful justification for action research is that teachers:

- work best on problems that they have identified for themselves;
- become more effective when they are encouraged to examine and assess their own work and then consider ways of working differently;
- help each other by working collaboratively;
- help each other in their professional development by working together.

She suggests that action research builds on, and builds in, these principles. Indeed action research is a potent form of participatory research (see Chapter 3; Kapoor and Jordan, 2009). 'Commitment' is a feature of participatory research (see Chapter 3), and participatory action research both requires and builds commitment (David, 2002). Participatory research breaks the separation of the researcher and the participants; power is equalized and, indeed, they may all be part of the same community. The research becomes a collective and shared enterprise in many spheres, including: research interests, agendas and problems; generation and analysis of data; equalization of power and control over the research outcomes, products and uses; development of participant voice, authorship and ownership; emancipatory agendas and political goals; a process-orientated and problem-solving approach; and ethical responsibility and behaviour. We refer the reader to Chapter 3 for a fuller discussion of this.

22.2 Defining action research

Action research comes in many forms, including action research, participatory action research, critical action research, diagnostic action research, practitioner research, classroom-based action research, empirical action research and many others (e.g. Jefferson, 2014). It is typically a small-scale intervention in the functioning of the 'real' world and a systematic, close examination, monitoring and review of the effects of such an intervention, combining action and reflection to improve practice (cf. Ebbutt, 1985, p. 156; Hopkins, 1985, p. 32; New South Wales Department of Education and Training, 2010). When operating with collaborative groups of teachers, it is designed to address collective improvement and development. Action research is an investigation which is intentionally directed towards solving a problem or focusing on an issue raised by, and owned by, an individual or a group (Kemmis and McTaggart, 1988, p. 5; McNiff, 2010). It has a deliberately applied focus (Creswell, 2012, p. 577) and is 'hands on' research (Denscombe, 2014, p. 122).

Piggot-Irvine *et al*. (2015) define action research as 'a collaborative transformative approach with joint focus on rigorous data collection, knowledge generation, reflection and distinctive action/change elements that pursue practical solutions' (p. 548). This draws attention to two key points taken up further in this chapter: the collaborative, emancipatory claims of action research, and its practical outcomes in terms of bringing about change.

The rigour of action research is attested by one of its founding fathers, Corey (1953, p. 6), who argues that it is a process in which practitioners study areas for development *scientifically* (our italics) so that they can

evaluate, improve and steer decision making and practice. (Helskog (2014) discusses the debate as to whether or not action research is a science and what the implications of this debate are in regard to justifying action research.) Kemmis and McTaggart (1992, p. 10) argue that action research requires systematic planning, acting, observing and reflecting in a manner that is more demanding and rigorous than in the everyday course of life.

A philosophical stance on action research that echoes the work of Habermas is taken by Carr and Kemmis (1986, p. 162), who regard it as a form of 'self-reflective enquiry' by participants which is undertaken in order to improve their understanding of their practices with a view to maximizing social justice (see also Gibbs *et al*., 2016). Grundy (1987, p. 142) regards action research as concerned with improving the 'social conditions of existence'. Kemmis and McTaggart (1992) suggest that action research is concerned with changing both individuals and the institutions, societies and cultures of which they are members.

Action research is designed to bridge the gap between research and practice (Somekh, 1995, p. 340), thereby striving to overcome the perceived persistent failure of research to impact on, or improve, practice. Stenhouse (1979) suggests that action research should contribute not only to practice but to a theory of education and teaching which is accessible to other teachers, making educational practice more reflective (Elliott, 1991, p. 54).

Action research combines diagnosis, action and reflection (McNiff, 2010), focusing on practical issues that have been identified by participants and which may somehow be both problematic yet capable of being changed (Elliott, 1978, pp. 355–6). McNiff (2010) places self-reflection at the heart of action research, suggesting that whereas in some forms of research, the researcher 'does research on other people', in action research, the researcher does it to herself/himself. Jefferson (2014) notes that key assumptions of action research include that 'practitioners work best on problems that they have identified themselves' and that they increase their effectiveness if they examine and 'assess their own work and then consider ways of working differently' (pp. 91–2) and work collaboratively, thereby developing their professional practices. Ferrance (2000) and McNiff (2010) note that it is not concerned simply with solving problems ('what is wrong'; p. 2) but is more concerned with how to improve. As Zuber-Skerritt (1996b, p. 83) remarks: 'the aims of any action research project or program are to bring about practical improvement, innovation, change or development of social practice, and the practitioners' better understanding of their practices'.

The several strands of action research are drawn together by Kemmis and McTaggart (1988) in their view of action research as a type of critical reflective enquiry which participants undertake on and for themselves, focusing on problems and practices which they identify themselves and which affect them, with the intention of understanding and improving the educational and social practices in which they are involved and the circumstances in which they take place, in order to promote social justice; it is undertaken collaboratively, albeit sometimes focusing on individuals in the group (p. 5).

Kemmis and McTaggart (1992, pp. 21–2) distinguish action research from the everyday actions of teachers: in four main ways:

- it is thinking in a more systematic and collaborative way than the customary, everyday ways in which teachers consider their own practices;
- it moves beyond problem solving alone to identifying and raising problems, regarding problem solving as opportunities for change, learning and improvement rather than as simply curing ills (a pathological model);
- it involves participants working on their self-identified areas of work, i.e. it is owned by the participants rather than external researchers;
- it adopts a heterogeneous rather than unitary concept of the science of teaching.

Noffke and Zeichner (1987) make several claims for action research with teachers, namely that it: brings about changes in their definitions of their professional skills and roles; increases their feelings of self-worth and confidence; increases their awareness of classroom issues; improves their dispositions towards reflection; changes their values and beliefs; improves the congruence between practical theories and practices; and broadens their views on teaching, schooling and society.

Action research lays claim to the professional development of teachers; action research for professional development is a frequently heard maxim (e.g. Somekh, 1995, p. 343, 2006; Winter, 1996; Ferrance, 2000; New South Wales Department of Education and Training, 2010). It is 'situated learning': learning *in* the workplace, *about* the workplace and *for* the workplace (cf. Collins and Duguid, 1989; NSW Department of Education and Training, 2010). The claims for action research, then, are several. Arising from these claims and definitions are several principles.

22.3 Principles and characteristics of action research

Hult and Lennung (1980, pp. 241–50), McKernan (1991, pp. 32–3), Ferrance (2000), the New South Wales Department of Education and Training (2010) and Kemmis *et al*. (2014) suggest that action research:

- makes for practical problem posing and problem solving as well as expanding scientific knowledge;
- enhances the competencies of participants;
- is collaborative;
- is undertaken directly *in situ*;
- uses feedback from data in an ongoing cyclical process;
- seeks to understand particular complex social situations;
- seeks to understand the processes of change within social systems;
- is undertaken within an agreed framework of ethics;
- seeks to improve the quality of human actions;
- focuses on those problems that are of immediate concern to practitioners;
- is participatory;
- frequently uses case study;
- tends to avoid the paradigm of research that isolates and controls variables;
- is formative, such that the definition of the problem, the aims and methodology may alter during the process of action research;
- includes evaluation and reflection;
- is methodologically eclectic;
- contributes to a science of education;
- strives to render the research useable and shareable by participants;
- is dialogical and celebrates discourse;
- has a critical purpose in some forms;
- strives to be emancipatory.

Zuber-Skerritt (1996b, p. 85) suggests that action research is: *critical* (and self-critical) collaborative inquiry by *reflective* practitioners being *accountable* and making results of their enquiry public, *self-evaluating* their practice and engaging in *participatory* problem solving and continuing professional development. This is echoed in Winter's (1996, pp. 13–14) six key principles of action research:

1. *reflexive critique*, which is the process of becoming aware of our own perceptual biases;
2. *dialectical critique*, which is a way of understanding the relationships between the elements that make up various phenomena in our context;
3. *collaboration*, which is intended to mean that everyone's view is taken as a contribution to understanding the situation;
4. *risking disturbance*, which is an understanding of our own taken-for-granted processes and willingness to submit them to critique;
5. *creating plural structures*, which involves developing various accounts and critiques, rather than a single authoritative interpretation;
6. *theory and practice internalized*, which is seeing theory and practice as two inter-dependent yet complementary phases of the change process.

Action research has been compared to, and claimed to differ from, 'formal research' in several respects (New South Wales Department of Education and Training, 2010, p. 1), for example: it requires little training (whereas formal research often requires extensive training); its intention is to focus on a local, institutional situation or practice with the intention of improving practice, in contrast to those kinds of research which seek generalizability; the sample comprises the relevant participants in the institution or situation rather than representing the wider population or being drawn randomly from the wider population; and it is of practical rather than theoretical significance.

Action research resists the criticism that it is not 'proper research' (Somekh, 2006), as it abides by many of the tenets of research (e.g. hypothesis generation and testing, new ways of looking at problems, generating knowledge, rigorous investigation) and, indeed, it benefits from insider knowledge. Similarly, Casey (2013) notes that action research benefits from being conducted by 'someone native to the field' and with action taken 'at the site where practice occurs' (p. 149). Teachers, for example, do it to and for themselves, becoming part of their everyday practices (p. 149).

The several features that the definitions at the start of this chapter have in common suggest that action research has key principles. These are summarized by Kemmis and McTaggart (1992, pp. 22–5), when they aver that action research:

- seeks to improve education by deliberately and deliberatively trying to change it, focusing on improving participants' own practices collaboratively and with consequent learning from these changes and their involvement in the process;
- involves ongoing, systematic and ongoing developmental cycles of planning, implementing, observing and reflecting (self-reflection) on changes. Such actions contribute to collaborative communities of

practitioners which are characterized by their self-critical reflection on, and insights into, relationships between contexts, actions and outcomes, and which promote emancipation, empowerment, legitimation and social justice in participants', others' and institutions' educational values and practices, thereby constituting a political process and endeavour;
- requires participants to enquire into and theorize about the conditions of, and circumstances and practices in, their own lives. In this process, their ideas, values and assumptions are tested against rigorous evidence in an open-minded, evidence-based, critical-analytical and reflexive spirit;
- leads to the development of a clearly justified, justifiable, reasoned, evidence-based rationale for educational practices;
- can begin small-scale, even on an individual or small-group level, and can spiral out to affect and involve others in communities of practice, thereby engaging issues of power and empowerment in decision making.
- can benefit from careful records of changes and improvement, the processes involved in making them, ways of perceiving and understanding them, the social relationships involved in them, and raised awareness of constraints on situations and participants.

Though these principles find widespread support in the literature on action research, they require some comment. For example, there is a strong emphasis in these principles on action research as a cooperative, collaborative activity (rather than an individualistic activity) (Kemmis and McTaggart, 1992, p. 15). Indeed Kemmis and McTaggart (1992) locate this in the work of Lewin himself, commenting on his commitment to group decision making (p. 6). They argue, too, that it is those groups who are involved in, or affected by, planned interventions and changes who should bear the prime responsibility for taking decisions on actions, based on reasoned, interrogated, evidence-based analysis and evaluation (p. 15).

The view of action research solely as a group activity, however, might be too restricting. It is possible for action research to be an individualistic matter as well, relating action research to the 'teacher-as-researcher' movement (Stenhouse, 1975; Pring, 2015). Whitehead (1985, p. 98) explicitly writes about action research in individualistic terms, and we can take this to suggest that a teacher can ask herself or himself: 'What do I see as my problem?' 'What do I see as a possible solution?' 'How can I direct the solution?' 'How can I evaluate the outcomes and take subsequent action?'

The adherence to action research as a group activity derives from several sources. *Pragmatically*, Oja and Smulyan (1989, p. 14), in arguing for collaborative action research, suggest that teachers are more likely to change their behaviours and attitudes if they have been involved in the research that demonstrates not only the need for such change but that it can be done – the issue of 'ownership' and 'involvement' that finds its parallel in management literature which suggests that those closest to the problem are in the best position to identify it and work towards its solution (e.g. Morrison, 1998).

Ideologically, there is a view that those experiencing the issue should be involved in decision making, itself hardly surprising given Lewin's own work with disadvantaged and marginalized groups, i.e. those groups with little voice (cf. David, 2002).

Politics and ideology are brought together in *participatory action research* and *action research as critical praxis*, and it is to this that we turn.

22.4 Participatory action research

Some researchers differentiate action research from participatory action research, the latter being a more specific subset of action research, whilst other researchers make no such distinction (Munn-Giddings, 2012, p. 72). Participatory action research has attracted attention across the world in its advocacy of democracy, empowerment and emancipation (cf. David, 2002; Jones and Stanley, 2010). Kemmis and McTaggart (2005) comment that participatory action research seeks to create conditions for people to work together collaboratively in the search for valid, authentic and morally correct and appropriate ways of understanding the world and participating in it (p. 578). Whereas some action research focuses on individuals, participatory action research is communitarian and social, seeking to bring about social change and improvement to the quality of people's lives (Creswell, 2012, pp. 582–3).

McTaggart (1989), Kemmis and McTaggart (2005), Locke *et al*. (2013) and Kemmis *et al*. (2014) suggest several tenets of participatory action research, indicating that it is a social process that focuses on the relationship between individuals and their social environment. It is deliberately practical, seeking to improve social practice and people by having them work on themselves. In doing this it requires authentic participation and is collaborative, establishing self-critical, non-hierarchical communities and partnerships. It is also a recursive and systematic process of learning, with planning, action, analysis and reflection leading to further planning, action, analysis and reflection. This involves

people in theorizing about their own practices and values, testing their own assumptions, values, ideas and practices in real-life practice; in other words it is reflexive, drawing together theory and practice. Participatory action research requires participants to build and keep evidential records of practice, theory and reflection and to provide a reasoned justification to others for their work. These, in turn, require participants to look at and document their own experiences objectively. Participatory action research is part of a political process (e.g. towards democracy) and involves people in making critical analyses of a situation, research and practice. It starts small and in small cycles, with small groups of people, and is critical and emancipatory, with participants addressing and interrogating unjust social structures which limit people's development and self-realization. It also disseminates findings to other practitioners and networks.

For Kemmis *et al*. (2014), adopting a critical/critical theory approach is a *sine qua non* of participatory action research, the major aim of which is to change from practice to praxis (committed, informed, self-realizing action, 'practical philosophy' which links theory, thinking and practice (Carr, 2005)), inspired by the language and operation of possibility, solidarity, open communication and freedom from dominatory and oppressive social conditions.

That there is a coupling of the ideological and political debate here has been brought into focus with the work of Freire (1972) and Torres (1992, p. 56) in Latin America, the latter setting out several principles of participatory action research:

- it commences with explicit social and political intentions that articulate with the dominated and poor classes and groups in society;
- it must involve popular participation in the research process, i.e. it must have a social basis;
- it regards knowledge as an agent of social transformation as a whole, thereby constituting a powerful critique of those views of knowledge (theory) as somehow separate from practice;
- its epistemological base is rooted in critical theory and its critique of the subject/object relations in research;
- it must raise the consciousness of individuals, groups and nations;
- it must lead to transformation and emancipation.

Participatory action research does not mean that all participants need to be doing the same. This recognizes a role for the researcher as facilitator, guide, formulator and summarizer of knowledge, raiser of issues (e.g. the possible consequences of actions, the awareness of structural conditions) (Weiskopf and Laske, 1996, pp. 132–3).

Participatory action research is distinguished not only by its methodology (collective participation) and its outcomes (democracy, voice, emancipation), but by its areas of focus (inequalities of power, grass-roots agendas for change and development, e.g. educational inequality, social exclusion, sexism and racism in education, powerlessness in decision making, student disaffection with a socially reproductive curriculum, elitism in education) and its intention to change society and social situations (cf. Fine, 2010; INCITE, 2010; Kemmis, 2010; Kemmis *et al*., 2014). Importantly here, the agendas and areas of focus are identified by the participants themselves, so they are rooted in reality, are authentic and are 'owned' by the participants and communities themselves.

Participatory action research – people acting and researching on, by, with and for themselves – is a democratic activity (Grundy, 1987, p. 142; David, 2002; Jones and Stanley, 2010; Kemmis *et al*., 2014). This form of democracy is participatory (rather than, for example, representative): a key feature of critical research (and Lewin – a key early figure in action research – advocated democratic workplaces) (Jefferson, 2014, p. 93). It is not merely a form of change theory, but addresses fundamental issues of power and power relationships, for, in according power to participants, action research is an empowering activity (David, 2002; Kemmis *et al*., 2014). Elliott (1991, p. 54) argues that such empowerment has to be at a collective rather than an individual level, as individuals do not operate in isolation from each other, but are shaped by organizational and structural forces.

The issue is important, for it begins to separate action research into different camps (Kemmis, 1997, p. 177). On the one hand are long-time advocates of action research such as Elliott (e.g. 1978, 1991) who, in the tradition of Schwab and Schön, emphasize reflective practice; this is particularly so in curriculum research with notions of the 'teacher-as-researcher' (Stenhouse, 1975) and the reflective practitioner (Schön, 1983, 1987). On the other hand are advocates of the 'critical' action research model, for example, Carr and Kemmis (1986), Kemmis *et al*. (2014).

22.5 Action research as critical praxis

Much of the writing in this type of action research draws on the Frankfurt School of critical theory (see Chapter 3), in particular the early work of Habermas.

(Kemmis (2006) addresses some of the later work of Habermas in his (Habermas's) concern for the 'public sphere'.) Indeed Weiskopf and Laske (1996, p. 123) and Kemmis *et al*. (2014) locate action research, in the German tradition, squarely as a 'critical social science' with an emancipatory interest: to challenge and thence to transform unjust and repressive, alienating social structures. Using Habermas's early writing on knowledge-constitutive interests (1972, 1974), a three-fold typology of action research can be constructed which comprises technical, practical and emancipatory (critical) interests; the classification was set out in Chapter 3, and is the basis for the seminal works of Carr and Kemmis (1986) and Grundy (1987) in the field of action research.

The work of Carr and Kemmis (1986) fuelled a tradition of critical action research and its 'explanatory, normative and practical dimensions' (Hawkins, 2015, p. 466). Critical theory advocates the understanding and ideological interrogation of social conditions, and aims to bring about democracy, equality and social justice, partly by exposing and working on the understandings of participants who are seeking such emancipation and societal transformation and also by looking at the 'conditions of possibility' (p. 466) for such to occur.

Grundy (1987, p. 154) argues that 'technical' action research is designed to render an existing situation more efficient and effective, to improve outcomes of practice (Kemmis, 2009, p. 469). In this respect it is akin to Argyris's notion of 'single-loop learning' (Argyris, 1990), being functional, often short-term and technical. It is also akin to Schön's (1987) notion of 'reflection-in-action' (cf. Luttenberg *et al*., 2016). Elliott (1991, p. 55) suggests that this view is limiting for action research since it is too individualistic and neglects wider curriculum structures, regarding teachers in isolation from wider factors.

By contrast, 'practical' action research is designed to promote teachers' professionalism by drawing on their informed judgement to enable them to act more wisely (Grundy, 1987, p. 154; Kemmis, 2009, p. 470). This underpins the 'teacher-as-researcher' movement, inspired by Stenhouse (cf. Pring, 2015). It is akin to Schön's 'reflection-on-action' and is a hermeneutic activity of understanding and interpreting social situations with a view to their improvement (Luttenberg *et al*., 2016). Echoing this, Kincheloe (2003, p. 42) suggests that action research rejects positivistic views of rationality, objectivity, truth and methodology, preferring hermeneutic understanding (phronesis) (Thomas, 2010) and emancipatory practice. As Kincheloe notes (p. 108), the teacher-as-researcher movement is a political enterprise rather than the accretion of trivial cookbook remedies (a technical exercise). Indeed Luttenberg *et al*. (2016) regard reflection on action as a moral activity, not simply a technical-instrumental matter. Marshall and Rossman (2016) state very clearly (p. 26) that action research eschews the claimed neutrality and objectivity of traditional research in favour of promoting values-based change in their own institutions.

Emancipatory action research has an explicit agenda which is as political as is it educational, promoting social justice (Gibbs *et al*., 2016). Grundy (1987) argues (pp. 146–7) that such emancipatory action research seeks to develop in participants their understandings of illegitimate structural and interpersonal constraints that are preventing the exercise of their autonomy and freedom. These constraints, she argues, are based on illegitimate repression, domination and control. When participants develop a consciousness of these constraints, she suggests, they begin to move from unfreedom and constraint to freedom, autonomy and social justice.

Kincheloe (2003, pp. 138–9) clarifies emancipatory action research as:

- constructing a system of meaning;
- understanding dominant research methods and their effects;
- selecting what to study;
- acquiring a variety of research strategies;
- making sense of information collected;
- gaining awareness of the tacit theories and assumptions which guide practice;
- viewing teaching as an emancipatory, praxis-based act.

'Praxis' here is defined as action informed through reflection, and with emancipation as its goal, a 'morally committed action' (Kemmis, 2009, p. 465), and emancipatory/critical action research is part of a collective and collaborative enterprise to transform social formations, structures and practices that are built into the architecture of our lives and societies and which are deemed to be unsustainable on moral, social, ecological, material, rational, ideological, personal, political and economic grounds (cf. Kemmis, 2009, pp. 470–1, 2010).

Action research, here, empowers individuals and social groups to take control over their lives within a framework of the promotion of rather than the 'suppression of generalizable interests' (Habermas, 1976, p. 113). It commences with a challenge to the illegitimate operation of power and requires participants to question and challenge given value systems. For

Grundy (1987), praxis fuses theory and practice within an egalitarian social order, and action research is designed with a political agenda of improvement towards a more just, egalitarian society. This accords to some extent with Lewin's view that action research leads to equality and cooperation, an end to exploitation and the furtherance of democracy (see also Carr and Kemmis, 1986, p. 163; Jones and Stanley, 2010). Zuber-Skerritt (1996a) suggests that:

> emancipatory action research … is collaborative, critical and self-critical inquiry by practitioners … into a major problem or issue or concern in their own practice. They own the problem and feel responsible and accountable for solving it through teamwork and through following a cyclical process of:
>
> 1 strategic *planning*;
> 2 *action*, i.e. implementing the plan;
> 3 *observation*, evaluation and self-evaluation;
> 4 critical and self-critical *reflection* on the results of points 1–3 and making decisions for the next cycle of action research.
>
> (Zuber-Skerritt, 1996a, p. 3)

Action research, she argues,

> is *emancipatory* when it aims not only at technical and practical improvement and the participants' better understanding, along with transformation and change within the existing boundaries and conditions, but also at changing the system itself or those conditions which impede desired improvement in the system/organization.… There is no hierarchy, but open and 'symmetrical communication'.
>
> (Zuber-Skerritt, 1996a, p. 5)

This form of participatory research forms 'empathetic and compassionate ties' (Hawkins, 2015, p. 468) that hold people together.

The emancipatory interest takes seriously the notion of action researchers as participants in a community of equals. This, in turn, is premised on Habermas's notion of the 'ideal speech situation' (Morrison, 1995a, pp. 99–104; cf. Hawkins, 2015, p. 468). Here action research is construed as reflective practice with a political agenda and in which all participants (and action research is participatory) are equal 'players'. Action research is necessarily dialogical – interpersonal – rather than monological (individual), and communication is an intrinsic element, with communication being among the community of equals (Grundy and Kemmis (1988, p. 87) term this 'symmetrical communication'). Because it is a community of equals, action research is necessarily democratic and promotes democracy. Indeed the search is for consensus (and consensus requires more than one participant), hence it requires collaboration and participation.

The link between Habermas's 'ideal speech situation' and action research is reinforced by Eady *et al*. (2015) in their argument that action research benefits from 'communicative space': a physical, emotional and temporal space in which 'professionals are able to engage in meaningful modes of collaboration, democratic and non-judgmental dialogue' (p. 107), i.e. learning together through dialogue.

Emancipatory action research fulfils the requirements of action research set out earlier by Kemmis and McTaggart (1988, 2005) and Kemmis *et al*. (2014); indeed it could be argued that *only* emancipatory action research (in the threefold typology) has the potential to do this.

Kemmis (1997, p. 177) suggests that the distinction between the two camps (the reflective practitioners and the critical theorists) lies in their interpretation of action research. For the former, action research is an improvement to professional practice at the local, perhaps classroom level, within the capacities of individuals and the situations in which they are working; for the latter, action research is part of a broader agenda of changing education, changing schooling and changing society.

A key term in action research is 'empowerment'; for the former camp, empowerment is largely a matter of the professional sphere of operations, achieving professional autonomy through professional development. For the latter, empowerment concerns taking control over one's life within a just, egalitarian, democratic society. Whether the latter is realizable or utopian is a matter of critique of this view. Where is the evidence that critical action research either empowers groups or alters the macro-structures of society? Is critical action research socially transformative?

Several concerns have been levelled at emancipatory action research (Gibson, 1985; Morrison, 1995a, 1995b; Somekh, 1995; Melrose, 1996; Grundy, 1996; Weiskopf and Laske, 1996; Webb, 1996; McTaggart, 1996; Kemmis, 1997; Elliott, 2005; Hadfield, 2012), including the views that:

1. it is utopian and unrealizable;
2. it is too controlling and prescriptive, seeking to capture and contain action research within a particular mould – it moves towards conformity;
3. it adopts a narrow and particularistic view of emancipation and action research, and how to undertake the latter;

4 it undermines the significance of the individual teacher-as-researcher in favour of self-critical communities. (Kemmis and McTaggart (1992, p. 152) pose the question 'why *must* action research consist of a *group* process?');
5 the threefold typification of action research is untenable;
6 it assumes that rational consensus is achievable, that rational debate will empower all participants (i.e. it understates the issue of power, wherein the most informed are already the most powerful. Grundy (1996, p. 111) argues that the better argument derives from the one with the most evidence and reasons, and that these are more available to the powerful, thereby rendering the conditions of equality suspect);
7 it overstates the desirability of consensus-oriented research (which neglects the complexity of power);
8 power cannot be dispersed or rearranged simply by rationality;
9 action research as critical theory reduces its practical impact and confines it to the commodification of knowledge in the academy;
10 it will promote conformity through slavish adherence to its orthodoxies;
11 is naive in its understanding of groups and celebrates groups over individuals, particularly the 'in-groups' rather than the 'out-groups';
12 privileges its own view of science (rejecting objectivity) and lacks modesty;
13 privileges the authority and supremacy of critical action research over other equally positive forms of action research;
14 critical action research has framed rather than changed or shaped social praxis;
15 is elitist whilst purporting to serve egalitarianism;
16 assumes an undifferentiated view of action research;
17 is attempting to colonize and redirect action research.

This critique serves to remind the reader that critical action research is problematical. It may be just as controlling as those controlling agendas that it seeks to attack (Morrison, 1995b). Indeed Melrose (1996, p. 52) suggests that because critical research is itself value-laden, it abandons neutrality; it has an explicit social agenda that, under the guise of examining values, ethics, morals and politics which operate in a particular situation, is actually aimed at transforming the status quo. This echoes the critique of non-neutral research by Hammersley (2000, 2014) in Chapter 3.

For a simple introductory exercise for understanding action research, see the accompanying website.

22.6 Action research and complexity theory

Action research links with participatory research and has affinities with complexity theory. Phelps and Graham (2010, p. 184) argue that action research 'can readily accommodate the key tenets of complexity theory' and that there is a 'deep complementarity' between them. For example, they note (p. 187) that action research accepts that systems are unpredictable, open and non-linear. It resonates with issues of adaptation to environment and can lead to bifurcation, i.e. when a system moves from one 'point of stability to another' (p. 190). It celebrates the interaction of participants and requires both feedback and feed forward. It is reflective and shows an interest in 'exceptions' or outliers (which can lead to major change) (p. 194). It is not concerned with controlling variables, and accepts that the systems in which it takes place are complex and dynamic (see also Davis and Sumara, 2005, p. 455). Action research, like complexity theory, celebrates self-organization, with new states and situations emerging from tipping points (Morrison, 2008): self-organized criticality (Bak, 1996). Similarly, Luttenberg *et al*. (2016) note that action research, and the reflection that it involves, produces outcomes and processes that are open, dynamic, non-linear, adaptive and co-adaptive (between components), and emergent, and that action research itself can be regarded as a complex system (pp. 6–12).

22.7 Procedures for action research

There are several ways in which steps in action research have been analysed. Lewin (1946, 1948) codified the action research process into four main stages: planning, acting, observing and reflecting (cf. New South Wales (NSW) Department of Education and Training, 2010). This operates in a cyclical process, with one cycle of this four-step approach leading into the subsequent four-step cycle. The NSW Department of Education and Training (2010) suggest that: between 'planning' and 'acting' come 'identifying', 'informing' and 'organising'; between 'acting' and 'observing' come 'trialling', 'collecting' and 'questioning'; between 'observing' and 'reflecting' come 'analysing', 'reporting' and 'sharing'; and between 'reflecting' and the new cycle comes 'planning', 'evaluating', 'implementing' and 'revising' (p. 3). Piggot-Irvine *et al*. (2015) note that, in fact, action research has no clearly defined ending (p. 549) and the end of one cycle leads into the beginning of the next.

Lewin (1946, 1948) suggests that action research commences with a general idea and data are sought about the presenting situation. The successful outcome

of this examination is the production of a plan of action to reach an identified objective, together with a decision on the first steps to be taken. Lewin acknowledges that this might involve modifying the original plan or idea. The next stage of implementation is accompanied by ongoing fact-finding to monitor and evaluate the intervention, i.e. to act as a formative evaluation. This feeds forward into a revised plan and set of procedures for implementation, themselves accompanied by monitoring and evaluation. Lewin (1948, p. 205) suggests that such 'rational social management' can be conceived of as a spiral of planning, action and fact-finding about the outcomes of the actions taken.

McKernan (1991, p. 17) suggests that Lewin's model of action research is a series of spirals, each of which incorporates a cycle of analysis, reconnaissance, reconceptualization of the problem, planning of the intervention, implementation of the plan and evaluation of the effectiveness of the intervention. Ebbutt (1985) adds that feedback within and between each cycle is important, facilitating reflection. This is reinforced in the model of action research by Altricher and Gstettner (1993) where, though they have four steps (p. 343) – (a) finding a starting point, (b) clarifying the situation, (c) developing action strategies and putting them into practice, (d) making teachers' knowledge public – they suggest that steps (b) and (c) need not be sequential, thereby avoiding the artificial divide that might exist between data collection, analysis and interpretation.

Zuber-Skerritt (1996b, p. 84) sets emancipatory (critical) action research into a cyclical process of: '(1) strategic planning, (2) implementing the plan (action), (3) observation, evaluation and self-evaluation, (4) critical and self-critical reflection on the results of (1) – (3) and making decisions for the next cycle of research.'

Bassey (1998) sets out eight stages in action research:

Stage 1: Defining the inquiry.
Stage 2: Describing the educational context and situation.
Stage 3: Collecting evaluative data and analysing them.
Stage 4: Reviewing the data and looking for contradictions.
Stage 5: Tackling a contradiction by introducing change.
Stage 6: Monitoring the change.
Stage 7: Analysing evaluative data about the change.
Stage 8: Reviewing the change and deciding what to do next.

Moroni (2011), deliberately echoing Zuber-Skerritt (1996b), sets out a five-step process of action research:

1. *Diagnosis* of a problem, which involves what is to be investigated and the purposes of the action research, for example, to answer a research question, to test a hypothesis, to improve practice.
2. *Planning* an intervention to address the problem, which involves considering what the intervention will comprise, what data are required and how to gather them, and what data-collection instruments are required.
3. *Action:* putting the intervention into practice, which involves consideration of timing and duration, participants, contents of the intervention.
4. *Assessment*: how far the intervention has met its objectives of solving the problem, which involves consideration of how to analyse and interpret the data.
5. *Critical reflection and communication of learning*: reflection on the experience and what has been learned, and sharing this, which involves consideration of how to disseminate the findings.

McAteer (2013) sets out a five-stage process of action research: identifying the research question; finding out about the present situation; identifying changes ('action steps') that can be made; evaluating the effects of such changes; and revising the original question as a consequence of the findings of the research (pp. 32–3).

An alternative, eight-stage model is thus:

Stage 1: Decide and agree one common problem that you are experiencing or need that must be addressed.
Stage 2: Identify some causes of the problem (need).
Stage 3: Brainstorm a range of possible practical solutions to the problem, to address the real problem and the real cause(s).
Stage 4: From the range of possible practical solutions decide *one* of the solutions to the problems, perhaps what you consider to be the most suitable or best solution to the problem. Plan how to put the solution into practice.
Stage 5: Identify some 'success criteria' by which you will be able to judge whether the solution has worked to solve the problem, i.e. how will you know whether the proposed solution, when it is put into practice, has been successful. Identify some practical criteria which will tell you how successful the project has been.
Stage 6: Put the plan into action; monitor, adjust and evaluate what is taking place.
Stage 7: Evaluate the outcome to see how well it has addressed and solved the problem or need, using the success criteria identified in Stage 5.
Stage 8: Review and plan what needs to be done in light of the evaluation.

The key features of action research here are:

- it works on, and tries to solve, real, practitioner-identified problems of everyday practice;
- it is collaborative and builds in teacher involvement;
- it seeks causes and tries to work on those causes;
- the solutions are suggested by the practitioners involved;
- it involves a divergent phase and a convergent phase;
- it plans an intervention by the practitioners themselves;
- it implements the intervention;
- it evaluates the success of the intervention in solving the identified problem.

We set out below our own eight-step process of action research, drawing together the several strands and steps of action research.

Step 1

The first step involves the identification, evaluation and formulation of the problem (widely defined, e.g. to include a need for innovation) perceived as critical in an everyday teaching situation. McAteer (2013) suggests that the problem should: be related to improving one's own practice; enable explanations and hypotheses to be developed (relating them to a broader base of theory); be within the action researcher's own power and control to change; and be professionally and personally important and pertinent (p. 28).

Step 2

The second step involves preliminary discussion and negotiations among the interested parties – teachers, researchers, advisers, sponsors, possibly – which may culminate in a draft proposal. This may include a statement of the questions to be answered (e.g. 'Under what conditions can curriculum change be best effected?' 'What are the limiting factors in bringing about effective pedagogical change?' 'What strong points of action research can be employed to bring about assessment change?'). The researchers in their capacity as consultants (or sometimes as programme initiators) may draw upon their expertise to bring the problem more into focus, possibly determining causal factors or recommending alternative lines of approach to established ones. This is often the crucial stage for the venture as it is at this point that the seeds of success or failure are planted, for, generally speaking, unless the objectives, purposes and assumptions are made perfectly clear to all concerned, and unless the role of key concepts is stressed, the enterprise can easily miscarry.

Step 3

The third step, in some circumstances, may involve a review of the research literature to find out what can be learned from comparable studies, their objectives, procedures and problems encountered.

Step 4

The fourth step may involve a modification or redefinition of the initial statement of the problem at Step 1. It may now emerge in the form of a testable hypothesis, or as a set of guiding objectives. Sometimes change agents deliberately decide against the use of objectives on the grounds that they have a constraining effect on the process itself. It is also at this stage that assumptions underlying the project are made explicit (e.g. in order to effect curriculum changes, the attitudes, values, skills and objectives of the teachers involved must be changed).

Step 5

The fifth step is concerned with the selection of research procedures – sampling, administration, choice of materials, methods of teaching and learning, allocation of resources and tasks, deployment of staff and so on. Here it must be stated that embedded within the overall scope of the term 'action research' might be a number of different research designs that include different methods of gathering data. A piece of action research might include, for example:

- an initial and end-of-intervention survey (a pre- and post-survey);
- an experimental or quasi-experimental design (e.g. where some students/teachers are involved in the intervention and some are not, or where pre- and post-testing of students/teachers is undertaken);
- a longitudinal study (over the duration of the intervention);
- participant and non-participant observation;
- interviews and field notes;
- one or more case studies;
- documentation from, and about, participants;
- questionnaire data.

In this respect readers are advised to go to the chapters in this book that address these methods, in particular on case study, experiments and quasi-experiments, and observation. Many novice researchers are unsure whether their research is action research or a case study; indeed it may be both, but a distinguishing feature may be whether the research involves an intervention on the part of the researcher(s), or whether the data are largely only collected. If it is the former

– concerning change, development and intervention – then it may be action research, whereas if it is largely the latter, then it may be more of a case study; one has to be very cautious in making this distinction because there can be gross overlaps between the two.

As action research is intended to bring about a change, with an intervention involved, then the researcher may wish to use an experimental or quasi-experimental approach in the action research in an attempt to identify causality through a controlled intervention, with control and experimental groups (see Chapter 20).

Step 6

The sixth step is concerned with the choice of the evaluation procedures to be used and takes into consideration that evaluation in this context will be continuous.

Step 7

The seventh step is the implementation of the intervention itself (over varying periods of time). It includes: the conditions and methods of data collection (e.g. fortnightly meetings, the keeping of records, interim reports, final reports, the submission of self-evaluation and group-evaluation reports, etc.); the monitoring of tasks and the transmission of feedback to the research team; and the classification and analysis of data.

Step 8

The eighth step involves the interpretation of the data; inferences to be drawn; and overall evaluation of the project (cf. Woods, 1989). Discussions of the findings take place in the light of previously agreed evaluative criteria. Errors, mistakes and problems are considered. A general summing-up may follow this in which the outcomes of the project are reviewed, recommendations made, and arrangements for dissemination of results to interested parties decided.

At every stage there is reflection and self-reflection, addressing reflexivity (discussed below). This eight-step process is set out in Figure 22.1. It does not *necessarily* follow a linear sequence, and steps may be recursive and in a different sequence. As Figure 22.1 indicates, evaluation and reflection accompany every stage of the process. Reflection can be descriptive (personal, looking back at what has happened), perceptive (e.g. emotional), receptive (relating views of others to one's own views), interactive (lining the past and present to future action) and critical (interrogating the context in which the teacher operates) (McAteer, 2013, p. 26). It can engage a retrospective analysis of critical incidents: those which make a significant difference or sudden solution to a situation (p. 72).

This is a basic framework; much activity of an incidental and possibly ad hoc nature will take place in and around it. This may comprise discussions among teachers, researchers and students; regular meetings among teachers or schools to discuss progress and problems and to exchange information; possibly regional conferences; and related activities, all enhanced by current hardware and software.

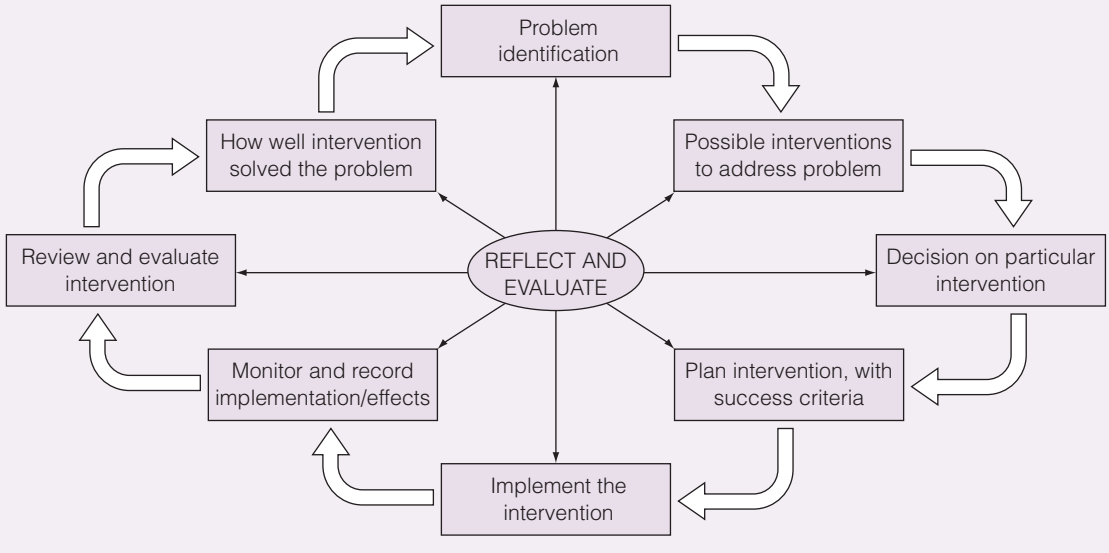

FIGURE 22.1 A framework for action research

Hopkins (1985), McNiff *et al*. (1996), McNiff and Whitehead (2009) and McNiff (2010) offer much practical advice on the conduct of action research, including 'getting started', operationalization, planning, monitoring and documenting the intervention, collecting data and making sense of them, using case studies, evaluating the action research, ethical issues and reporting. We urge readers to go to these helpful sources. These are useful introductory sources and guides for practice, in particular McNiff (2010). Indeed McNiff (2010) takes the reader, novice or experienced, through key features of action research, including: what it is, how it differs 'traditional research' and how it fits western research traditions; why people should do it; how to do it; who can do it; where to do it; what it involves; how to start and how to identify a concern; matters of values; kinds of action; how to reflect on its different aspects and elements; action planning, data collection and analysis; how to ensure that conclusions are fair, valid and reliable; how to judge its significance; implications of the action research for different parties; how to write up, report and disseminate action research, and how to use it in the development of a professional portfolio. Along the way, she raises a range of clearly expressed questions, points for reflection, including action perspectives and research perspectives (p. 22), and 'difficult questions' such as 'Whose practice?' 'Whose research?' 'Whose voice?' 'Whose theory?' and 'Who speaks?' (p. 57). She stresses the importance of setting evaluative criteria. Without success criteria it is impossible for the researcher to know whether, or how far, the action research has been successful. Action researchers could ask themselves 'How will we know whether we have been successful?' Her volume is a tour de force for action researchers.

Kemmis and McTaggart (1992, pp. 25–7) offer a useful series of observations for beginning action research which involves:

- convening and organizing a group of action researchers as participants, even if the group is small;
- being prepared to start small and expanding over time, keeping a focus on the longer term and larger issues (e.g. whole-school issues) as well as the shorter term and immediate issues;
- setting time frames and actions in them, including support and development activity;
- building in tolerance, involvement of all participants and support as participants learn by doing, reflecting on what is happening and taking responsibility for actions and consequences;
- scrupulously recording developments and progress in a timely fashion, and disseminating these beyond the group of action researchers, indicating clearly the progress that has been made;
- bring in outsiders (e.g. external consultants) where appropriate, for example, to provide legitimation for the action research;
- ensuring that the action research enables participants to put their educational values into practice.

It is clear from this list that action research is a blend of practical and theoretical concerns; it is both action and research.

In conducting action research the participants can be both methodologically eclectic and can use a variety of instruments for data collection: questionnaires, diaries, interviews, case studies, observational data, experimental design, field notes, photography, audio and video recording, sociometry, rating scales, biographies and accounts, documents and records, in short the full *gamut* of techniques (for a discussion of these see Parts 3 and 4 of the present volume).

22.8 Reporting action research

McNiff and Whitehead (2009, p. 15) suggest that, in reporting action research, it is important to note not only the action but the research element, including the rigorous methodology and interpretation of data, and that it is important to state clearly:

- the research issue and how it came to become a research issue in the improvement of practice;
- the methodology of, and justification for, the intervention, and how it was selected from among other possible interventions;
- how the intervention derived from an understanding of the situation;
- what data were collected, when and from whom;
- how data were collected, processed and analysed;
- how the ongoing intervention was monitored and reviewed;
- how reflexivity was addressed;
- what were the standards and criteria for success, and how these criteria were derived;
- how conclusions were reached and how these were validated;
- what and how the researcher learnt as a consequence of the action research;
- how practice was changed as a consequence of the findings.

The authors note that validity is a key concern in reporting, that warrants have to be justified for the conclusions drawn, that these warrants reside in the

evidential trail provided in the research (p. 23) and that reflection and reflexivity must be demonstrated (p. 28).

It was noted at the start of this chapter that the goal of action research is improvement; therefore the report must indicate not only what the improvement was, but that it was attributable to the intervention and not to other factors, i.e. that causality is demonstrated. This requires a level of rigour that is indicated in the 'research' part of the 'action research'. More than this, given that action research concerns research, the report should indicate not only how the research led to improvement in practice, but how the action research in question contributes to the expansion of knowledge, scholarship and scholarly enquiry, i.e. what significance the research has for both the academic and professional communities. The report, then, serves a dual set of criteria: (a) criteria for the planning, conduct, reporting and evaluation of the research; and (b) criteria for the planning, conducting, reporting and evaluation of practice/action.

Given that the intervention is into a 'real-life' situation, it is important to include in the report some information about the 'real-life' context of the intervention, so that the reader has a clear picture of this. This means that the report must include necessary descriptive data (McNiff and Whitehead, 2009, p. 37), together with scholarly enquiry (e.g. a literature review), explanations, reflections, research methodology, data collection, analysis and interpretation, consideration of alternative explanations, and, of course, evidence that there has been an improvement in practice and in the development of the researcher (e.g. in terms of pedagogy, subject knowledge, researcher ability and skills, reflective capacity).

Action research may be reported in narrative form (e.g. McNiff and Whitehead, 2009, p. 49; McNiff, 2010) and must be written with the reader in mind. An action research report should address (cf. McNiff and Whitehead, 2009, p. 56; McNiff, 2010):

- the action researcher's concern and the reason for that concern;
- an indication of the presenting situation at the start of the action research;
- a review of what, how and why the action researcher moved into action and reflection;
- what methodology, design and data were used in the action research (e.g. it was suggested earlier that embedded in action research might be a case study, an experimental or quasi-experimental approach, a survey, an ethnography);
- what were the research questions;
- what were the problems that the action research was intended to address/solve;
- what possible interventions were considered, and why some of these were rejected/accepted (e.g. on what criteria);
- how the intervention was planned and implemented;
- how ongoing data were gathered, processed and used during the action research;
- what were the roles of the action researcher;
- what was discovered during, and as a consequence of, the action research;
- what conclusions were drawn, and how they were valid (their warrants);
- an indication of the significance of the action research – for action and for research;
- an indication of how practice was modified and improved as a consequence of the action research;
- an indication of, and justification for, the success criteria used to evaluate the action research;
- the reflections of the action researcher, together with evidence of growth in reflective ability (and the criteria used to evaluate this).

The action researcher has to adopt a potentially schizophrenic stance to the action and the research, being both in it and of it, but also having to stand back from the situation and viewing it with as much objectivity as possible; subjectivity and objectivity (or, perhaps better, relative subjectivity and objectivity) are combined in a single action researcher.

22.9 Reflexivity in action research

The analysis so far has made much of the issue of reflection, be it reflection-in-action, reflection-on-action or critical reflection. Reflection, it has been argued, occurs at every stage of action research. Beyond reflection, *reflexivity* is central to action research, because the researchers are also the participants and practitioners in the action research – they are part of the social world that they are studying (Hammersley and Atkinson, 1983, p. 14). Hall (1996, p. 29) suggests that reflexivity is an integral element and epistemological basis of emancipatory action research because it takes as its basis the view of the construction of knowledge in which: (a) data are authentic and reflect the experiences of all participants; and (b) democratic relations exist between all participants in the research; the researcher's views (which may be theory-laden) do not hold precedence over the views of participants.

Reflexivity requires a self-conscious awareness of the effects that the participants-as-practitioners-and-researchers are having on the research process, how their values, attitudes, perceptions, opinions, actions, feelings etc. are feeding into the situation being studied

(akin, perhaps, to the notion of counter-transference in counselling). The participants-as-practitioners-and-researchers need to apply to themselves the same critical scrutiny that they are applying to others and to the research, as discussed in Chapter 14.

Reflexivity also links to awareness of possible bias, in that the practitioner is also the researcher and may not be entirely disinterested. For example, in an attempt to impress a senior manager, a teacher who is an action researcher may present a rosier picture of the outcome of the action research than is really the case, or, by contrast, a teacher who may be pressing for increased resources may present the outcome more negatively than it is. Here ethics, validity and political agendas coincide.

22.10 Ethical issues in action research

Action research is not exempted from the ethical issues that were identified in Chapter 7. It requires the informed consent of participants, options for teachers/students not to take part, and with no penalty (Nolen and Vander Putten, 2007), and confidentiality and autonomy of participants to be respected. Whilst referring the reader to Chapter 7, we also note that there is a blurred dividing line between the teacher qua teacher and qua researcher, and that effective teaching also concerns effective researching. Perhaps, also, the fact that minors attend school on a compulsory basis already gives the teacher automatic right to research them as part of her everyday teaching. Where is the dividing line?

Gibbs *et al*. (2016) draw attention to the ethical challenges faced by insider and outsider action researchers, for example: 'fiduciary responsibilities' to whom and for what; the principle of 'do no harm' (p. 7); ownership of intellectual property (pp. 11–12).

Locke *et al*. (2013, pp. 109, 119–20) and Denscombe (2014, p. 127) identify a range of ethical issues that action research should address:

- how to maintain confidentiality whilst acknowledging others' contributions, and how to address the balance between confidentiality and disclosure;
- the potential knock-on effects of the action research on participants and other relevant parties;
- how to avoid doing harm to participants (e.g. from disclosure);
- how to corroborate the data and interpretation;
- the need to seek approval and clearance for the research (i.e. simply because it is action research does not exempt the researcher from seeking ethical approval);
- how to address 'bad news', i.e. reporting negative results and presenting results in a bad light;
- informed consent;
- the increased workload on participants that is likely to come with action research;
- protection of vulnerable people;
- recognition that protection from harm trumps personal beneficence or benefit;
- equitable selection and inclusion of participants.

Locke *et al*. (2013) set out key ethical principles for action research (pp. 113–14):

- respect for all participants as stakeholders who genuinely share decisions (the 'principle of inclusivity');
- respect for all participants, in whatever roles, as 'full members' of the action research group (the 'principle of maximal participant recognition');
- aims, content and operation of the research and ownership of the data and report agreed and decided in consultation by all participants ('the principle of negotiation and consensus');
- rights of withdrawal and renegotiation of grounds for participation ('the principle of communicative freedom');
- use of plain, comprehensible language by all parties ('the principle of plain speaking');
- ensuring that all 'members' collaboratively adjudicate the moral rightness of the aims, processes and understandings of the research ('the principle of right action');
- ensuring questioning of, and transparency in, the 'discursive assumptions' that participants bring to the research ('the principle of critical self-reflexivity');
- ensuring that the feelings of all participants are respected and count ('the affective principle').

22.11 Some practical and theoretical matters

Much has been made in this chapter of the democratic principles that underpin some types of action research. The ramifications of this are several. For example, there must be a free flow of information between participants and communication must be extensive (Elliott, 1978, p. 356). Further, communication must be open, unconstrained and unconstraining – the force of the better argument in Habermas's 'ideal speech situation'. That this might be problematic in some organizations has been noted by Holly (1984, p. 100), as action research and schools are often structured differently, with schools being hierarchical, formal and bureaucratic whilst action research is collegial, informal, open,

collaborative and crosses formal boundaries. In turn this suggests that, for action research to be successful, the conditions of collegiality have to be present, echoing Habermas's 'ideal speech situation', for example (Morrison, 1995a, 1998, pp. 157–8, 2011, p. 153):

- participatory approaches to decision making;
- democratic and consensual decision making;
- shared values, beliefs and goals;
- equal rights to determine policy;
- equal voting rights on decisions;
- the deployment of sub-groups who are accountable to the whole group;
- shared responsibility and open accountability;
- an extended view of expertise;
- judgements and decisions based on the power of the argument rather than the positional power of the advocates;
- orientation to a common interest ascertained without deception;
- everyone's freedom to enter a discourse, to check questionable claims, to evaluate explanations, to modify a given conceptual framework and to reflect on the nature of both knowledge and political will;
- everyone's freedom to assess justifications and to alter norms;
- mutual understanding between participants;
- recognition of the legitimacy of each subject to participate in the dialogue as an autonomous and equal partner, with equal opportunity for discussion;
- discussion to be free from domination and distorting or deforming influences;
- all motives except for the cooperative search for truth are excluded;
- the speech act validity claims of truth, legitimacy, sincerity and comprehensibility are all embodied;
- illocutions (where the outcome is open or negotiable) replace perlocutions (achieving a given, predetermined, non-negotiable outcome by saying something);
- shared ownership of decisions and practices.

Zuber-Skerritt (1996b, p. 90) suggests that the main barriers to emancipatory action research are: (a) single-loop learning (rather than double-loop learning) (Argyris, 1990); (b) overdependence on experts or seniors to the extent that independent thought and expression are stifled; (c) an orientation to efficiency rather than to research and development (one could add here 'rather than to reflection and problem posing'); (d) a preoccupation with operational rather than strategic thinking and practice. She suggests (1996a, p. 17) four practical problems that action researchers might face:

- How can we formulate a method of work which is sufficiently economical as regards the amount of data gathering and data processing for a practitioner to undertake it alongside a normal workload, over a limited timescale?
- How can action research techniques be sufficiently specific to enable a small-scale investigation by a practitioner to lead to genuinely new insights, and avoid being accused of being either too minimal to be valid, or too elaborate to be feasible?
- How can these methods, given the above, be readily available and accessible to anyone who wishes to practise them, building on the competencies which practitioners already possess?
- How can these methods contribute a genuine improvement of understanding and skill, beyond prior competence, in return for the time and energy expended – that is, a more rigorous process than that which characterizes positivist research?

Another issue of some consequence concerns headteachers' and teachers' attitudes to the possibility of change as a result of action research. Hutchinson and Whitehouse (1986), for example, note possible resistance from headteachers and teachers themselves.

Further, Jones and Stanley (2010) comment that action research involving university researchers and public stakeholders seriously challenges 'the democratic principles commonly associated with this genre of critical enquiry' (p. 161), as micro-politics can frustrate the endeavour to be truly democratic. Kemmis (2006) and Gibbs *et al*. (2016) question whether individual or even collaborative action research can really live up to its claim to radically challenge and change injustice, i.e. whether its putative emancipatory potential is realizable in practice, and that it is more descriptive of the reflective process than being evaluative or emancipatory (p. 7).

Piggot-Irvine *et al*. (2015) comment that more needs to be done to evaluate the outcomes and impact of action research rather than its predominant focus on process, and they indicate criteria, foci and indicators for evaluating precursors/foundations, processes/activities, outcomes and impacts. Similarly, Heikkinen *et al*. (2012) suggest five principles for the validation of action research: *historical continuity* (locating the research in its antecedents and unfolding course of action); *reflexivity* (awareness and disclosure of the impact of personal experience on the research); *dialectics* (inclusion of multiple voices in the research and its interpretation); *workability and ethics* (whether the research has led to changes in practice and addresses ethical issues transparently); and *evocativeness* (how

effectively the research evokes images and emotions in the reader). Pring (2015, p. 160) adds that including externality in action research can increase the public perception of its validity and rigour, though how far this addresses 'objectivity' is a moot point.

22.12 Conclusion

Action research is a potential means of empowering teachers, though this chapter has questioned the extent of this. As a research device it combines six notions:

1. A straightforward cycle of identifying a problem, planning an intervention, implementing the intervention, evaluating the outcome.
2. Reflective practice.
3. Political emancipation.
4. Critical theory.
5. Professional development.
6. Participatory practitioner research.

Action research is a flexible, situationally responsive methodology that offers rigour, authenticity and voice. This chapter has tried to expose both the attractions and problematic areas of action research. In its thrust towards integrating action and research one has to question whether this is an optimistic way of ensuring that research impacts on practice for improvement, or whether it is a recessive hybrid. There are several journals that focus on action research in education, for example: *Educational Action Research* and *Action Research Reflective Practice*, and some key websites:

http://cadres.pepperdine.edu/ccar/about.html (the Centre for Collaborative Action Research)
www.jeanmcniff.com (the website of Jean McNiff)
www.actionresearch.net (the website of Jack Whitehead)
http://aral.com.au (the website of Bob Dick)

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Virtual worlds, social network software and netography in educational research

CHAPTER 23

Stewart Martin

Virtual worlds, social network software and netography are key features of contemporary concern in educational research. This chapter introduces researchers to this field, addressing:

- key features of virtual worlds
- social network software
- using virtual worlds and social media in educational research
- netography, virtual worlds and social media network software
- opportunities for research with virtual worlds, social network software and netography
- ethics
- guidelines for practice
- data

23.1 Introduction

Virtual worlds are computer-based multi-user simulations that are shared online by individuals, who appear as a graphical character: an interactive icon or *avatar*. Although creative inventions, these environments have *persistence*; they continue to exist and change with possible consequences for an avatar, even when a user is not present online, because of the ongoing actions of other online users. Current computer technology enables virtual worlds to offer increasingly convincing three-dimensional imagined environments for individuals to explore alone or as a member of a community and, because of their great versatility and realistic appearance, they are commonly dedicated to entertainment or social interaction or are found in military or commercial applications. However, they are increasingly used in educational and research settings for exploring languages, ethics, management, history, psychology, design, pedagogy and a rapidly widening range of other areas (see Peachey *et al*., 2010; Hinrichs and Wankel, 2011; Hunsinger and Krotoski, 2012; Gregory *et al*., 2015).

In a virtual world, individuals can project their actions, views or values through their avatar and receive feedback from others in the system.[1] Projection techniques can encourage a sense of authenticity to externalize the self and create an impression of presence in an environment that we are not physically part of. This relies on the 'willing suspension of disbelief" (Coleridge, 1817) to create an 'illusory shift in point of view' (Dennett, 1978, p. 312) as well as on the use of our own knowledge, imagination and enthusiasm (Zhao, 2003). Our sense of being present in the physical world appears to be an essential component of consciousness but is not something we normally think about unless prompted by a displacement of our self-perception, for example, through a dream, literature, film or theatrical experience. Any relative lack of realism is not therefore an obstacle to user acceptance of a virtual world and many early examples were effective and engaging, despite having poor graphics; some included no pictorial images at all (Nelson and Erlandson, 2012; Martin, S., 2014).

23.2 Key features of virtual worlds

Virtual worlds are often three-dimensional, visually realistic and attractively designed; they can be useful in stimulating participants' imagination where the sense of being in a real place may be important, for example, to encourage engagement in exploring moral dilemmas (Martin, 2015). Creating a sense of life as a virtual experience may also be valuable for investigating socially sensitive issues by invoking a feeling of a 'safe distance' between the individual and the thing being explored, as the avatar becomes the presenter of a particular perspective or behaviour. Such 'projection' may help to displace any associated difficulty or stress away from the individual and ease the exploration of sensitive or highly charged issues (Freud, 1936). Virtual worlds can also be valuable for developing otherwise inaccessible or impossible environments to explore

human interaction, agency, values and perceptions, such as historical locations and experiences, future imagined scenarios or uninhabitable settings.

These features make virtual worlds particularly effective training environments, where the depiction of a hostile environment (e.g. fire-fighter training for casualty location) can be enhanced to offer more realism without physical risk, or otherwise impossible experiences can be created, such as that of being immobile or disabled, or being a member of a different social or ethnic group.

The low risk and 'repeatability' of experiences in virtual worlds have advantages not just because of the safety in otherwise dangerous or unpredictable environments, but also because, despite their heightened sense of realism compared to other approaches, they afford *discardable experiences* at relatively lower personal, experiential or emotional cost, for example: when training armed forces in decision making in pressured situations; or training medics to treat 'real' casualties; or advancing views, proposals or identity depictions in hostile situations (Waller *et al*., 1998; Martin, S., 2013). Virtual worlds therefore have advantages of *economy* (being cheaper to create and use than real-life settings); of *visibility* (important things can be made clearer and more accessible); of *control* (much more control of the setting is possible than in real life); and of *safety*, where situations can be used that in real life would be too dangerous, difficult, sensitive or ethically questionable (Bailey, 2007; Nelson and Erlandson, 2012).

Together with a configurable avatar, these features make virtual worlds effective technologies for studying and affording rehabilitation experiences for individuals who have undergone traumatic experiences such as domestic violence, or by offering opportunities for people to make otherwise unavailable choices regarding actions, gender or personality. Their potential for exploiting role/real playing and the blending of physical real-world activity with virtual activity offers scope for research using innumerable scenarios. These are environments in which participants could project, share and reflect on their own and others' actions and views, which may lead to the surfacing and exploration of further, often sensitive, issues for investigation and possible resolution, the reconciliation of potential conflict and disagreement, and hence to the development and enlargement of understanding. Although the Internet and its increasingly varied digital spaces offer some distortions in the portrayal of everyday life, through the creation of virtual spaces and communication within them, participants can be encouraged to be more open, honest and authentic in disclosing their views, their values and their beliefs about real or created situations and issues.

23.3 Social network software

Social network software is constantly developing, increasingly multimodal and dynamic, and is used for a wide range of purposes including communication, self-expression, maintaining friendships, sharing information and for enjoyment. Boyd and Ellison (2007) define them as 'web-based services that allow individuals to construct a public or semi-public profile within a bounded system' (p. 211); Kaplan and Haenlein (2010) add that they are also 'a group of Internet-based applications that build on the ideological and technological foundations of Web 2.0, and that allow the creation and exchange of User Generated Content' (p. 61). All media foster communication and so to some degree are social by definition (Papacharissi, 2011) and it may often be useful to use one or more of them as part of data gathering and communication in research.

Social media vary and include networking services for sharing personal information (e.g. Facebook); sites for content sharing or discussion (e.g. Flickr, YouTube, Instagram, WhatsApp, Digg or Reddit); forums (e.g. wikis such as wiktionary.org); professional networking sites (e.g. LinkedIn); blogs (e.g. Twitter, Blogspot); virtual social worlds (e.g. Habbo Hotel, Club Penguin, Second Life); and massive multiplayer online role-playing games (MMORPGs) such as World of Warcraft, Final Fantasy and Skyrim. Although used for different purposes, these technologies can have features in common; platforms such as Twitter or Facebook have shared content that is generated, blended or re-posted by users.

23.4 Using virtual worlds and social media in educational research

The popularity of social network sites reflects the significance of communication in contemporary society and influences values, ideas and behaviours that are often of interest to researchers. Digital spaces have architectures that affect the way people work and live in them, and social media offer opportunities to circumvent traditional power relationships and create a greater likelihood that individuals may feel free to express themselves. Virtual worlds and social media can therefore help individuals to communicate more freely and engage with a kind of 'ideal speech' (Habermas, 1979, 1982, 1984, 1987b; see Chapter 14 of the present volume). These ideal speech features can support research by encouraging participants to more openly:

- enter a discourse and check questionable claims;
- evaluate explanations and assess justifications;

- modify a given conceptual framework and influence norms;
- reflect on the nature of political views and action;
- develop mutual understanding between participants, accept that consensus is derived from the better argument and not from the influence or authority of individual participants, and accept that the cooperative search for truth should be the only motive;
- recognize the legitimacy of others to participate in the dialogue as an autonomous and equal partner, and to promote equal opportunity for discussion.

(after Morrison, 1995a, p. 102)

These features may influence who participates and what kinds of things are shared, as not everyone may feel comfortable in such contexts; this should be borne in mind when considering the topic and desired participants for a research project. Cultural or individual differences may also predispose some individuals to accept or decline an invitation to participate and so affect the sample, with implications for the representativeness of a study and for the nature and robustness of its possible conclusions.

Since its founding in 2006 as a simple way to help friends stay in touch, the microblogging and social network site Twitter has become a popular communication medium alongside its earlier counterpart Facebook. The use of Twitter and Facebook in many western high schools is common as young people create content and tag and communicate this to interact socially in school and in informal spaces beyond school. Users typically set Twitter accounts to 'public' to share their social lives widely and this information can be used to study connections between people, their self-expression and engagement with resources and learning communities. Both Facebook and Twitter, as 'always on' technologies, are thought to particularly encourage social participation and interaction by facilitating communication and collaboration among students and with teachers, peer assessment and learning.

Despite the ubiquity and high consumption of such media, surprisingly little research has been done to explore why and how they are used to make meaning and this offers considerable opportunity for new studies (Gleason, 2016). The use of such technologies in formal settings such as educational institutions also offers rich opportunities to study changes to the historical 'imbalance of power within most educational uses of technology' (Selwyn, 2010, p. 71). Twitter and Facebook, like all digital technologies, have particular histories, constraints and affordances that bear on the ways people use them to communicate. Some, like Twitter, have potential to blend private and public spaces and to fuse authorship and readership and create what some see as new expressions and forms of literacy that also offer research opportunities (Greenhow and Gleason, 2012; Stevens *et al*., 2015).

Social media offer ways of exploring the space between institutionally managed systems and non-institutional personal usage; such *liminal* (boundary) areas are seen as fascinating 'third spaces' (Bhabha, 2004; Turkle, 2007; Aaen and Dalsgaard, 2016). However, participants may prefer to keep their social and academic presences separate, so it may be better to explore informal learning using media such as Facebook or Moodle and use other methods for traditional, more formal activity. The division between first (formal) learning spaces and second (informal) spaces can be conscious and functional rather than unconscious, accidental or disruptive; a number of studies have found that students and their teachers often dislike blending study and their social life (Manca and Ranieri, 2013). Research may therefore encounter resistance to using social network technologies for educational uses, as participants may prefer more traditional approaches to learning; in the interests of promoting high-quality research, any such preferences should be incorporated and not overlooked. Additionally, while many Facebook groups are 'open' (public), many are 'closed', and participation may require an invitation (consent) from group members.

23.5 Netography, virtual worlds and social media network software

Developed by Kozinets (2002, 2010), netography (*net*work ethn*ography*) relies heavily on observation and, like traditional ethnography, is an immersive and interpretive exploration of a particular space – in this case of embedded technology. The traditional prolonged immersion of ethnographic research is equally effective in digitally mediated settings, but engagement may be more about following connections than continuous physical presence in one 'space'. As a general rule, researchers should try to engage as fully as possible with the digital environment being studied, but this does not mean that they must participate in every activity in order to conduct meaningful observation. Sometimes full participation is not possible or desirable and total immersion is not essential in ethnography. Nonetheless, such factors may significantly affect how other participants perceive and engage with the researcher, and sufficient expertise with the environment will be a prerequisite for conducting any study, and the persona being portrayed may need to be consistent and coherent across all digital platforms employed.

Netography often uses multifaceted engagement with a setting for studying online hyperlinked resources such as websites, Facebook pages or blogs which have been created by individuals to project their 'fame' (compare with Malinowski, 1922; Munn, 1986). Such studies may include a number of sites and different forms of data collection such as: formal interviews; observing individuals both online and in the physical world (e.g. in cybercafes or game conventions, or whilst physically present but online); watching and chatting to members of the online community being studied, or during casual encounters online and offline. Big data may also be important in this field and Chapter 8 contains an exploration of the implications of its use.

A sense of presence ('being there') in these spaces is likely to be highly individual and conditional upon the user's level of control over the environment (Sheridan, 1992; Ijsselsteijn *et al*., 2000; Sadowski and Stanney, 2002). An *immersive* experience results when presence in an environment is augmented by its apparent overall fidelity to physical reality (Slater and Steed, 2007) and appears when being there is augmented by a total response of 'making sense there' (Schuemie *et al*., 2001; Riva *et al*., 2003). Presence in an online community is often a prerequisite for engagement; new participants often have to be invited or accepted and there may be official gatekeepers or a formal arrangement for gaining access – a rite of passage that existing community members will have gone through so as to be able to participate comfortably in the digital environment. Sometimes it may instead just be a case of building an identity and presence in whatever ways the platform allows, and creating an array of connections over time.

Facebook involves signing up for an account, deciding what photographs and information to upload, which individuals to 'friend' (connect to) and how often to update information; to use Twitter the researcher must decide on a name and what personal information to reveal in the profile and the nature of any 'tweets' or 'retweets' (messages) to be made. These processes are relatively straightforward; but platforms such as World of Warcraft and Final Fantasy are likely to require considerable familiarity and skill with navigation, raids, questing and other features of the environment to facilitate extended contact with other players and acquiring these might take significant time (Sveinsdottir, 2008).

The purpose of both physical world and digital ethnography is not just empirical description but also about developing a theoretically rich description that relates to the particular issue or area of study and connects with wider discussions (Hine, 2015). Many important norms, beliefs, attitudes and behaviours that could be of interest to the researcher can be so taken for granted by participants in a given setting (so 'normal') that they are not remarked or reflected upon by them (Malinowski, 1922). Not all data are therefore accessible through interviews or other traditional means of data recording (indispensable though these are) and so participant observation plays an especially important role. Participant observation within virtual worlds and social network platforms can offer significant opportunities, as the extended timeframe allows the researcher to reflect, revise classifications, assumptions and analysis and to discuss with participants any emerging themes and interpretations. These promote reflection and the revision of assumptions, classifications and analysis. The 'participant' role of the researcher entails searching for unremarked-upon things proactively and being aware that what is observed, even if only a partially glimpsed pattern or behaviour, may be valuable and should be recorded and followed up, even if (perhaps *especially* if) the rest of the community appears to pay it little attention. These processes make short studies more difficult as they require substantial and sustained time and commitment from the researcher, so when planning a project it is important to allow for regular engagement with the community of interest over extended periods (e.g. weeks and months).

Before 1910, there was surprisingly little in the literature of the social sciences about the now commonplace notion of 'community' and the first clear definition of it focused on defining rural communities around villages (Galpin, 1915); in the forty years following, over 100 other definitions appeared (Hillery, 1955). The notion of 'community' in the social sciences grew to include the idea of community as a *value* (see Frazer, 2002) and increasingly embraced overlapping descriptions or ideas that mingled together and became difficult to separate, as, for example, when applied to the study of ideas of solidarity, trust, mutuality, fellowship or conflict. The more recent additions of communities that are 'imagined' or 'virtual' have extended this range and complexity even further (e.g. Anderson, 1983; Rheingold, 2000).

The first task of a researcher studying a community is therefore to clarify what is to be meant in their study by 'community', as communities within digital environments are often only very loosely bounded and dynamic by nature; hence it is important to be able to distinguish who and what is 'in' and 'out' of the study and how this is to be decided. This is what ethnographers would usually think of as identifying the 'field-site', which may traditionally have been one or more geographical areas with relatively clear boundaries (e.g. a village), perhaps with more fluid boundaries for particular social groups. Group 'types' are sometimes also

used this way in researching the digital world and might include professional organizations (communities of practice), or communities that are workgroups, families, friendship groups or diasporic groups or guilds of people who join together for some other activity (e.g. in online games). Researchers may also study online groups, not so much by community membership but by activity, so they may focus on novice participants, or those with longer engagement who may act as managers or leaders, or those who are present but do not otherwise engage ('lurkers'). So a fieldsite can be thought of as a collection of places, individuals or practices that might be physical or virtual or some combination of these; and this kind of study is sometimes called 'connective ethnography' where researchers seek to describe the use of these related sites and explore the connections between them (Leander and McKim, 2003; Hine, 2007; Taylor, 2009).

In netographic research it can be difficult to separate the offline and online lives of individuals, as their online engagement may be deeply enmeshed with their life in the physical world. The researcher cannot then follow the traditional ethnographic methodology of visiting a physical organization or place because online and virtual communities exist in placeless spaces. The online/offline distinction also seems increasingly artificial, as many new digital technologies claim to have a 'social' element. The use of social media is participatory and collaborative by nature, but it is also often complex and intermingled with issues of identity and social relationships (Selwyn and Stirling, 2016). Some suggest that these new media challenge and destabilize the very concept of self (Baudrillard, 2012). One consequence of this is that maintaining boundaries between the research and other aspects of the researcher's life may become difficult; they may have a digital presence that reaches far beyond their project that participants may access. These complexities arise largely because the rise of social network software has shifted Internet use from passive consumption towards active participation, from 'pull' to 'push' behaviours. Conducting participant observation in such settings may be difficult to characterize, as when deciding what 'participation' means and what exactly is being 'observed'; the researcher may be observing interactions which they have in part created, so are in some senses observing themselves (Law, 2004).

However, ethnography never provides a neutral or objective account of what is studied, as the researcher always plays some part in constructing the object of their study, although it is important for them to maintain an awareness of this phenomenon and its likely consequences (see Clifford and Marcus, 1986). Seeking to minimize this effect by adopting only passive observation strategies may prove unworkable, as online communities may detect and censure those online who are not participating (lurking) and using covert observation raises further ethical issues. Visibility is therefore important but does not need to be in every communication medium or to be constant, and it is possible and often acceptable to other participants to observe an online discussion group without posting messages. However, avoiding lurking by posting repeatedly without contributing to the aims and goals of the group would often breach group etiquette and is best avoided.

23.6 Opportunities for research with virtual worlds, social network software and netography

Studies of online communities may involve: study but not participation, which some may regard as somewhat contradictory and ethically questionable; or study with some participation; or study plus offline/online interviews; or study which also includes offline research methods. Deciding on data collection and other appropriate methodology for exploring virtual worlds or digital social networks in educational research, therefore, often involves considering a range of offline and online tools (Fielding *et al*., 2008; Markham and Baym, 2008). Existing community members may have several means of communicating, such as email, face-to-face meetings or through blogging, so a study may not be confined to a single 'site' or software but could include and draw upon a range of online and offline settings. As a result, mixed methods/mixed worlds/mixed media approaches are increasingly common (Johnson *et al*., 2007; Martin *et al*., 2010), although these can exacerbate some research problems, especially of maintaining user engagement (see the case study in Livingstone and Bloomfield, 2010).

Virtual world and social network platforms can provide environments that reflect and include features of 'real life' and are valuable for studying interactions between individuals, especially when we wish to explore contexts where sensitive issues may be the focus. They can be useful for the study of interaction, especially in dynamic, fluid, uncertain or contested contexts, for exploring complex behaviour and for monitoring developments over time. By their nature, virtual worlds, especially the perceptually realistic ones that are increasingly common, offer the researcher an opportunity to exploit a sense of immersion in the created world (a sense of being *there*) and also the sense of a shared experience with others (a sense of *being* there). Both immersion and co-presence have

been recognized as important facilitators of user engagement in a time when media consumers demand more and deeper experiences (Turkle, 2000; Riva *et al*., 2003; Boellstorff, 2008).

Behaviours and attitudes towards others can be explored in such contexts to study contested opinions or beliefs, or individual and self-perceptions in relation to others and how these might change over time. This makes virtual worlds useful places for researching the development of understanding, of perception, of processes where negotiated meaning is important, and of the dynamics that generate consensus and discord. Research should always be focused and highly contextualized but also relate to wider issues of interest; virtual worlds and other social network software are well placed to provide insights into embodiment, selfhood, globalization or learning and many other topics that may be important for those with little interest in digital environments.

Another advantage of virtual worlds lies in exploring contexts where the experimenter neither desires nor is able to exert control over every aspect of the situation and where behaviour is shaped by the agency of participants. Virtual worlds are also highly suited to mixed methods approaches, the development of research methodology and activity design and the exploitation of game theory (Broadribb *et al*., 2009). Technologies such as Second Life, Club Penguin, Facebook or Twitter are collaborative environments suited to 'inclusive' research practices where researchers and subjects engage on equal terms and therefore offer opportunities to develop scenarios of 'ideal speech' (Rybas and Gajjala, 2007; Sheehy, 2010), discussed earlier.

Researchers have explored the influence of social media on campus life, identity, sexuality, relationships and attitudes towards 'others'; some feel that such technologies relax compliance with the social norms that affect inter-person spaces, and that this allows observation of communication with fewer constraints from the social conventions that may appear in traditional face-to-face interactions such as focus groups or interviews (Pitcher, 2016). Social media also have significant potential to disrupt established modes of interaction or hierarchies of authority and power within institutions, to challenge and sometimes remake them, from settings of political activism to those between students and teachers (Selwyn and Stirling, 2016).

However, the open, social and collaborative nature of participatory networks are often seen as also posing challenges for education, implying possible shifts in the roles of learner and teacher, making institutions more porous and raising concerns about untangling collaborative from individual learning and the challenges this presents for fair assessment (Manca and Ranieri, 2016). The effects of social media use in education tend to be quite diverse and sometimes negative; so whilst their use can be correlated with increased student involvement (Junco, 2012) and time on Facebook has been associated with academic success (Labus *et al*., 2015), it has also been found to be inversely correlated with academic progression (Paul *et al*., 2012). Results from different studies sometimes conflict and so can be difficult to integrate, perhaps because different features of particular social media can support diverse forms of involvement and different activities may produce different effects (Matzat and Vrieling, 2016).

Social media can also be used to study a range of demographic and other variables in relation to topics such as teacher networking, student expectations, peer feedback, identity presentation and development, support, maintaining relationships and different phases of transition, in addition to their possible academic uses, which have received relatively little attention. Social media can also present some conundrums for educational institutions; the lack of accountability and other effects of anonymity can lead to cyber-bullying, racial hostility or the promotion of damaging lifestyles. This *disinhibition effect* can occur when anonymity encourages feelings of a 'safe barrier' between perpetrator and victim. Control of content and interaction can also be a 'sharing' that looks like intimacy but is actually a kind of distancing (Burbules, 2016). However, more positive outcomes for classroom engagement and study can also arise from online disinhibition: for example, students may more freely share their academic work, or feelings and problems that they might not reveal offline. Both positive and negative scenarios highlight the need for great care with ethics, where informed consent, data security and participant anonymity may present particular challenges (Rowan-Kenyon *et al*., 2016; see also Chapter 8 of the present volume).

Exposure to conflicting values is likely to be an unavoidable feature of many social media and research into or with them is therefore likely to encounter tensions. In education, this raises questions for the kinds of educational spaces being fostered, as short and perhaps superficial critique from anonymous others may expose students to points of view or ideas that may challenge and disturb them. The 'messy democracy' of social media affords particular kinds of robust interaction for which the researcher and participants need to be prepared; they can be productive and creative but also can be hypercritical and forceful (Burbules, 2016).

Some commentators suggest that: the benefits of social media have been exaggerated and that using such technology actually minimizes opportunities for collab-

oration, as people may work on their own on separate parts of a project; such media therefore lead to greater misunderstanding, less knowledge sharing and less creative or higher-order cognitive processes; using social media such as Facebook is time-wasting and that both students and academics dislike the blurring of their social and professional identities and raise concerns about how they become represented (Manca and Ranieri, 2013; Salmon *et al*., 2015; Stirling, 2016). Twitter is argued by some to have a zero or negative effect on learning (Kucuk and Sahin, 2013; Arabacioglu and Ajar-Vural, 2014), whilst others find its influence positive (Evans, 2014; Ricoy and Feliz, 2016). Kirschner (2015) challenges the idea that Facebook can be useful for formal learning outcomes, citing its inadequacy for academic discussion, knowledge construction and argument; and others find that it encourages narcissism, tribalism and superficiality by connecting individuals with similar views and thus discouraging openness to differing views and the reflective and objective analysis of evidence and extended argument (Manca and Ranieri, 2016). Facebook has also been found to reinforce culturally embedded relations of power distance, as more successful or able students, or students wishing to manifest gratitude or respect, tend to benefit from exchanges with teachers whilst others do not (Tananuraksakul, 2014; Manca and Ranieri, 2016).

Many studies using self-report methods focus on positive implications for learner attitudes, engagement or attendance, whereas studies finding benefits for academic knowledge, understanding or attainment are less common, and those finding negative effects tend to have used objective data (Tess, 2013). Opportunities exist for more empirical studies of direct benefits for 'hard' outcomes such as academic progression, knowledge, understanding or attainment when comparing settings with and without the use of social media integration (Ricoy and Feliz, 2016). Other potential areas of study include implicit and explicit institutional policies and traditional pedagogic and role expectations, which may be especially interesting in cultural settings where the maintenance of social harmony is important.

23.7 Ethics

How should we treat information posted online, such as images from a mobile phone or information perhaps of a personal nature intended for family and friends but not for others? This could be important when individuals may not have a strong understanding of the possible long-term ramifications of such posting, even though the data are potentially discoverable and therefore already 'public'. It is no excuse for the researcher to say that participants should know the terms of service and functionality of platforms such as Twitter or Facebook when they open an account. It is likely that many experienced users of Facebook remain unaware that people who have not 'friended' them can nonetheless access their photo albums, or that images uploaded to social media often include embedded metadata with details including author, location, time and much more (see Raynes-Goldie, 2010).

Social media and virtual worlds present particular problems for traditional frames of reference for ethical research, especially when children or young people are involved. It may be unclear who the participants actually are, to whom the data belongs, what data can legitimately be regarded as 'public' or 'private'; and the possible consequences for participants and their networks now and in the future may be unknowable. The main ethical issues here concern informed consent, the vulnerability and individual risk with online identities, the public/private nature of communication, security and confidentiality. There is no single template for ethical research and Internet-mediated research is no exception; the context and nature of the study will influence ethical considerations. For example, covert observation is often frowned upon because it violates the principle of informed consent but it may be ethically acceptable and individuals' informed consent may not be necessary in online or other contexts where data exist within the public domain and where the risk of harm to users is low (Steven *et al*., 2015). Other covert or 'unobtrusive' methods may rely on publicly available data, as one kind of unstructured observation of things that the researcher might not be able to obtain or ask about directly. Such methods may be helpful and ethical where participants could find it difficult to give authentic or honest answers, perhaps because these may be socially undesirable, or sensitive, or where not employing unobtrusive approaches would encourage only 'diplomatic' responses.

Unobtrusive methods may not engage participants, or solicit comments from them and therefore use the role of lurker or voyeur. Users may not have agreed to participate (and may not have been asked) and so anonymizing the data becomes especially important. Examples of unobtrusive ways of collecting social media data may include: online discussion forums; Google Trends data (see www.google.com/trends); Facebook and Twitter postings; YouTube videos; and downloaded 'chats' from message rooms, community sites or user forums. However, such 'found' or 'non-reactive' data may easily become 'reactive' if reinserted into the digital setting, such as, for example, when presented to participants to ask them what they made of it.

It may be ethically problematic to analyse found data in the absence of participant consent, unless interpretations are depersonalized and carefully justified. However, depersonalizing is no longer a strong guarantee of anonymity, as '[t]oday, the private man is a public entity, even a public display, that he controls only partly' (International Council on Human Rights Policy, 2011) because

> in an international and pervasive network (e.g. the Internet) that is persistent in its records, and increasingly searchable across indexes, databases and other taxonomies, ultimately every interaction online has the potential to be traceable, either now or in the future.
>
> (Henderson *et al*., 2013, p. 551)

One solution might be to adopt the principle of 'non-alienation' (Bakardjieva and Feenberg, 2000), where data may not be removed from someone's control or used for things they were not aware of without their explicit permission, which employs the principle of consent being ongoing, where participants are consulted at all stages of the research so as to have more control over data collection, analysis and reporting of research (Henderson *et al*., 2013; Ramírez and Palu-ay, 2015).

The notion of informed consent is therefore potentially complex with all social digital media, even when the risk to participants may be outweighed by the potential benefits to knowledge about the field of study (Pitcher, 2016). Nonetheless covert or unobtrusive data collection is common (arguably necessary) in some disciplines even when it 'potentially poses a substantial threat to those who are involved or have been involved in it' (Lee, 1993, p. 4), or when those studied may view the research as somehow undesirable (Van Meter, 2000). This is because the research may be deemed to have overriding benefits for the good of wider society (e.g. when studying illegal activity). Chapter 8 of the present volume discusses further a range of ethical issues in Internet research.

23.8 Guidelines for practice

A range of issues have to be considered when conducting research using virtual worlds and social networks (Moschini, 2010; Hine, 2015) and each may be more or less prominent depending on the setting and nature of the research:

- The holistic approach of netography means remaining alert for unanticipated acts of meaning-making and for how activities make sense to the individuals engaged in them (Lewis and Allan, 2005).
- Fieldsites are rarely online or offline but are fluid, and researchers may need to engage with both; do not assume the existence of boundaries (Johnson *et al*., 2007; Martin *et al*., 2010).
- Explore all stages and forms of engagement and use a range of tools for recording and interpretation (Broadribb *et al*., 2009).
- Virtual worlds and social media sites have customs and norms that mediate communication, but to their users may be simply 'the way things are'; adopting the perspective of the stranger can help to understand why this may be so or could be otherwise (Malinowski, 1922).
- Expect a variety of different media and experiences across multiple platforms.
- Expect uncertainty: digital spaces often do not provide a single, verifiable or 'objective' reality.
- Allow sufficient time: familiarity and expertise may be needed to engage with the community and gain acceptance.
- Ensure anonymity of data, whether participants request it or not; no one can know what may happen in future, and identifying an individual may also identify their social networks once data and analysis are in the public sphere (Henderson *et al*., 2013).
- When participating within a particular group, avoid taking sides; avoid conflict.
- Remain alert to the way the researcher's own agency intrudes in the process of creating an authentic, rich and thick account of the 'messy reality' of the digital cultural space as perceived and understood by participants (Law, 2004).
- Be aware that study participants may have access to the researcher's own online identity; consider whether and how this may influence the study and plan accordingly.
- Ideally all forms of misrepresentation or deception are best avoided; they are antithetical to openness and trust. Covert observation is a form of deception that cannot be guaranteed to be free of potential harm because we do not know what may be observed. However, some kinds of research may be less reliable or even impossible without some form of deception, and the balance and degree of any potential harm/benefit requires careful consideration and justification throughout (Steven *et al*., 2015).

In addition to the usual decisions to be made when designing a research project, using a virtual world or social network will require it to be set up and managed and may need someone with technical expertise to help decide whether to make use of an existing commercial product or to create a purpose-built environment. The

former is more straightforward but the options available for customization may be more limited, so it is important to be clear in advance which features are required for the study, what data need to be collected, and how this will be done. A customized platform may be the ideal, particularly in the case of a virtual world, but the resource implications may be significant and, in the interests of viability, it may instead be worth adjusting the research methodology to allow the use of a commercial product.

A prerequisite for research in any online environment is sufficiently high-quality online availability, and a prudent researcher will check this and software/system requirements at an early stage. The researcher must also fully understand the protocols, etiquette and common practices of the fieldsite(s) sufficiently for them to engage and blend in with the community they wish to study. This may require technical and personal preparation before beginning the study, and the time and energy that will need to be dedicated to such 'acculturation' should not be underestimated.

As with all contexts for research, enquiry into digital artefacts such as virtual worlds, digital social networks, online forums, blogs or wikis should be driven primarily by research questions, not by decisions about which methodology to adopt, and no particular mode of study should be automatically privileged above others. Instead, what matters is a clear and careful link between the research question and the methodological design of the research. This is often an iterative process and an effective researcher will always be open to the possibility of adjusting (or even sometimes discarding) his/her original research question as exploration proceeds and new insights appear. Exploration and insights offer valuable opportunities to redirect the research to exploit them, and research should always respond to the pressure of evidence (Malinoswki, 1922).

By their nature, virtual worlds and social networks lend themselves to projects which do not require participants or researchers to be physically located near each other. However, much existing research with these technologies focuses on single groups of educators or students or members of a specific university, so a project with more breadth than this would have increased value. Collaborative affordances may then become important if using a research team, and researcher collaboration can be facilitated by technologies such as Google docs or Dropbox to share documents, spreadsheets and databases, and work on them to develop understandings or dynamic trend analysis using notes, 'mind-maps', graphs, charts or tools such as Gapminder.

Challenges can emerge when creating common protocols for a research team, especially if individuals are based in different institutions or countries, as these may apply different procurement constraints, use dissimilar and sometimes incompatible IT infrastructures, or have policies with very different embedded institutional and cultural assumptions about the nature of academic roles and responsibilities (e.g. for academics and instructors or for students and research participants). When using virtual worlds, having computers with appropriate specifications will also be important (check the software's website), along with sufficient bandwidth and safe passage through institutional network firewalls, so discussions with institutional IT managers are important when planning a study.

Whilst participant enthusiasm is common, it should not be assumed and some studies have found to their cost that participants who are initially enthusiastic find that time constraints, the relative complexity of virtual worlds and bandwidth demands (which can create operational slowness) can prove a disincentive for continuing engagement (see Jarmon *et al*., 2009). Despite the visual and conceptual allure of virtual worlds and the popularity of social media, successful participant recruitment may require careful preparation (Fetscherin and Lattemann, 2007). Consider who might facilitate recruitment beyond known contacts, to include local authorities, professional organizations, universities or employers. It may be useful to set up a website to explain the research and provide information and documentation, and this will also facilitate engaging with, and recruiting, potential participants.

23.9 Data

Because virtual world and social media fieldsites may be large, diffuse and engage with different media, it can be hard to establish the target population or get a sense of how representative a given sample may be (Hine, 2015). In many virtual environments, events and objects may also be connected to other online technologies such as blogs, wikis, questionnaires, rating systems, databases, etc. and increasingly to in-world tools. In such circumstances, careful planning of data-collection strategies is essential.

Communication in virtual worlds via text, chat, voice and signing can all be captured for later analysis via recording and transcription and, because data can be time-stamped, it is possible to compare the outcomes from analysis from these different communication channels for data triangulation (Martin and Vallance, 2008). By providing a scaffolded vocabulary, researchers may also more easily collect data from individuals with communication difficulties, where the slower pace of interaction and reduced amount of data involved in communication in these environments (such as lack of subtle

facial or body-language communication) may be advantageous (Ravenscroft and McAllister, 2006). These data can be converted to numbers for quantitative analysis or can be used to develop a richer understanding through interpretative, phenomenological analysis, which is a useful form of qualitative analysis when we are interested in describing how people negotiate, understand and make sense of the world. Both quantitative and qualitative data need to be used in light of the perspective adopted, the kind of information collected and the assumptions and objectives of the research.

Field notes are an important element of data collection in netography but they should be more than just descriptive accounts; they can be early interpretations of what happens, notes about feelings, ideas about what these might mean, why things happened or did not happen, 'to do' lists, as well as notes of frustrations or puzzles. They might include sketches to suggest meaning, proximity or relationships, or be loosely organized reflections and ideas for later use and reflection. The researcher may wish also to blog or tweet about the research or post things on Facebook or Instagram to encourage further interaction and debate, although the consequences may be some potentially awkward decisions about what to reveal and concerns about 'over-sharing' that may preempt later and more thoughtful analysis (Boellstorff, 2008; Boellstorff *et al*., 2012; Hine, 2015).

Screen shots, field notes and other data should be numbered, dated, time-stamped and written up immediately after an intervention. Making notes with a word processor can make it easier to search for keywords later, and audio or video recording of sessions can be useful for future analysis and allow the researcher to concentrate on making observations during sessions. Virtual worlds and social media allow researchers to collect more participant data than are otherwise possible, by capturing text, chat and user presentations from the in-world environment and by recording activity. It is important to establish whether the chosen online setting will automatically capture data from features like chatlogs and, if so, this should be tested to make sure the date and time are always recorded.

It may not be immediately clear what valuable information is within such data, as it will often contain intermingled issues, but it cannot be collected retrospectively, so capturing it as work progresses is important. Each specific event should be recorded with a unique filename so that data can be correctly sequenced and matched together later, as it might be extremely difficult to do this retrospectively. Collecting data from online environments is relatively easy and can quickly generate large amounts of material, so all relevant information needs to be kept together as it is collected. Leaving this task until later may be unwise, as it may then be difficult to remember which data goes where and to what other data it is related.

Before choosing software to be used for recording data it is important to consider:

- whether it will meet the research needs;
- whether it can be supported by and run effectively on the computer system to be used (e.g. PC, Mac, smartphone);
- whether enough storage is available, and how long recordings will usually be and how many of these there might be. How much detail is important: do video recordings need to be full-screen or high-definition? These considerations will affect the size of recorded files, so using a large-capacity external drive may be necessary;
- whether advanced editing features will be needed or just a basic package;
- testing all software thoroughly with the system on which it will be used before adopting or purchasing it, and running extensive tests before the research begins, to minimize the risk of technical problems.

Visual representations such as screenshots can be useful when combined with other data, either to illustrate an observation in the field notes or to remind the researcher of some important event or pattern of behaviour. Using visual records from online environments, whether single images or video, requires careful ethical consideration and participants need to be aware that such records will be collected and to have given prior and informed consent. Individuals must also not be identifiable from visual data; care must be taken to anonymize any that are used by removing identifying elements (see also Chapter 31 of the present volume).

Visual data are not always available, as some online environments can be entirely composed of text, or have only text chat as their means of communication. For many others, voice chat is increasingly an inbuilt feature, but where not it is common for online communities to employ additional software, effectively a phone service over the Internet known as Voice over Internet Protocol (VoIP). The researcher may therefore need to make enquiries within the community to be studied to determine whether VoIP is used, and then adopt it to augment the research data by capturing important communications, ambient sounds or music.

Participants in an online environment may also make use of associated separate communication media, but the individuals in any of these other communications may not necessarily be frequent, or the same users as found in the main study site, and careful notes will help with

mapping these different audiences and sub-groups to ensure clarity and avoid unhelpful confusion during analysis. As is the case for all data, keeping notes of filenames and associated other data will be essential, so as to know which participants were present, the time, the event(s) and location and any other relevant details. Finally, offline gatherings such as refreshment places, conventions and workshops are sometimes associated with, and used by, particular online communities and can be valuable sites for gathering additional data and meeting known or new members.

23.10 Conclusion

This chapter has argued that a range of emergent, contentious or sensitive topics can be usefully explored using virtual environments and networked social media and that these present both opportunities and challenges. Virtual worlds and increasingly other social media can offer high levels of interaction and embodiment and heightened immersion via technologies such as Oculus Rift, PlayStation VR or HTC Vive. This combination of technologies offers rich communication affordances and some unique opportunities for data capture,[2] including the ability to record sound, chat and text as well as contemporaneous images and video in real time.

In such research settings there may be a need to scrutinize what is understood by ethnographic or qualitative approaches such as participant observation, focus groups and interviewing. The traditional assumptions that are made when deploying methodological tools may need to be revisited to verify whether they are still applicable in these digitally blended communities, in which alternative values and different articulations of reality are to be found, where participants may alter their displayed embodiment at will, and in which we may simultaneously conduct our research with individuals in different locations around the world. By exposing the researcher and practitioner to new constructions, expressions and transformations of identity, reality and community, virtual worlds and other social network software offer many unique opportunities to re-examine the nature of community and self across the virtual/physical world and to rethink, refine and improve existing pedagogy and research methodology and instrumentation.

The companion website to the book provides worked examples of virtual world, social media and netography research, together with website references for the topics addressed in this chapter, virtual world research methods and PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: www.routledge.com/cw/cohen.

Notes

1 The term ‘virtual world’, as used here, presumes the presence of human users, although strictly speaking even when empty of participants such an environment may remain a virtual world. Part of the reason for the ongoing debate about what is and what is not a virtual world, and whether these things should be given a different name, is that the use of virtual world features is becoming more common in the technologies of the World Wide Web, in which one increasingly sees visually realistic three-dimensional virtual environments on websites, discussion forums, blogs, chat rooms and social network sites where user involvement is mediated by avatars.

2 Many commercial companies invest a great deal of time and money acquiring and analysing data from social media. These companies often use expensive specialist companies to do this work but are sometimes prepared to offer substantially lower prices to students or academic institutions, so check to see if your institution has or can secure this. There are also some relatively straightforward methods of collecting social media data that can be used by researchers for free or at minimal cost.

Twitter: Entrepreneur (www.entrepreneur.com/article/242830); The Chorus Project (http://chorusanalytics.co.uk) (see also Tweetcatcher).

Facebook: Graph (www.facebook.com/graphsearcher); Statista (www.statista.com/statistics/264810/number-of-monthly-active-facebook-users-worldwide) (check to see if your institution provides access).

VennMaker (a mapping tool for collecting and analysing data in social network analysis) (www.vennmaker.com/?lang=en).

Some straightforward guidance is also available on obtaining data from most social media software at WikiHow (www.wikihow.com/Main-Page).

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Part 4
Methods of data collection

This section moves to a closer-grained analysis of instruments for collecting data, how they can be used, how they can be constructed, what are their strengths and weaknesses, how to work with them and what considerations have to be borne in mind when deciding on the most appropriate choice of instrumentation. We identify eight main kinds of data-collection instruments, with many variants included in each: questionnaires (with greater coverage of online questionnaires); interviews; observations; tests; personal constructs (written by Richard Bell); role-playing (written by Carmel O'Sullivan); an entirely new chapter on using secondary data in educational research; and an updated chapter on visual media in educational research. We have expanded our discussion of material from the previous editions, particularly in respect of questionnaire design, online interviews and the increasing use of visual media in educational research, including photo-elicitation and video research and the ethical issues surrounding these.

Selecting the instrument(s) for data collection, like deciding on methodologies in Part 3, is not a matter of preference, arbitrary or automatic decision making, but, like other aspects of research, is a deliberative process in which the key is the application of the notion of *fitness for purpose*. The intention of this part is to enable researchers to decide on the most appropriate instruments for data collection, and to carry out the practical, careful design and use of such instruments. The strengths and weaknesses of these instruments are set out, so that decisions on their suitability and the criterion of *fitness for purpose* can be addressed. Hence this part not only introduces underlying principles that underpin instruments, but also offers sound, tested, practical advice for their usage, to enable researchers to gather useful and usable data. There is greater coverage of conducting research that involves children. We provide practical advice to researchers who are considering these instruments for data collection and how to use them, what safeguards to address, what challenges they might face and how to overcome them.

The companion website to the book provides supporting materials and PowerPoint slides for Part 4. This resource can be found online at: www.routledge.com/cw/cohen.

Questionnaires

CHAPTER 24

The chapter follows a sequence in designing a questionnaire, thus:

- ethical issues
- planning the questionnaire
- types of questions
- avoiding pitfalls in question writing
- sequencing questions and the layout of the questionnaire
- covering letters/sheets and follow-up letters
- piloting the questionnaire
- administering questionnaires
- processing questionnaire data

24.1 Introduction

Questionnaires offer benefits of standardized and open responses to a range of topics from a large sample or population. They can be cheap, reliable, valid, quick and easy to complete. The field of questionnaire design is vast. This chapter provides a straightforward introduction to its key elements, indicating main issues to be addressed, some important challenges and how they can be resolved. We advise readers to take this chapter together with the chapters in this book on surveys, sampling and interviewing (Chapters 17, 12 and 25 respectively). Chapter 18 (Internet surveys) addresses important material on online questionnaires, and we advise readers to consult that in detail, as we do not address such questionnaires in the present chapter, other than in passing. Part 5 concerns data analysis and this can include analysis of quantitative and qualitative data from questionnaires.

We suggest that researchers may find it useful to work through these issues in sequence, though, clearly, a degree of recursion is inevitable. Whilst many questionnaires are devised electronically, with templates and attractive layouts, these do not obviate the need for careful consideration of the issues addressed in this chapter, as, regardless of the software available, the researcher has to take a wide variety of decisions on all aspects of the questionnaire.

The questionnaire is a widely used and useful instrument for collecting survey information, providing structured, often numerical data, able to be administered without the presence of the researcher and often comparatively straightforward to analyse. These attractions have to be counterbalanced by the time taken to develop, pilot and refine the questionnaire, by the possible unsophistication and limited and superficial scope of the data that are collected and by the likely limited flexibility of response (though, as Wilson and McLean (1994, p. 3) observe, this can frequently be an attraction). The researcher will have to judge the appropriateness of using a questionnaire for data collection, and, if so, what kind of questionnaire it should be.

24.2 Ethical issues

The questionnaire will always be an intrusion into the life of the respondent, be it in terms of time taken to complete the instrument, the level of threat or sensitivity of the questions, or the possible invasion of privacy. Questionnaire respondents are not passive data providers for researchers; they are subjects not objects of research. There are several ethical sequiturs that flow from this; we introduce these below, and advise readers also to review Chapters 7 and 8 of the present volume.

Respondents cannot be coerced into completing a questionnaire. They might be strongly encouraged, but the decision whether to become involved and when (and if) to withdraw from the research is entirely theirs. Their involvement in the research is likely to be a function of:

- their *informed consent* (see Chapter 7);
- their *rights to withdraw* at any stage or *not to complete* particular items in the questionnaire;
- the potential of the research to improve their situation (the issue of *beneficence*);
- the guarantees that the research will not harm them (the issue of *non-maleficence*);
- the guarantees of *confidentiality*, *anonymity* and *non-traceability* in the research;
- the degree of *threat* or *sensitivity* of the questions (which may lead to respondents' over-reporting or under-reporting (Sudman and Bradburn, 1982));

- factors in the questionnaire itself, for example, its coverage of issues, its ability to catch what respondents want to say rather than to promote the researcher's agenda, i.e. the avoidance of bias and the assurance of validity and reliability in the questionnaire – *methodological rigour* and *fairness*. Methodological rigour is an ethical not simply a technical matter, and respondents have a right to expect reliability and validity;
- the *reactions* of the respondents. For example, they may react strongly if they consider an item to be offensive, intrusive, misleading, biased, misguided, irritating, inconsiderate, impertinent or abstruse.

These factors impact on every stage of the use of a questionnaire, suggesting that attention has to be given to the questionnaire itself, the approaches made to the respondents, the explanations given to the respondents, the data analysis and the data reporting.

24.3 Planning the questionnaire

The overall plan

At the preliminary stage of design, it can sometimes be helpful to use a flow chart to plan the questionnaire. In this way, researchers are able to anticipate the type and range of responses that their questions are likely to elicit. We set out a staged sequence for planning a questionnaire in Figure 24.1.

Within these stages there are several subcomponents, and this chapter addresses these. Further, though these stages are set out in a sequence, the process is recursive as the questionnaire design and refinement take place. These are introductory issues, and the remainder of this chapter takes each of these and unpacks them in greater detail.

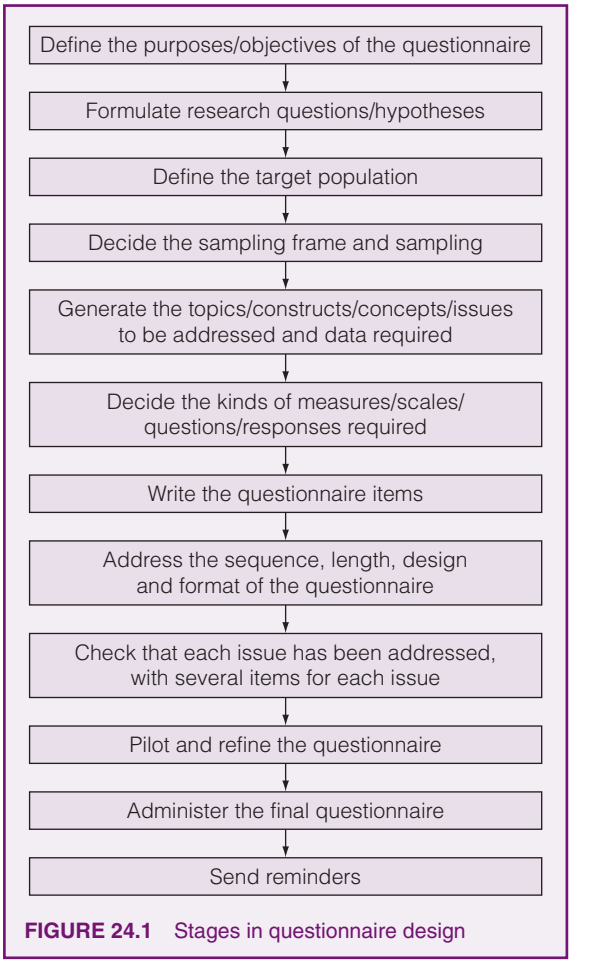

FIGURE 24.1 Stages in questionnaire design

Operationalizing the questionnaire

The process of operationalizing a questionnaire is to take a general purpose or set of purposes and turn these into concrete, researchable fields about which actual data can be gathered. First, a questionnaire's general purposes must be clarified and then translated into a specific, concrete aim or set of aims. Thus, 'to explore teachers' views about in-service work' is somewhat nebulous, whereas 'to obtain a detailed description of primary and secondary teachers' priorities in the provision of in-service education courses' is reasonably specific. Write the purposes of the questionnaire and review them to make them concrete, focused and specific.

Having decided upon and specified the primary objectives of the questionnaire, the second phase of the planning involves the formulation of the research questions to be answered and/or hypotheses to be tested. We refer the reader to Chapter 10 here, noting that the research questions, deriving from the overall purposes, must be concrete, specific and focused, enabling concrete answers to be given.

Then follows the identification of the target population and sampling, as this influences the framing of the questions, their terminology, their level of demand and the medium for administering the questionnaire (e.g. post, face-to-face interview, Internet and email, drop-off).

Then follows the identification and itemizing of subsidiary topics that relate to its central purpose. In our example above, subsidiary issues might well include: the types, contents, location, timing, design and financing of courses.

After the identification and itemization of subsidiary topics there follows the formulation of specific information requirements relating to each of these. For

example, with respect to the type of courses required, detailed information would be needed about the duration of courses (one meeting, several meetings, a week, a month, a term or a year), the status of courses (non-award bearing, award bearing, with a certificate, diploma, degree granted by a university) and the orientation of courses (theoretically oriented involving lectures, readings, etc., and/or practically oriented involving workshops and the production of curriculum materials).

What we have in the example, then, is a move from a generalized area of interest or purpose to a very specific set of features about which direct data can be gathered.

Wilson and McLean (1994, pp. 8–9) suggest an alternative approach, which is to identify the research problem, then to clarify the relevant concepts or constructs, then to identify what kinds of measures (if appropriate) or empirical indicators there are of these, i.e. the kinds of data required to give the researcher relevant evidence about the concepts or constructs, for example, their presence, their intensity, their main features and dimensions, their key elements etc. We have included such matters in Figure 24.1.

What unites these two approaches is their recognition of the need to ensure that the questionnaire: (a) is clear on its purposes; (b) develops concrete research questions which lead into the formulation of the questionnaire items; (c) is clear on what needs to be included or covered in the questionnaire in order to meet the purposes and research questions; (d) is exhaustive in its coverage and inclusion of items; (e) asks the most appropriate *kinds* of question; (f) elicits the most appropriate *kinds* of data to answer the research purposes and sub-questions; asks (g) and for empirical data. We address these points below.

Planning with the data analysis in mind

When planning a questionnaire it is important to plan so that it is set up – structured – in such a way that the data analysis can proceed as planned. For example, if the researcher wishes to conduct multiple regression (e.g. to find out the relative weights of a range of independent variables on a dependent variable), then both the independent and dependent variables must be included in the questionnaire and must be ratio data (discussed below).

For example, let us imagine that the researcher is investigating the relative strengths of reasons (independent variables) why undergraduate students take part-time jobs (dependent variable) (cf. Morrison and Tam, 2005). She asks the respondents about the level of importance of each of the following reasons, awarding a mark out of 10 for each reason, where 0 = 'of no importance' and 10 = 'of very great importance':

- meet necessary study expenses;
- meet living expenses;
- purchase better consumer products;
- support entertainment expenses;
- for extra money to spend;
- support family expenses;
- gain job experience;
- fill in spare time;
- influence of peer group.

She can then conduct a multiple regression to see the relative importance of each of these independent variables on the dependent variable (e.g. see Chapter 42).

If the researcher wishes to conduct factor analysis then the variables must be at the ratio level of data (discussed below). If structural equation modelling is required then both variables and factors have to be calculated, and these must be able to be calculated in the questionnaire. If simple frequencies, percentages and correlations are to be calculated then the questions must be framed in such a way that they can be calculated. This is a statement of the obvious, but, in our experience, too many students neglect the obvious. As Voltaire remarked, 'commonsense is not so common'.

A researcher may not wish to conduct such high-level data analysis, and often simple frequencies will suffice and can be very persuasive. This, too, can suggest causality (though not prove it – see Chapter 6), or at least correlation. Let us imagine that the researcher is looking into the effects of communication on leadership in a secondary school (160 teachers). She asks three simple questions:

1 Generally, how effective is the overall leadership in the school (tick one only):
☐ Good ☐ Not Good

2 Generally, how effective is the principal's communication in the school (tick one only):
☐ Good ☐ Not Good

3 Generally, how willing to communicate is the school principal (tick one only):
☐ Good ☐ Not Good

These simple dichotomous questions require respondents to come to a judgement; they are not permitted to 'sit on the fence', they have to make up their minds. In tabular form, the results could be presented as shown in Table 24.1 (fictitious figures) (cf. Hellevik, 1988).

TABLE 24.1 CROSSTABULATION OF RESPONSES TO TWO KEY FACTORS IN EFFECTIVE LEADERSHIP

Effective leadership	*Principal's communication*	*Willingness to communicate*	*Frequency (% rounded)*
Good	Good	Good	45 (28.1%)
Good	Good	Not good	15 (9.4%)
Good	Not good	Good	10 (6.2%)
Good	Not good	Not good	12 (7.5%)
Not good	Good	Good	3 (1.9%)
Not good	Good	Not good	12 (7.5%)
Not good	Not good	Good	5 (3.1%)
Not good	Not good	Not good	58 (36.3%)
Total			**160 (100%)**

In Table 24.1, using fictitious figures, 'effective leadership' is reported by eighty-two respondents (51.2 per cent) (45+15+10+12); 'not good' leadership is reported by seventy-eight respondents (48.8 per cent) (3+12+5+58). Table 24.1 indicates that for 'good' leadership to be present in its strongest form, the factors 'principal's communication' and 'willingness to communicate' are required to be present and 'good', and that if either or both of these factors is 'not good' then 'good' management drops dramatically.

The point to be made here is that the questionnaire is designed – set up – with the analysis in mind; the researcher knows in advance how she wants to analyse the data, and the structure and contents of the questionnaire follow from this.

Considering the demands on the respondent

It is important to avoid putting too much strain on the respondent, for example, in relying on their recall (Champagne, 2014), in the sensitivity of the issue, in the time taken to complete the questionnaire, in understanding the question. Too much strain can lead to poor-quality or incorrect responses, non-response or quitting. Denscombe (2014) comments that having too long a questionnaire can lead to respondent fatigue. He notes (pp. 172–3) that completing a questionnaire can be mentally demanding, and researchers should consider the burden of effort and demand placed on the respondent: too much and they will not take part, withdraw partway through or give responses which are 'satisficing' (discussed later). Simply because the researcher is keen to acquire data does not mean that the respondent is interested in or concerned about the matter, hence the researcher needs to motivate the respondent and make the topic interesting, meaningful, of concern and motivating. A topic which really concerns the respondent is likely to have a better response than one which is perceived to be irrelevant or of no importance or interest to him/her.

Structured, semi-structured and unstructured questionnaires

Though there are many types of questionnaire, there is a simple rule of thumb: the larger the size of the sample, the more structured, closed and numerical the questionnaire may have to be, and the smaller the size of the sample, the less structured, more open and word-based the questionnaire can be.

The researcher can select several types of questionnaire, from highly structured to unstructured. If a closed and structured questionnaire is used, enabling patterns to be observed and comparisons to be made, then the questionnaire will need to be piloted and refined so that the final version contains as full a range of possible responses as can be reasonably foreseen. Such a questionnaire is heavy on time early in the research; however, once the questionnaire has been 'set up' then the mode of analysis might be comparatively rapid. For example, it may take two or three months to devise a survey questionnaire, pilot it, refine it and set it out in a format that will enable the data to be processed and statistics to be calculated. However, the 'trade-off' from this is that the data analysis can be undertaken fairly rapidly; we already know the response categories, the nature of the data and the statistics to be used; it is a matter of processing the data (e.g. by computer) and analysing and reporting the results.

It is perhaps misleading to describe a questionnaire as being 'unstructured', as the whole devising of a questionnaire requires respondents to adhere to some form of given structure. That said, between a completely open questionnaire that is akin to an open invitation to 'write what one wants' and a completely

closed, completely structured questionnaire, there is the powerful tool of the semi-structured questionnaire. Here a series of questions, statements or items are presented and the respondents are asked to answer, respond to or comment on them as they wish. There is a clear structure, sequence and focus, but the format is open-ended, enabling respondents to reply in their own terms. The semi-structured questionnaire sets the agenda but does not presuppose the nature of the response.

24.4 Types of questionnaire items

There are several kinds of question and response modes in questionnaires, including: dichotomous questions; multiple-choice questions; rating scales; constant sum questions; ratio data; and open-ended questions. These are considered below (see also Wilson, 1996). Questions must be straightforwardly presented, comprehensible at first glance, concrete, specific, unambiguous and able to be answered, which means that assumptions are made that: (a) the respondents know the answers and have an opinion; (b) the demand and effort placed upon them are not too great and that they can actually articulate their response; (c) their recollection and memory are reliable and so on. It is essential that question types are fit for purpose (Champagne, 2014), being suitably focused and concrete (rather, than, for example, being too general and abstract), yielding useable and relevant data, measuring what they are intended to measure and avoiding questions to which the researcher already knows the answer. We consider these and other points below.

Open-ended questions

The open-ended question is an attractive device for smaller-scale research or for those sections of a questionnaire that invite an honest, personal comment from respondents in addition to ticking numbers and boxes. Here the questionnaire puts the open-ended questions and leaves a space (or draws lines) for a free response. Open-ended responses might contain the 'gems' of information that otherwise might not be caught in the questionnaire. Further, it puts the responsibility for, and ownership of, the data much more firmly into respondents' hands.

It is useful for the researcher to provide some support for respondents, so that they know the kind of reply being sought. For example, an open question that includes a prompt could be:

'Please indicate the most important factors that reduce staff participation in decision making';
'Please comment on the strengths and weaknesses of the mathematics course';
'Please indicate areas for improvement in the teaching of foreign languages in the school'.

An open-ended question might frame the answer, just as the stem of a rating scale question might frame the response given. However, an open-ended question can catch the authenticity, richness, depth of response, honesty and candour which, as is argued elsewhere in this book, are hallmarks of valid qualitative data.

Oppenheim (1992, pp. 56–7) suggests that a sentence-completion item is a useful adjunct to an open-ended question, for example:

> Please complete the following sentence in your own words:
>
> An effective teacher …
>
> or
>
> The main things that I find annoying with disruptive students are …

Open-endedness also carries problems of data handling: too many answers to be able to summarize easily; data overload. If one tries to convert opinions into numbers (e.g. so many people indicated such-and-such a degree of satisfaction with the new principal's management plan) – quantitizing qualitative data – then maybe the questionnaire should have used rating scales in the first place. Further, it might well be that the researcher here is in danger of violating one principle of word-based data, which is that they are not validly susceptible to aggregation, i.e. trying to bring to word-based data some principles of numerical data, borrowing from quantitative, positivist methodology to inform a qualitative, interpretive methodology.

Further, if a genuinely open-ended question is being asked, responses may not bear such a degree of similarity to each other to enable them to be aggregated too tightly. Open-ended questions make it difficult for the researcher to make comparisons between respondents, as there may be little in common to compare. Moreover, to complete an open-ended questionnaire takes much longer than placing a tick in a rating scale response box; not only will time be a constraint here, but there is an assumption that respondents will be sufficiently or equally capable of articulating their thoughts and committing them to paper or to the box on a screen.

In practical terms, Redline *et al*. (2002) report that using open-ended questions can lead to respondents

overlooking instructions, as they are occupied with the more demanding task of writing in their own words than reading instructions.

Despite these cautions, an open-ended question is a window of opportunity for the respondent to shed light on an issue, and thus has much to recommend it.

Open-ended questions are useful if the possible answers are unknown or the questionnaire is exploratory (Bailey, 1994, p. 120), or if there are so many possible categories of response that a closed question would contain an extremely long list of options. They also enable respondents to answer as much as they wish, and in their own words, and are particularly suitable for investigating complex issues, to which simple answers cannot be provided. They can generate rich data. Open questions can be useful for generating items that will subsequently become the stuff of closed questions in the final version of a questionnaire (i.e. part of a pre-pilot). Krosnick and Presser (2010, p. 267) note that open items often provide more valid and reliable responses than closed items, but that respondents are more likely to opt for a 'don't know' response rather than take the time to complete an open question.

Open questions enable participants to write a free account in their own terms, to explain and qualify their responses and avoid the limitations of pre-set categories of response. On the other hand, they can lead to irrelevant and redundant information; they may be too open-ended for the respondent to know what *kind* of information is being sought; they may require much more time from the respondent to enter a response (thereby leading to refusal to complete the item); respondents may have difficulty in articulating their thoughts; and open-ended questions may make the questionnaire appear long and discouraging. With regard to analysis, the data are not easily compared across participants, and the responses are difficult to code, classify and analyse.

Closed questions

Closed questions prescribe the range of responses from which the respondent may choose. Highly structured, closed questions are useful in that they can generate frequencies of response amenable to statistical treatment and analysis. They also enable comparisons to be made across groups in the sample (Oppenheim, 1992, p. 115). They are quicker to code and analyse than word-based data (Bailey, 1994, p. 118), and, often, they are directly to the point and deliberately more focused than open-ended questions, helping the respondent to answer easily, as response categories are provided; processing vast quantities of word-based data in a short time frame is extremely demanding.

If a site-specific case study is required, then qualitative, less structured, word-based and open-ended questionnaires may be more appropriate as they can capture the specificity of a particular situation. Where measurement is sought then a quantitative approach is required; where rich and personal data are sought, then a word-based qualitative approach might be more suitable.

In general, closed questions (dichotomous, multiple choice, constant sum and rating scales) are quick to complete and straightforward to code (e.g. for computer processing), and do not discriminate unduly on the basis of how articulate respondents are. On the other hand, they do not enable respondents to add any remarks, qualifications and explanations to the categories, and there is a risk that the categories might not be exhaustive and that there might be bias in them (Oppenheim, 1992, p. 115). Further, they can encourage mindless or less thought-through responses (Krosnick and Presser, 2010).

We consider in more detail below the different kinds of closed questions.

Scales of data

The questionnaire designer must choose the metric – the scale of data – to be adopted (Abascal and Diaz de Rada, 2014), and this will affect the possible statistical analysis. This concerns numerical data and which statistics can be used with which types of numerical data, and we advise readers to turn to Part 5 for an overview of the different scales of data that can be gathered (nominal, ordinal, interval and ratio), and the different statistics that can be used for analysis with them. Nominal data indicate categories; ordinal data indicate order ('high' to 'low', 'first' to 'last', 'smallest' to 'largest', 'strongly disagree' to 'strongly agree', 'not at all' to 'a very great deal'); ratio data indicate continuous values and a true zero (e.g. marks in a test, number of attendance per year, hours spent on study), thus:

QUESTION TYPE	*LEVEL OF DATA*
Dichotomous questions	Nominal
Multiple choice questions	Nominal
Rank ordering	Ordinal
Rating scales	Ordinal
Constant sum questions	Ordinal
Ratio data questions	Ratio
Open-ended questions	Word-based data

Dichotomous questions

A highly structured questionnaire asks closed questions. These can take several forms. *Dichotomous* questions have a 'yes'/'no' response, for example, 'have you ever had to appear in court?', 'do you prefer didactic methods to child-centred methods?'. The layout of a dichotomous question can be thus:

Sex (please tick): Male ☐ Female ☐

The dichotomous question is useful, for it compels respondents to 'come off the fence' on an issue. It provides for a clear, unequivocal response. Further, it is possible to code responses quickly, there being only two categories of response. A dichotomous question is also useful as a funnelling or sorting device for subsequent questions, for example: 'If you answered "yes" to question X, please go to question Y; if you answered "no" to question X, please go to question Z' (see the section below on contingency, skip and branching questions). This applies to paper-based questionnaires. In electronic/Internet questionnaires, based on the responses given, the computer can automatically take the respondent directly to the appropriate next place in the questionnaire, without instructions being given. Sudman and Bradburn (1982, p. 89) suggest that if dichotomous questions are being used, then it is desirable to use several to gain data on the same topic, in order to reduce the problems of respondents 'guessing' answers.

On the other hand, the researcher must ask whether a 'yes'/'no' response actually provides any useful information. Requiring respondents to make a 'yes'/'no' decision may be inappropriate; it might be more appropriate to have a range of responses, for example in a rating scale. A 'yes' or a 'no' may be inappropriate for a situation whose complexity is better served by a series of questions which catch that complexity. Further, Youngman (1984, p. 163) suggests that it is a natural human tendency to agree rather than to disagree with a statement ('acquiescence', discussed below); this suggests that a simple dichotomous question might build in respondent bias. People may be more reluctant to agree with a negative statement than to disagree with a positive question (Weems *et al*., 2003).

In addition to dichotomous questions ('yes'/'no' questions), a piece of research might ask for information about further dichotomous variables, for example, gender (male/female), type of school (elementary/secondary), type of course (vocational/non-vocational). Here, again, only one of two responses can be selected. Such nominal data can then be processed using the chi-square statistic, the binomial test, the G-test and cross-tabulations (for examples, see Cohen and Holliday, 1996). Dichotomous questions are treated as nominal data (see Part 5).

Multiple-choice questions

To try to gain some purchase on complexity, the researcher can move towards *multiple-choice* questions, where the range of choices is designed to include the likely range of responses to given statements. Champagne (2014) argues against the use of residual categories such as 'other', as these might insult the respondent, suggesting that the researcher has not done sufficient preparation work in identifying the likely categories of response, i.e. it is important to avoid items which have 'missing choices' (p. 41).

For example, the researcher might ask a series of questions about a new chemistry scheme in the school; a statement precedes a set of responses thus:

The New Intermediate Chemistry Education (NICE) is:

(a) a waste of time;
(b) an extra burden on teachers;
(c) not appropriate to our school;
(d) a useful complementary scheme;
(e) a useful core scheme throughout the school;
(f) well-presented and practicable.

The categories have to be discrete (i.e. having no overlap, being mutually exclusive) and have to exhaust the possible range of responses. Guidance has to be given on the completion of the multiple-choice, clarifying, for example, whether respondents are able to tick only *one* response (a *single answer* mode) or a *constrained number* of choices (e.g. three priorities from a list of ten possible choices) or a *free choice* (tick as many as you wish from the list). Like dichotomous questions, multiple-choice questions can be quickly coded and quickly aggregated to give frequencies of response. If that is appropriate for the research, then this might be a useful instrument.

The layout of a multiple-choice question can be thus:

Number of years in teaching
1–5 ☐ 6–14 ☐ 15–24 ☐ 25+ ☐

Which age group do you teach at present (you may tick more than one)?
Infant/kindergarten ☐
Primary ☐
Secondary (excluding sixth form) ☐
Sixth form only ☐

Just as dichotomous questions have their parallel in dichotomous variables, so multiple-choice questions have their parallel in *multiple elements of a variable*. For example, the researcher may be asking to which form a student belongs – there being up to, say, forty forms in a large school, or the researcher may be asking which post-16 course a student is following (e.g. academic, vocational, interest-based). In these cases only one response may be selected. As with the dichotomous variable, the listing of several categories or elements of a variable (e.g. form membership and course followed) enables nominal data to be collected and processed using the chi-square statistic, the G-test and cross-tabulations (Cohen and Holliday, 1996). Multiple-choice questions are treated as nominal data (see Part 5).

It is important to include in the multiple choices those that will enable respondents to select the response that most closely represents their view; hence a pilot is needed to ensure that the categories are comprehensive, exhaustive and representative. On the other hand, the researcher may be interested only in certain features, and it is these which would figure in the response categories.

The multiple-choice questionnaire seldom gives more than a crude statistic, for words are inherently ambiguous. In the example above, of chemistry, the notion of 'useful' is unclear, as are 'appropriate', 'practicable' and 'burden'. Respondents could interpret these words differently in their own contexts, thereby rendering the data ambiguous. One respondent might see the utility of the chemistry scheme in one area and thereby say that it is useful – ticking category (d). Another respondent might see the same utility in that same one area, but, because it is only useful in that single area, may see this as a flaw and therefore not tick category (d). With an anonymous questionnaire this difference is impossible to detect.

This is the heart of the problem of questionnaires: different respondents interpret the same words differently. 'Anchor statements' can be provided to allow a degree of discrimination in response (e.g. 'strongly agree', 'agree' etc.) and this yields greater reliability (Krosnick and Presser, 2010), but there is still no guarantee that respondents will interpret them in the way that is intended. In the example above this might not be a problem as the researcher might only be seeking an index of utility, without wishing to know the areas of utility or the reasons for that utility. The evaluator might be wishing only for a crude statistic (which might be very useful in making a decisive judgement about a programme). In this case a rough and ready statistic might be perfectly acceptable.

One can see in the example of chemistry above not only ambiguity in the wording but a very incomplete set of response categories which is hardly capable of including all aspects of the chemistry scheme. That this might be politically expedient cannot be overlooked, and if the choice of responses is limited then those responses might build bias into the research. For example, if the responses were limited to statements about the *utility* of the chemistry scheme, then the evaluator would have little difficulty in establishing that the scheme was useful. By avoiding the inclusion of negative statements or the opportunity to record a negative response the research will surely be biased.

Multiple-choice items are also prone to problems of word order and statement order. For example, Dillman *et al*. (2003, p. 6) report a study of sports, in which tennis was found to be less exciting than football when the tennis option was presented before the football option, and more exciting when the football option was placed before the tennis option. This suggests that respondents tend to judge later items in terms of the earlier items, rather than vice versa, and that they overlook features specific to later items if these are not contained in the earlier items. This is an instance of the 'primacy effect' or 'order effect', wherein items earlier in a list are given greater weight than items lower in the list. Order effects are resilient to efforts to minimize them, and primacy effects are particularly strong in Internet questionnaires (p. 22). Preceding questions and the answers given may influence responses to subsequent questions (Schwartz *et al*., 1998, p. 177).

Order effects and the primacy effect are examples of context effects, in which some questions (sometimes coming later in the questionnaire, as respondents do not always answer questions in the given sequence, and may scan the whole questionnaire before answering specific items) may affect the responses given to other questions (Friedman and Amoo, 1999, p. 122), biasing the responses by creating a specific mindset, i.e. a predisposition to answering questions in a particular way.

Further, questionnaires designers must be aware of the recency effect, i.e. respondents tend to remember the last item in a list rather than what precedes it, and this affects their response.

Rank ordering

The rank order question is akin to the multiple-choice question in that it identifies options from which respondents can choose, yet it moves beyond multiple-choice items in that it asks respondents to identify priorities. This enables a *relative* degree of preference, priority, intensity etc. to be charted. Rank ordering requires respondents to *compare* values across variables; in this

respect they are unlike rating scales in which the values are entered independently of each other (Ovadia, 2004, p. 404), i.e. the category 'strongly agree' can be applied to a single variable without any regard to what one enters for any other variable. In a ranking exercise the respondent is required to take account of the other variables, because he/she is being asked to see their *relative* value, weighting or importance. This means that, in a ranking exercise, the task must be fair, i.e. the variables are truly able to be compared and placed in a rank order, and they lie on the same scale and/or can be judged on the same criteria.

In the rank ordering exercise, a list of factors is set out and the respondent is required to place them in a rank order, for example:

Please indicate your priorities by placing numbers in the boxes to indicate the ordering of your views, 1 = the highest priority, 2 = the second highest, and so on.

The proposed amendments to the mathematics scheme might be successful if the following factors are addressed:

- the appropriate material resources are in school; ☐
- the amendments are made clear to all teachers; ☐
- the amendments are supported by the mathematics team; ☐
- the necessary staff development is assured; ☐
- there are subsequent improvements to student achievement; ☐
- the proposals have the agreement of all teachers; ☐
- they improve student motivation; ☐
- parents approve of the amendments; ☐
- they will raise the achievements of the brighter students; ☐
- the work becomes more geared to problem-solving. ☐

In this example ten items are listed. Whilst this might be enticing for the researcher, enabling fine distinctions possibly to be made in priorities, it might be asking too much of the respondents to make such distinctions. They genuinely might not be able to differentiate their responses, or they simply might not feel strongly enough to make such distinctions. The inclusion of too long a list might be overwhelming. Indeed Wilson and McLean (1994, p. 26) suggest that it is unrealistic to ask respondents to arrange priorities where more than five ranks are requested. In the case of the list of ten points above, the researcher might approach this problem in one of two ways. The list in the questionnaire item can be reduced to five items only, in which case the *range* and comprehensiveness of responses that fairly catches what the respondent feels is significantly reduced. Alternatively, the list of ten items can be retained, but the request can be made to the respondents only to rank their first five priorities, in which case the range is retained and the task is not overwhelming (though the problem of sorting the data for analysis is increased).

An example of a shorter list might be:

Please place these in rank order of the most to the least important, by putting the position (1–5) against each of the following statements, number one being the most important and number 5 being the least important:

Students should enjoy school	[ ]
Teachers should set less homework	[ ]
Students should have more choice of subjects in school	[ ]
Teachers should use more collaborative methods	[ ]
Students should be tested more, so that they work harder	[ ]

Rankings may also assume that the different items can truly be placed on a single scale. Consider the example above, where the respondent is required to place five items on a single scale of importance. Can these items really be differentiated according to the single criterion of 'importance'? Surely 'fitness for purpose' and context would suggest that a fairer answer is that 'it all depends' on what is happening in a specific context, i.e. even though one could place items in a rank order, in fact it may be meaningless to do so. The items may truly not be comparable (Ovadia, 2004, p. 405). As Ovadia (2004, p. 407) notes, valuing justice may say nothing about valuing love, so to place them in a single ranking scale of importance may be meaningless.

Rankings are useful in indicating *degrees* of response. In this respect they are like rating scales, discussed below. Ranking questions are treated as ordinal data (see Part 5 for a discussion of ordinal data). However, rankings do not enable sophisticated statistical analysis to be conducted (Ovadia, 2004, p. 405), as the ranks are inter-dependent rather than independent, and these vary for each respondent, i.e. not only does the rank '1st' mean different things to different respondents, but there are no equal intervals between each rank, and the rank of, say, '3rd' has a different

meaning for different respondents, which is relative to their idea of what constitutes '2nd' and '4th', i.e. the rankings are inter-dependent; there is no truly common metric here. Further, because rankings force a respondent to place items in a rank order, differences between values may be overstated. The difference between ranks 1 and 2 might be large, whereas the difference between ranks 5 and 6 might be negligible; simply placing items in a ranks order here, therefore, might be dangerous if too much weight is put on them.

Rankings operate on a zero-sum model (Ovadia, 2004, p. 406), i.e. if one places an item in first position then this means that another item drops in the ranking; this may or may not be desirable, depending on what the researcher wishes to find out. Researchers using rankings will need to consider whether it is fair to ask respondents really to compare items and to judge one item in relation to another; to ask 'are they really commensurable?' (able to be measured by the same single standard or criterion). It might be preferable to use rating scales.

Rating scales

One way in which degrees of response, intensity of response and the move away from dichotomous questions and rankings have been managed can be seen in the notion of *rating scales*: Likert scales, semantic differential scales, Thurstone scales and Guttman scaling. These are useful devices for the researcher, as they build in a degree of sensitivity and differentiation of response whilst still generating numbers. Here we focus on the first two of these, though readers will find the others discussed in Oppenheim (1992), Krosnick and Presser (2010) and Dillman *et al*. (2014). A Likert scale (named after its deviser, Rensis Likert, 1932) provides a range of responses to a given question or statement, for example:

How important do you consider work placements to be for secondary school students?

1 = not at all
2 = very little
3 = a little
4 = quite a lot
5 = a very great deal

All students should have access to free higher education.

1 = strongly disagree
2 = disagree
3 = neither agree nor disagree
4 = agree
5 = strongly agree

Such a scale could be set out thus:

Please complete the following by placing a tick in one space only, as follows:

1 = strongly disagree; 2 = disagree;
3 = neither agree nor disagree;
4 = agree; 5 = strongly agree

Senior school staff should teach more

1	2	3	4	5
[ ]	[ ]	[ ]	[ ]	[ ]

In these examples the categories need to be discrete and to exhaust the range of possible responses which respondents may wish to give. Notwithstanding the problems of interpretation which arise as in the previous example – one respondent's 'agree' may be another's 'strongly agree', one respondent's 'very little' might be another's 'a little' – the greater subtlety of response which is built into a rating scale renders this a very attractive and widely used instrument in research, particularly for gathering data on attitudes and opinions.

These two examples both indicate an important feature of an attitude scaling instrument, namely the assumption of *unidimensionality* in the scale; the scale should only be measuring one thing at a time (Oppenheim, 1992, pp. 187–8). Indeed this is a cornerstone of Likert's own thinking (1932).

It is a very straightforward matter to convert a dichotomous question into a multiple-choice question. For example, instead of asking dichotomous ('yes/no') questions such as 'do you?', 'have you?', 'are you?', 'can you?', a simple addition to wording will convert it into a much more subtle rating scale, by substituting the words 'to what extent?', 'how far?', 'how much?', 'how often?' etc.

A semantic differential is a variation of a rating scale which operates by putting an adjective at one end of a scale and its opposite at the other, for example:

How informative do you consider the new set of history textbooks to be?

	1	2	3	4	5	6	7	
useful	_	_	_	_	_	_	_	useless

Respondents indicate their opinion by circling or putting a mark on that position on the scale which most represents what they feel. Researchers devise their own terms and their polar opposites, for example:

Approachable	… Unapproachable
Generous	… Mean
Friendly	… Hostile
Caring	… Uncaring
Attentive	… Inattentive
Hard-working	… Lazy

Osgood *et al.* (1957), the pioneers of this technique, suggest that semantic differential scales are useful in three contexts: *evaluative* (e.g. valuable–valueless, useful–useless, good–bad); *potency* (e.g. large–small, weak–strong, light–heavy); and *activity* (e.g. quick–slow, active–passive, dynamic–lethargic). However, Champagne (2014) argues against not defining each scale point, as, if numbers have no anchor statement indicating what each point means, respondents people will interpret them very differently, building in unreliability. He strongly advocates including descriptors for every scale point, as this makes for greater clarity, reduced ambiguity and more useable results, for example: 1 = definitely no; 2 = probably no; 3 = probably yes; 4 = definitely yes (p. 45).

There are several commonly used categories in rating scales, for example:

- strongly disagree/disagree/neither agree nor disagree/agree/strongly agree
- very seldom/occasionally/quite often/very often
- very little/a little/somewhat/quite a lot/a very great deal
- never/almost never/sometimes/often/very often
- not at all important/unimportant/neither important nor unimportant/important/very important
- very true of me/a little bit true of me/don't know/not really true of me/very untrue of me
- strongly agree/agree/uncertain (or 'neither agree nor disagree')/disagree/strongly agree

To these could be added the category 'don't know' or 'have no opinion'. On the other hand, Krosnick and Presser (2010, p. 284) and Champagne (2014) warn that the inclusion of a 'don't know' category can be used by respondents not as a genuine category but because of satisficing (discussed below), intimidation and self-protection, ambivalence and problems in understanding the question or how to respond. Indeed Krosnick and Presser note (p. 285) that the inclusion of this category might compromise the quality of the data, and this might apply particularly if sensitive questions are being asked where socially undesirable response categories are included (p. 287).

Champagne (2014) reminds researchers of the need to ensure that the response scale actually matches the item (p. 47). For example, many researchers will use categories such as: 'strongly agree', 'agree', 'neither agree nor disagree', 'disagree' and 'strongly disagree', but the questions to which these scale points are used might be inappropriate, for example:

- 'I regularly spoke with my department head' (which concerns consistency and frequency);
- 'I meet my department head by appointment' (which requires either a 'yes/no' answer or an answer concerning frequency);
- 'The pace of this staff meeting was satisfactory' (which does not tell us, for example, whether the pace was fast or slow, or too fast or too slow).

Rating scales are widely used in research, and rightly so, for they combine the opportunity for a flexible response with the ability to determine frequencies, correlations and other forms of quantitative analysis. They afford the researcher the freedom to fuse measurement with opinion, quantity and quality.

Though rating scales are useful in research, the investigator, nevertheless, needs to be aware of their limitations. For example, the researcher may infer a degree of sensitivity and subtlety from the data that they cannot bear. There are other cautionary factors about rating scales and we set these out below.

1 Equal intervals

There is no assumption of equal intervals between the categories, hence a rating of 4 indicates neither that it is twice as powerful as 2 nor that it is twice as strongly felt; one cannot infer that the intensity of feeling in the Likert scale between 'strongly agree' and 'agree' somehow matches the intensity of feeling between 'strongly disagree' and 'disagree'. These are illegitimate inferences. The problem of equal intervals has been addressed in Thurstone scales (Thurstone and Chave, 1929; Oppenheim, 1992, pp. 190–5). Friedman and Amoo (1999, p. 115) suggest that if the researcher wishes to assume equal intervals ('equal-sized gradations') between points in the rating scale, then he or she must ensure that the category descriptors are genuinely equal interval. Take, for example, the scale 'not at all', 'very little', 'a little', 'quite a lot', 'a very great deal'. Here the conceptual distance between 'a little' and 'quite a lot' is much greater than between 'very little' and 'a little', i.e. there are not equal intervals.

2 The meaning of numbers

Numbers have different meanings for different respondents, so one person may use a particular criterion to award a score of '6' on a seven-point scale, whilst

another person using exactly the same criterion would award a score of '5' on the same scale. Here '6' and '5' actually mean the same but the numbers are different. Alternatively, one person looking at a score of, say, 7 marks out of 10 on a ten-point scale would consider that to be a high score, whereas another person looking at the same score would consider it to be moderate only. Similarly, the same word has a different meaning for different respondents; one teacher may think that 'very poor' is a very negative descriptor, whereas another might think less negatively about it, and what one respondent might term 'poor', another respondent, using the same criterion, might term 'very poor'. Friedman and Amoo (1999, p. 115) report that there was greater consistency between subjects on the meanings of positive words rather than negative words, and they suggest that, therefore, researchers should use descriptors that have lesser strength at the negative pole of a scale (p. 3). Further, they suggest that temporal words (e.g. 'very often', 'seldom', 'fairly often', 'occasionally' etc.) are open to great variation in their meanings for respondents (p. 3).

3 Unrealistic choices

Some rating scales are unbalanced, forcing unrealistic choices to be made, for example, in the scale 'very acceptable', 'quite acceptable', 'a little acceptable' 'acceptable' and 'unacceptable', or in the scale 'excellent, 'very good', 'quite good', 'good' and 'poor', there are four positive categories and only one negative category (cf. Friedman and Amoo, 1999, p. 119). This can skew results. Such imbalance could even be called unethical.

4 Layout effects

Respondents are biased towards the left-hand side of a bipolar scale (Friedman and Amoo, 1999, p. 120; Hartley and Betts, 2010, p. 25). For example, if the scale 'extremely good' to 'extremely poor' runs from left to right respectively, then the results will be different when the same scale is reversed ('extremely poor' to 'extremely good') and runs from left to right (or, for example, 'strongly agree' on the left to 'strongly disagree' on the right, and vice versa). Typically, categories on the left-hand side of a scale are used more frequently than those on the right-hand side of a scale. Hartley and Betts (2010, p. 25) found that those scales which had a positive label on the left-hand side would elicit higher scores than other orderings. Hence researchers must be cautious about putting all the positive categories on the left-hand side alone, as this can result in more respondents using those categories than if they were placed on the right-hand side of the scale, i.e. rating scales may want to mix the item scales so that sometimes there are positive scores on the left and sometimes positive scores on the right (but too much mixing is confusing and might lead to a non-response or an unintended response).

5 Direction of comparison

The 'direction of comparison' (Friedman and Amoo, 1999, p. 120) also makes a difference to results. The authors cite an example where students were asked how empathetic their male and female teachers were in regard to academic and personal problems. When the question asked 'would you say that female teachers were more empathetic … than the male teachers?' the mean score of the responses on a nine-point scale was different from when the question was 'would you say that male teachers were more empathetic … than the female teachers?' In the former, 41 per cent of responses indicated that female teachers were more empathetic, whereas in the latter only 9 per cent of responses indicated that female teachers were more empathetic.

6 Truthfulness of responses

We have no check on whether respondents are telling the truth. Some may be deliberately falsifying their replies.

7 Inadequate categories

We have no way of knowing if the respondent wishes to add any other comments about the issue under investigation. It might be that there is something far more pressing about the issue than the rating scale includes but which is condemned to silence for want of a category. A straightforward way to circumvent this issue is to run a pilot and also to include a category entitled 'other (please state)'.

8 Number of scale points

Most of us would not wish to be called extremists; we may prefer to appear like each other in many respects. For rating scales this means that we avoid the two extreme poles at each end of the continuum of the rating scales, reducing the number of positions in the scales to a choice of three (in a five-point scale). That means that *in fact* there could be very little choice for us. Further, a trichotomous scale (dislike/neutral/like) may not catch the sensitivity of a larger scale, for example, a respondent may wish to record a 'moderately like' response but there is no category for this. The way round these problems is to create a larger scale than a five-point scale, for example a seven-point scale. To go beyond a seven-point scale is to invite a

degree of detail and precision which might be inappropriate for the item in question, particularly if the argument set out above is accepted, namely, that one respondent's scale point 3 might be another's scale point 4.

Friedman and Amoo (1999, p. 120) suggest that five-point to eleven-point scales might be most useful, whilst Schwartz *et al*. (1991, p. 571) and Krosnick and Presser (2010) suggest that seven-point scales seem to be preferable in terms of reliability, the ability of respondents to discriminate between the values in the scales, and the percentages of respondents who are 'undecided'. If a differentiated, fine-grained response is sought then a larger (five- or seven-point) rather than a smaller scale is preferable. Indeed they suggest that reliability is lower for those scales which have few scale points and higher for those which have more scale points, levelling off from seven points or more, with validity lowering if there are many scale points.

9 Labelling scale points

Schwartz *et al*. (1991, p. 571), Krosnick and Presser (2010) and Champagne (2014) report that rating scales that have a verbal label for each point in the scale are more reliable than rating scales which provide labels only for the end-points of the numerical scales. Indeed Krosnick and Presser (2010) report that respondents prefer to have such labels.

10 Ratio data

If the researcher wishes to use ratio data (see Part 5) in order to calculate more sophisticated statistics (e.g. regressions, factor analysis, structural equation modelling), then a ratio scale must have a true zero ('0') and equal intervals. Many rating scales use an eleven-point scale here that runs from 0 to 10, with 0 being 'not at all' (or something equivalent to this, depending on the question/item) and 10 being the highest score (e.g. 'completely' or 'excellent').

11 End-point descriptors

The end-point descriptors on a scale have a significant effect on the responses (Friedman and Amoo, 1999, p. 117). For example, if the end-points of a scale are extreme (e.g. 'terrible' and 'marvellous') then respondents will avoid these extremes, whereas if the end-points are 'very bad' and 'very good' then more responses in these categories are chosen.

12 Number, nature and order of scale points

The nature of the scaling may affect significantly the responses given and the range of responses actually given (Schwartz and Bienias, 1990, p. 63). Hartley and Betts (2010) and Dillman *et al*. (2014) note that even different rating scale order exerts an influence on responses. Schwartz *et al*. (1991) found that if a scale only had positive integers (e.g. 1 to 10) on a scale of 'extremely successful' to 'not at all successful', then 34 per cent of respondents chose values in the 1–5 categories. However, when the scale was set at −5 for 'not at all successful' and +5 for 'extremely successful', then only 13 per cent of respondents chose the equivalent lower five values (−5 to 0). The authors surmised that the former scale (0–10) was perceived by respondents to indicate degrees of success, whereas the latter scale (−5 to 0) was perceived by respondents to indicate not only the absence of success but the presence of the negative factor of failure (see also Schwartz *et al*., 1998, p. 177). Indeed they reported that respondents were reluctant to use negative scores (1991, p. 572) and that responses to a −5 to +5 scale tended to be more extreme than responses to a 0–10 scale, even when they used the same scale verbal labels.

Schwartz *et al*. also suggest (1991, p. 577) that, in a −5 to +5 scale, zero (0) indicates absence of an attribute, whereas in a 0–10 scale a zero (0) indicates the presence of the negative end of the bipolar scale, i.e. the zero has two different meanings, depending on the scale used. Hence researchers must be careful about not only the verbal labels that they use, but also the scales and scale points that they use with those same descriptors. Kenett (2006, p. 409) also comments, in this respect, that researchers will need to consider whether they are asking about a bipolar dimension (e.g. 'very successful' to 'very unsuccessful') where an attribute and its opposite are included, or whether a single pole is being used (e.g. only degrees of positive response or presence of a factor). For a bipolar dimension, a combination of negative and positive numbers on a scale may be useful (with the cautions indicated above), whereas for a single polar dimension then only positive numbers should be used (cf. Schwartz *et al*., 1991, p. 577). In other words, if the researcher is looking to discover the intensity of a single attribute then it is better to use positive numbers only (p. 578).

13 Terminology of response categories

Response alternatives may signal the nature of the considerations to be borne in mind by respondents (Gaskell *et al*., 1994, p. 243). For example, if one is asking about how often there are incidents of indiscipline in a class, the categories 'several times each lesson', 'several times each morning', 'several times each day' may indicate that a more inclusive, wider definition of 'indiscipline' is required than if the categories of 'several times each week', 'several times each month'

or 'several times each term' were used. The terms used may frame the nature of the thinking or responses that the respondent uses. Gaskell *et al*. suggest that this is particularly the case if some vague phrases are included in the response categories (p. 242). Obtained responses, as Schwartz and Bienias (1990, p. 62) indicate, are a function of the response alternatives that the researcher has provided. Indeed Bless *et al*. (1992, p. 309) indicate that scales which offer higher response categories/values tend to produce higher estimates from the respondents and that this tendency increases as questions become increasingly difficult (p. 312).

14 Clustering of responses

Respondents tend to cluster their responses (e.g. around the centre or around one end or another of the scale), and their responses to one item may affect their responses to another item (i.e. creating a single mindset).

15 Forced choices

Choices may be 'forced' by omitting certain categories (e.g. 'no opinion', 'undecided', 'don't know', 'neither agree nor disagree'). If the researcher genuinely believes that respondents do, or should, have an opinion then such omissions may be justified. Alternatively, it may be unacceptable to force a choice for want of a category which genuinely lets respondents say what is in their minds, even if their minds are not made up about a factor or if they have a reason for concealing their true feelings. Forcing a choice may lead to respondents having an opinion on matters that they really have no opinion about (Friedman and Amoo, 1999, p. 118), and respondents may object to them.

16 Mid-points

There is a tendency for participants to opt for the mid-point of a 5- or seven-point scale (the central tendency). This is notably an issue in East Asian respondents, where the 'doctrine of the mean' is advocated in Confucian culture. One way to overcome this is to use an even number scaling system, as there is no mid-point. On the other hand, it could be argued that if respondents wish to 'sit on the fence' and choose a mid-point, then they should be given the option to do so. Krosnick and Presser (2010, p. 274) note that reliability and validity increase with the use of mid-points, and they advise using them.

On some scales there are mid-points; on the five-point scale it is category 3, and on the seven-point scale it is category 4. However, choosing an even number of scale points, for example a six-point scale, might *require* a decision on rating to be indicated. For example, suppose a new staffing structure has been introduced into a school and the headteacher/principal is seeking some guidance on its effectiveness. A six-point rating scale might ask respondents to indicate their response to the statement:

> The new staffing structure in the school has enabled teamwork to be managed within a clear model of line management.
>
> (Circle one number)
>
> | | 1 | 2 | 3 | 4 | 5 | 6 | |
> |---|---|---|---|---|---|---|---|
> | strongly agree | _ | _ | _ | _ | _ | _ | strongly disagree |

Let us say that one member of staff circled 1, eight staff circled 2, twelve staff circled 3, nine staff circled 4, two staff circled 5 and seven staff circled 6. There being no mid-point on this continuum, the researcher could infer that those respondents who circled 1, 2 or 3 were in some measure of agreement, whilst those respondents who circled 4, 5 or 6 were in some measure of disagreement. That would be very useful for, say, a headteacher/principal in publicly displaying agreement, there being twenty-one staff (1+8+12) agreeing with the statement and eighteen (9+2+7) displaying a measure of disagreement. However, one could point out that the measure of 'strongly disagree' attracted seven staff – a very strong feeling – which was not true for the 'strongly agree' category, which attracted only one member of staff. The extremity of the voting has been lost in a crude aggregation.

Further, if the researcher were to aggregate the scoring around the two mid-point categories (3 and 4), there would be twenty-one members of staff represented, leaving nine (1+8) from categories 1 and 2 and nine (2+7) from categories 5 and 6; adding together categories 1, 2, 5 and 6, a total of eighteen is reached, which is less than the twenty-one total of the two categories 3 and 4. It seems on this scenario that it is far from clear that there was agreement with the statement from the staff; indeed taking the high incidence of 'strongly disagree', it could be argued that those staff who were perhaps ambivalent (categories 3 and 4), coupled with those who registered a 'strongly disagree', indicate not agreement but disagreement with the statement.

The interpretation of data has to be handled very carefully; ordering them to suit a researcher's own purposes might be very alluring but quite illegitimate. The golden rule here is that crude data can only yield crude interpretation; subtle interpretations require subtle data. The interpretation of data must not distort the data unfairly. Rating scale questions are treated as ordinal

data (see Part 5) and use modal scores and non-parametric data analysis, though one can find very many examples where this rule has been violated, and non-parametric data have been treated as parametric data. Indeed there is an argument that, in fact, a Likert scale with anchor statements (scale point labels) is really a nominal scale, though typically it is taken to be ordinal.

It has been suggested that the attraction of rating scales is that they provide more opportunity than dichotomous questions for rendering data more sensitive and responsive to respondents. This makes rating scales particularly useful for tapping attitudes, perceptions and opinions. The need for a pilot study to devise and refine categories, making them exhaustive and discrete, has been suggested as a necessary part of this type of data collection.

Rating scales are more sensitive than dichotomous scales. Nevertheless they are limited in their usefulness to researchers by their fixity of response caused by the need to select from a given choice. A questionnaire might be tailored even more to respondents by including *open-ended* questions to which they can reply in their own terms and own opinions. For further reviews of rating scales, we refer the reader to Hartley and Betts (2010).

Ranking or rating?

If the researcher wishes respondents to *compare* variables (items) and award scores for items in relation to each other, then rankings are suitable. If the researcher wishes respondents to give a response/score to variables (items) that are independent of the score awarded to any other variables (items), then ratings should be considered. In the latter, the score that one awards to one variable has no bearing or effect on the score that one awards to another. In practice, the results of many rating scales may enable the researcher to place items in a rank order (Ovadia, 2004, p. 405), but rating scales may also result in many variables having ties (the same score) in the values given, which may be coincidental or, indeed, the 'result of indifference' (p. 405) on the part of the respondent to the variable in question (e.g. respondents simply and quickly tick the middle box (e.g. '3' in a five-point scale) going down a list of items).

Rankings may force the respondent to use the full range of the scale (the scale here being the number of items included, e.g. if there are ten items then up to ten rankings might be required). By contrast, ratings do not have such a stringent requirement; respondents may cluster their responses to all the items around one end of a scale (e.g. points '5', '6' and '7' in a seven-point scale, or point '3' in a five-point scale).

Let us imagine that a researcher asked respondents to indicate the importance of three items in respect of student success, and that the scale used was to award points out of ten. Here are the results for respondent A and respondent B (cf. Ovadia, 2004, p. 407):

Respondent A: working hard (9 points); family pressure (6 points); enjoyment of the subject (5 points).

Respondent B: working hard (6 points); family pressure (4 points); enjoyment of the subject (2 points).

A ranking exercise would accord the same positioning of the items on these two scores: in first place comes 'working hard', then 'family pressure', and in the lowest position, 'enjoyment of the subject'. However, as we can see, the *actual* scores are very different, and respondent A awards much higher scores than respondent B, i.e. for respondent A these items are much more important than for respondent B, and any single item is much more important for respondent A than for respondent B. Whilst rankings and ratings here yield equally valid results, the issue is one of 'fitness for purpose': if the researcher wishes to *compare* then rankings might be useful, whereas if the researcher wishes to examine actual values then ratings might be more useful.

Further, let us imagine that for respondent A in this example, the score for 'working hard' drops by 2 points over time, the score for 'family pressure' drops by 1 point and the score for 'enjoyment of the subject' drops by 3 points over time. The result of the ranking, however, remains the same, i.e. even though the level of importance has dropped for these three items, the ranking is insensitive to these changes.

Constant sum questions

In this type of question respondents are asked to distribute a given number of marks (points) between a range of items, for example:

'Please distribute a total of ten points among the sentences that you think most closely describe your behaviour. You may distribute these freely: they may be spread out, or awarded to only a few statements, or all allocated to a single sentence if you wish.'

I can take advantage of new opportunities	[ ]
I can work effectively with all kinds of people	[ ]
Generating new ideas is one of my strengths	[ ]
I can usually tell what is likely to work in practice	[ ]
I am able to see tasks through to the very end	[ ]
I am prepared to be unpopular for the good of the school	[ ]

This enables priorities to be identified, comparing highs and lows, and for equality of choices to be indicated, and, importantly, for this to be done in the respondents' own terms. It requires respondents to make comparative judgements and choices across a range of items. For example, we may wish to distribute ten points for aspects of an individual's personality:

Talkative	[ ]
Cooperative	[ ]
Hard-working	[ ]
Lazy	[ ]
Motivated	[ ]
Attentive	[ ]

This means that the respondent has to consider the *relative* weight of each of the given aspects before coming to a decision about how to award the marks. To accomplish this means that the all-round nature of the person, in the terms provided, has to be considered in order to see, on balance, which aspect is stronger when compared to another.

The difficulty with this approach is to decide how many marks can be distributed (a round number, e.g. ten, makes subsequent calculation easily comprehensible) and how many statements/items to include, for example, whether to have the same number of statements as there are marks, or more or fewer statements than the total of marks. Having too few statements/items does not do justice to the complexity of the issue, and having too many statements/items may mean that it is difficult for respondents to decide how to distribute their marks. Having too few marks available may be unhelpful, but, by contrast, having too many marks and too many statements/items can lead to simple computational errors by respondents. Our advice is to keep the number of marks to ten and the number of statements to around six to eight. Constant sum data are ordinal, and this means that non-parametric analysis can be performed on the data (see Part 5). Constant sum questions may place too great an onus on participants to decide, and this could lead to non-response or withdrawal.

Ratio data questions

We discuss ratio data in Part 5 and we refer the reader to the discussion and definition there. For our purposes here we suggest that ratio data questions deal with continuous variables where there is a true zero, for example:

How much money do you have in the bank?	____
How many times have you been late for school?	____
How many marks did you score in the mathematics test?	____
How old are you (in years)?	____

Here no fixed answer or category is provided, and the respondent puts in the numerical answer that fits his/her exact figure, i.e. the accuracy is higher, much higher than in *categories* of data. This enables averages (means), standard deviations, range and high-level statistics to be calculated, for example, regression, factor analysis, structural equation modelling (see Part 5).

An alternative form of ratio scaling is where the respondent has to award marks out of, say, ten, or a percentage, for a particular item (e.g. Kgaile and Morrison, 2006), as illustrated in Table 24.2.

This kind of scaling is often used in telephone interviews, as it is easy for respondents to understand. The argument could be advanced that this is a sophisticated form of rating scale, but the terminology used in the instruction clearly suggests that it asks for ratio scale data. Ratio data that ask for a percentage assume a degree of sensitivity that may be unwarranted, i.e. what

TABLE 24.2 A MARKING SCALE IN A QUESTIONNAIRE

'Please give a mark from 0 to 10 for the following statements, with 10 being excellent and 0 being very poor. Please circle the appropriate number for each statement.'

Teaching and learning	*Very poor*										*Excellent*
1 The attention given to teaching and learning at the school	0	1	2	3	4	5	6	7	8	9	10
2 The quality of the lesson preparation	0	1	2	3	4	5	6	7	8	9	10
3 How well learners are cared for, guided and supported	0	1	2	3	4	5	6	7	8	9	10
4 How effectively teachers challenge and engage learners	0	1	2	3	4	5	6	7	8	9	10
5 The educators' use of assessment for maximizing learners' learning	0	1	2	3	4	5	6	7	8	9	10
6 How well students apply themselves to learning	0	1	2	3	4	5	6	7	8	9	10
7 Discussion and review by educators of the quality of teaching and learning	0	1	2	3	4	5	6	7	8	9	10

is the real difference between 70 per cent and 71 per cent or between 31 per cent and 32 per cent?

Champagne (2014) advises against grouping what should be ratio data into categorical data (groups). He gives the example of asking how many scoops of ice cream a person would like (p. 54): we would not expect a person to say 'between 1 and 4'; rather we would expect an exact answer. The person who answers '4 scoops' could well be a glutton, whilst the person who answers '1 scoop' could well be more diet conscious, but this point would be lost if the data were put into a group of '1–4'. If categories/groups are to be used, they must be meaningful and reasonable, i.e. 'all the choices within the group are treated as equal', so that within-group differences are unimportant and between-group differences are realistic (p. 56). This applies, for example, if we are grouping the ages of people into age groups. Champagne (p. 103) argues for keeping the ratio scale (and indeed the rating scale) as it is rather than regrouping/combining them into categories.

Matrix questions

Matrix questions do not concern types of questions but their layout, enabling the same kind of response to be given to several questions, for example 'strongly disagree' to 'strongly agree'. The matrix layout helps to save space, for example:

Please complete the following by placing a tick in one space only, as follows:

1 = not at all; 2 = very little; 3 = a moderate amount; 4 = quite a lot; 5 = a very great deal

How much do you use the following for assessment purposes?

		1	2	3	4	5
a	commercially published tests	[ ]	[ ]	[ ]	[ ]	[ ]
b	your own made-up tests	[ ]	[ ]	[ ]	[ ]	[ ]
c	students' projects	[ ]	[ ]	[ ]	[ ]	[ ]
d	essays	[ ]	[ ]	[ ]	[ ]	[ ]
e	samples of students' work	[ ]	[ ]	[ ]	[ ]	[ ]

Here five questions have been asked in only five lines, excluding, of course, the instructions and explanations of the anchor statements. Such a layout is economical on space.

A second example indicates how a matrix design can save a considerable amount of space in a questionnaire. Here the size of potential problems in conducting a piece of research is asked for, and data on how much these problems were soluble are requested. For the first issue (the size of the problem), 1 = no problem, 2 = a small problem, 3 = a moderate problem, 4 = a large problem, 5 = a very large problem. For the second issue (how much the problem was solved), 1 = not solved at all, 2 = solved only a very little, 3 = solved a moderate amount, 4 = solved a lot, 5 = completely solved (see Table 24.3).

Here thirty questions (15 × 2) have been covered in just a short amount of space.

Laying out the questionnaire like this enables the respondent to fill in the questionnaire rapidly. On the other hand, it risks creating a mindset in the respondent (a 'response set' (Baker, 1994, p. 181)) in that the respondent may simply go down the questionnaire columns and write the same number each time (e.g. all number 3) or, in a rating scale, tick all number 3. Such response sets can be detected by looking at patterns of replies and eliminating response sets from subsequent analysis (though this may be illegitimate, as the researcher has no way of knowing what was in the respondent's mind).

The conventional way of minimizing response sets has been by reversing the meaning of some of the questions so that the respondents will need to read them carefully. However, Weems *et al*. (2003) argue that using positively and negatively worded items within a scale is not measuring the same underlying traits. They report that some respondents will tend to disagree with a negatively worded item, that the reliability levels of negatively worded items are lower than for positively worded items and that negatively worded items receive greater non-response than positively worded items. Indeed they argue against mixed-item formats, and supplement this by reporting that inappropriately worded items can induce an artificially extreme response which, in turn, compromises the reliability of the data. Mixing negatively and positively worded items in the same scale, they argue, compromises both validity and reliability. Indeed they suggest that respondents may not read negatively worded items as carefully as positively worded items. Mixing positively and negatively worded items is confusing for respondents.

Contingency and skip questions, filters and branches

Contingency and skip questions depend on responses to earlier questions, for example: 'if your answer to question (1) was 'yes' please go to question (4)'. The earlier question acts as a filter for the later question, and the later question is contingent on the earlier, and is a branch of the earlier question. Some questionnaires will spell out the number of the question to which to go (e.g. 'please go to question 6'); others (in paper versions) will place an arrow to indicate the next question to be

TABLE 24.3 POTENTIAL PROBLEMS IN CONDUCTING RESEARCH

Potential problems in conducting research	*Size of the problem (1–5)*	*How much the problem was solved (1–5)*
1 Gaining access to schools and teachers; 2 Gaining permission to conduct the research (e.g. from principals); 3 Resentment by principals; 4 People vetting what could be used; 5 Finding enough willing participants for your sample; 6 Schools suffering from 'too much research' by outsiders and insiders; 7 Schools/people not wishing to divulge information about themselves; 8 Schools not wishing to be identifiable, even with protections guaranteed; 9 Local political factors that impinge on the school; 10 Teachers' fear of being identified/traceable, even with protections guaranteed; 11 Fear of participation by teachers (e.g. if they are critical of the school or others they could lose their contracts); 12 Unwillingness of teachers to be involved because of their workload; 13 The principal deciding on whether to involve the staff, without consultation with the staff; 14 Schools'/institutions' fear of criticism/loss of face; 15 The sensitivity of the research: the issues being investigated.		

answered if your answer to the first question was such-and-such.

A funnelling process moves from the general to the specific, asking questions about the general context or issues and then moving towards specific points within that. A filter is used to include and exclude certain respondents, i.e. to decide if certain questions are relevant or irrelevant to them, and to instruct respondents about how to proceed (e.g. which items to jump to or proceed to). For example, if respondents indicate a 'yes' or a 'no' to a certain question, then this might exempt them from certain other questions in that section or subsequently.

Contingency and filter questions may be useful for the researcher, but, in a paper-based questionnaire, they can be confusing for the respondent as it is not always clear how to proceed through the sequence of questions and where to go once a particular branch has been completed. Redline *et al*. (2002) found that respondents tend to ignore, misread and incorrectly follow branching instructions, such that item non-response occurs for follow-up questions that are only applicable to certain sub-samples, and respondents skip over, and therefore fail to follow up on, those questions that they should have completed. The authors found that the increased complexity of the questionnaire brought about by branching instructions negatively influenced its correct completion.

Redline *et al*. report (2002, p. 7) that the number of words in the question affects the respondents' ability to follow branching instructions: the more words there are in the question, the greater is the likelihood of the respondents overlooking the branching instructions. They also report that up to seven items, and no more, can be retained in the short-term memory. This has implications for the number of items in a list of telephone interviews, where there is no visual recall or checking possible. Similarly, the greater the number of answer categories, the greater is the likelihood of making errors, for example, overlooking branching instructions (p. 19). They report that respondents tend to see branching instructions when they are placed by the last category, particularly if they have chosen that last category.

Redline *et al*. note (2002, p. 8) that sandwiching branching instructions between items which do not branch is likely to lead to errors of omission and commission being made: omitting to answer all the questions and answering the wrong questions respectively. Further, locating the instructions for branching some distance away from the preceding answer box can also lead to errors in following the instructions. They report (p. 17) that 'altering the visual and verbal design of branching instructions has a substantial impact on how well respondents read, comprehend, and act upon the branching instructions'. It follows from this that the

clear location and *visual impact* of instructions are important for successful completion of branching instructions. Most respondents, they acknowledge, do not deliberately ignore branching instructions; they simply are unaware of them. The implications of the findings from Redline *et al*. (2002) are that instructions for branching and skipping should be placed where they are to be used and where they can be seen.

However, with the rise of electronic surveys, problems of instructions, skipping, filtering and branching are reduced immensely, as, depending on the answer given, the computer automatically takes the respondent to the next appropriate place.

We advise judicious and limited use of filtering and branching devices in paper questionnaires. It is particularly important to avoid having participants turning pages forwards and backwards in a questionnaire in order to follow the sequence of questions that have had filters and branches following from them.

24.5 Asking sensitive questions

Sudman and Bradburn (1982) draw attention to the important issue of including sensitive items in a questionnaire. Whilst the anonymity of a questionnaire and, frequently, the lack of face-to-face contact between the researcher and the respondents in a questionnaire might facilitate responses to sensitive material, the issues of sensitivity and threat cannot be avoided, as they might lead to under-reporting (non-disclosure and withholding data) or over-reporting (exaggeration) by participants. Some respondents may be unwilling to disclose sensitive information, particularly if it could harm themselves or others. Why should they share private matters (e.g. about family life and opinions of school managers and colleagues) with a complete stranger (Cooper and Schindler, 2001, p. 341)? Details of age, income, educational background, qualifications and opinions can be regarded as private and/or sensitive matters.

Sudman and Bradburn (1982, pp. 55–6) identify several important considerations in addressing potentially threatening or sensitive issues, for example socially undesirable behaviour (e.g. drug abuse, sexual offences, violent behaviour, criminality, illnesses, employment and unemployment, physical features, sexual activity, behaviour and sexuality, gambling, drinking, family details, political beliefs, social taboos). They suggest that:

- Open rather than closed questions might be more suitable to elicit information about socially undesirable behaviour, particularly about their frequency.
- Long rather than short questions might be more suitable for eliciting information about socially undesirable behaviour, particularly about their frequency.
- Using familiar words might increase the number of reported frequencies of socially undesirable behaviour.
- Using data gathered from informants, where possible, can enhance the likelihood of obtaining reports of threatening behaviour.
- Deliberately loading the question so that overstatements of socially desirable behaviour and understatements of socially undesirable behaviour are reduced might be a useful means of eliciting information.
- With regard to socially undesirable behaviour, it might be advisable first to ask whether the respondent has engaged in that behaviour previously, and then move to asking about his or her current behaviour. By contrast, when asking about socially acceptable behaviour the reverse might be true, i.e. asking about current behaviour before asking about everyday behaviour.
- In order to defuse threat, it might be useful to locate the sensitive topic within a discussion of other more or less sensitive matters, in order to suggest to respondents that this issue might not be too important.
- It is useful to have alternative ways of asking standard questions, for example, sorting cards, or putting questions in sealed envelopes, or repeating questions over time (this has to be handled sensitively, so that respondents do not feel that they are being 'checked'), in order to increase reliability.
- Asking respondents to keep diaries can increase validity and reliability.
- At the end of an interview-based questionnaire, it is useful to ask respondents their views on the sensitivity of the topics that have been discussed.
- It is important to find ways of validating the data.

Sudman and Bradburn suggest (p. 86) that as questions become more threatening and sensitive, it is wise to expect greater bias and unreliability. They draw attention to the fact (p. 208) that several nominal, demographic details might be considered threatening by respondents. This has implications for their location within the questionnaire (discussed below). The issue here is that sensitivity and threat are to be viewed through the eyes of respondents rather than the questionnaire designer; what might appear innocuous to the researcher might be highly sensitive or offensive to participants. We refer readers to Chapter 13 on sensitive educational research.

24.6 Avoiding pitfalls in question writing

Though there are several kinds of questions available, there are some caveats about the framing of questions in a questionnaire:

1. *Don't assume respondent knowledge, opinions or viewpoints*. There is often an assumption that respondents will have the information or have an opinion about the matters in which researchers are interested. This is a dangerous assumption. It is particularly a problem when administering questionnaires to children, who may write anything rather than nothing. This means that the opportunity should be provided for respondents to indicate that they have no opinion, or that they don't know or don't have the answer to a particular question, or that they feel the question does not apply to them. This is frequently a matter in surveys of customer satisfaction in social science, where respondents are asked, for example, to answer a host of questions about the services provided by utility companies (electricity, gas, water) about which they have no strong feelings, and, in fact, they are only interested in whether the service is uninterrupted, reliable, cheap, easy to pay for and that their complaints are solved.
2. *Don't assume that respondents understand difficult terms*. It is essential that, regardless of the type of question asked, the language and the concepts behind the language should be within the grasp of the respondents. Simply because the researcher is interested in, and has a background in, a particular topic is no guarantee that the respondents will be like-minded. The effect of the questionnaire on the respondent has to be considered carefully.
3. *Don't assume respondent interest in, or concern about, the questionnaire*. Just because the researcher is interested in the topic does not mean that the respondent will be at all concerned about the topic, interested in it or concerned about its supposed importance and meaningfulness. The researcher has to make the questionnaire interesting and motivating.
4. *Avoid leading questions*. Avoid questions which are worded (or their response categories presented) in such a way as to suggest to respondents that there is only one acceptable answer, and that other responses might or might not gain approval or disapproval respectively. For example: 'Do you prefer abstract, academic-type courses, or down-to-earth, practical courses that have some pay-off in your day-to-day teaching?' The guidance here is to check the 'loadedness' or possible pejorative overtones of terms or verbs.
5. *Avoid highbrow questions*, even with sophisticated respondents, for example: 'What particular implications of the current positivistic/interpretive debate would you like to see reflected in a course of developmental psychology aimed at a teacher audience?' Where the sample being surveyed is representative of the whole adult population, misunderstandings of what researchers take to be clear, unambiguous language are commonplace. Therefore it is important to use clear and simple language.
6. *Avoid complex questions*, for example: 'Would you prefer a short, non-award bearing course (3, 4 or 5 sessions) with part-day release (e.g. Wednesday afternoons) and one evening per week attendance with financial reimbursement for travel, or a longer, non-award bearing course (6, 7 or 8 sessions) with full-day release, or the whole course designed on part-day release without evening attendance?'
7. *Avoid irritating questions*. Avoid irritating, insulting, embarrassing questions or instructions, for example: 'Have you ever attended an in-service course of any kind during your entire teaching career?' 'If you are over forty, and have never attended an in-service course, put one tick in the box marked NEVER and another in the box marked OLD.'
8. *Avoid complicated instructions*. If your instructions are too difficult to understand at first glance then the respondent could well give up. Golden rule: make the instructions clear, simple and easy to understand.
9. *Avoid negatives and double negatives*. Avoid questions that use negatives and double negatives (Oppenheim, 1992, p. 128), for example: 'How strongly do you feel that no teacher should enrol on the in-service, award-bearing course who has not completed at least two years full-time teaching?' Or: 'Do you feel that without a parent/teacher association or committee teachers are unable to express their views to parents clearly?' In this case, if you feel that a parent/teacher association or committee *is* essential for teachers to express their views, do you vote 'yes' or 'no'? The hesitancy involved in reaching such a decision and the possible required re-reading of the question could cause the respondent simply to leave it blank and move on to the next question. The problem is the double negative: 'without' and 'unable'; it creates confusion.

10 *Avoid too many open-ended questions on self-completion questionnaires*. Because self-completion questionnaires cannot probe respondents to find out just what they mean by particular responses, open-ended questions are problematic. (This caution does not hold in the interview situation, however.) Open-ended questions, moreover, are demanding of most respondents' time and take a lot of time for researcher analysis. Nothing can be more off-putting than the following format:

Use pages 5, 6 and 7 respectively to respond to each of the questions about your attitudes to in-service courses in general and your beliefs about their value in the professional life of the serving teacher.

11 *Avoid extremes in rating scales*, for example, 'never', 'always', 'totally', 'not at all', unless there is a good reason to include them. Most respondents are reluctant to use such extreme categories (Anderson and Arsenault, 1998, p. 174).

12 *Avoid pressuring/biasing by association*, for example: 'Do you agree with your headteacher/principal that boys are more troublesome than girls?' In this case the reference to the headteacher/principal should simply be excised.

13 *The base-rate problem*. Avoid statements with which people generally tend to either disagree or agree, i.e. that have built-in skewedness: the 'base-rate' problem, in which natural biases in the population affect the sample results.

14 *Avoid ambiguous questions*. Avoid ambiguous questions or questions that could be interpreted differently from the way intended. The problem of ambiguity in words is intractable; at best it can be minimized rather than eliminated altogether. The most innocent of questions is replete with ambiguity. Take the following examples:

- Does your child regularly do homework?

What does 'regularly' mean – once a day; once a year; once a term; once a week?

- How many students are there in the school?

What does this mean: on roll, on roll but absent; marked as present but out of school on a field trip; at this precise moment or this week (there being a difference in attendance between a Monday and a Friday), or between the first term of an academic year and the last term of the academic year for secondary school students as some of them will have left school to go into employment and others will be at home revising for examinations or have completed them?

- How many computers do you have in school?

What does this mean: present but broken; including those out of school being repaired; the property of the school or staff's and students' own computers; on average or exactly in school today?

- Have you had a French lesson this week?

What constitutes a 'week': the start of the school week (i.e. from Monday to a Friday), since last Sunday (or Saturday depending on one's religion), or, if the question were put on a Wednesday, since last Wednesday; how representative of all weeks is this week, there being public examinations in the school for some of the week?

It is essential to ensure that questions and their reference are explicit, specific and concrete.

15 *Have discrete categories*. Ensure that categories do not overlap, for example:

- How old are you?

15–20
20–30
30–40
40–50
50–60

Here the categories are not discrete; will an old-looking forty-year-old flatteringly put himself in the 30–40 category, or will an immature twenty-year-old seek the maturity of being put into the 20–30 category? The rule in questionnaire design is to avoid any overlap of categories.

16 *Ask one question at a time*. Ensure that each question only asks about one point. Consider, for example:

- Vocational education is only available to the lower-ability students but it should be open to every student.

This is, in fact, a double question. What does the respondent do who agrees with the first part of the sentence – 'vocational education is only available to the lower-ability students' – but disagrees with the latter part of the sentence, or vice versa? The rule in questionnaire design is to ask only one question at a time.

Though it is impossible to legislate for the respondents' interpretation of wording, the researcher, of course, has to adopt a common-sense approach to this, recognizing the inherent ambiguity but nevertheless still feeling that it is possible to live with this indeterminacy. Piloting can also identify ambiguities and differences of interpretation.

An ideal questionnaire possesses the same properties as a good law, being clear, unambiguous and practicable, reducing potential errors in participants and data analysts, being motivating for participants and ensuring as far as possible that respondents are telling the truth.

17 *Minimize satisficing, acquiescence and social desirability*. Krosnick (1991, 1999) found that the more difficult a question is, the greater is the likelihood of 'satisficing', i.e. choosing the first reasonable response option in a list, rather than working through the list methodically to find the most appropriate or authentic response category. Krosnick and Presser (2010, p. 265) comment that in answering questions, respondents first have to understand and interpret what the question means and is seeking; second, they have to search their memories and minds for relevant information and responses; third, they have to put this all together in coming to a single judgement; and finally they have to convert this judgement into the response. Given these demands, the authors suggest that there is a risk of satisficing, taking shortcuts to give an answer, being less thorough and thoughtful in each of these four stages, giving a satisfactory or what they deem to be an acceptable rather than an accurate answer or even any answer rather than no answer. Krosnick and Presser also comment (p. 271) that the use of a mid-point in a scale may encourage satisficing. Satisficing may also become an issue if the questionnaire is long, as respondent fatigue sets in (p. 292).

Krosnick and Presser (2010, p. 275) note the risk of acquiescence, i.e. where respondents tend to agree with the statement being made, regardless of its content. This may arise for several reasons, for example a wish not to be oppositional or confrontational or to disagree, or a wish to be polite. They note that acquiescence is common in people in lower social positions, with lower intelligence, less formal education, less willingness to think deeply, less concern to present a socially desirable response and where a question is demanding. This places upon researchers the need to ensure that their questions are easy to understand and answer, clear, motivating and neutrally worded.

Respondents may also give an answer in terms of what they think is socially desirable, rather than what they really feel. This leads to bias in answers given, and unreliability. It can be attenuated by careful wording. For example, instead of asking teachers 'how many times have you been absent from school because of stress?', one could ask 'have you ever felt under pressure to come to school even when you knew it was going to be stressful?', and then have a follow-up question: 'has this ever led to you absenting yourself from school?'

The golden rule is to keep questions and questionnaires as short, simple, interesting and easy to complete as possible.

24.7 Sequencing questions

To some extent, the order of questions is a function of the target sample (e.g. how they will react to certain questions), the purposes of the questionnaire (e.g. to gather facts or opinions), the sensitivity of the research (e.g. how personal and potentially disturbing the issues are) and the overall balance of the questionnaire (e.g. where best to place sensitive questions in relation to less threatening questions, and how many of each to include).

The ordering of the questionnaire is important, for early questions may set the tone or the mindset of the respondent to later questions. For example, a questionnaire that makes a respondent irritated or angry early on is unlikely to have managed to enable that respondent's irritation or anger to subside by the end of the questionnaire. As Oppenheim remarks (1992, p. 121), one covert purpose of each question is to ensure that the respondent will continue to cooperate.

Further, a respondent might 'read the signs' in the questionnaire, seeking similarities and resonances between statements so that responses to early statements will affect responses to later statements and vice versa. Whilst multiple items may act as a cross-check, this very process might be irritating for some respondents.

Krosnick and Alwin (1987) report a 'primacy effect' (discussed earlier), i.e. respondents tend to choose items that appear earlier in a list rather than those that appear later in a list. The key principle, perhaps, is to avoid creating a mood-set or a mindset early on in the questionnaire. For this reason it is important to commence the questionnaire with non-threatening questions that respondents can readily answer. After that it might be possible to move towards more personalized questions.

Similarly, the recency effect can bias a response (discussed earlier: respondents remember the last item in a list, rather than the entire list in, for example, a multiple-choice question or a rating scale, particularly in a telephone interview). Hence, for example, a telephone questionnaire should contain short rather than long lists of choices.

Completing a questionnaire can be seen as a learning process in which respondents become more at home with the task as they proceed. Initial questions should

therefore be simple, have high interest value and encourage participation. This will build up the confidence and motivation of the respondent. The middle section of the questionnaire should contain the difficult questions; the last few questions should be of high interest in order to encourage respondents to return the completed schedule.

A common sequence of a questionnaire is:

- Commence with unthreatening factual questions (that, perhaps, will give the researcher some nominal data about the sample).
- Move to closed questions (e.g. dichotomous, multiple choice, rating scales, constant sum questions) about given statements or questions, eliciting responses that require opinions, attitudes, perceptions, views.
- Move to more open-ended questions (or, maybe, intersperse these with more closed questions) that seek responses on opinions, attitudes, perceptions and views, together with reasons for the responses given. These responses and reasons might include sensitive or more personal data.
- Close with potentially sensitive demographic questions, for example, age, qualifications, income.

The move is from objective facts to subjective attitudes and opinions through justifications and to sensitive, personalized data. Clearly the ordering is neither as discrete nor as straightforward as this. For example, an apparently innocuous question about age might be offensive to some respondents; a question about income is unlikely to go down well with somebody who has just become unemployed; and a question about religious belief might be seen as an unwarranted intrusion into private matters. Many questionnaires keep questions about personal details until the end.

The issue here is that the questionnaire designer has to anticipate the sensitivity of the topics in terms of the respondents, and this has a large socio-cultural dimension. What is being argued here is that the *logical* ordering of a questionnaire has to be mediated by its *psychological* ordering. The instrument has to be viewed through the eyes of the respondent as well as the designer.

In considering the sequence of the questionnaire items, then, there are some straightforward guidelines:

- put general, non-threatening questions first;
- make the first questions easy, interesting and able to be answered;
- put important items in the first half of the questionnaire;
- put sensitive or potentially embarrassing questions later in the questionnaire;
- move from factual to abstract questions over the course of the questionnaire;
- put open questions later rather than earlier;
- put demographic and personal questions at the end of the questionnaire.

24.8 Questionnaires containing few verbal items

The discussion so far has assumed that questionnaires are entirely word-based. This might be off-putting for many respondents, particularly children (Smith and Haslett, 2016). In these circumstances a questionnaire might include visual information and ask participants to respond to this (e.g. pictures, cartoons, diagrams), or might include some projective visual techniques (e.g. to draw a picture or diagram, to join two related pictures with a line, to write the words or what someone is saying or thinking in a 'bubble' picture), to tell the story of a sequence of pictures together with personal reactions to it.

The issue here is that in tailoring the format of the questionnaire to the characteristics of the sample, a very wide embrace might be necessary to take in non-word-based techniques. This is not only a matter of *appeal* to respondents, but also, perhaps more significantly, a matter of *accessibility* of the questionnaire to the respondents, i.e. a matter of reliability and validity.

24.9 The layout of the questionnaire

The appearance of the questionnaire is important (e.g. Diaz de Rada, 2005; Dillman *et al*., 2014). It must look easy, attractive and interesting rather than complicated, unclear, forbidding and boring. A compressed layout is uninviting and it clutters everything together; a larger questionnaire with plenty of space for questions and answers is more encouraging to respondents. Verma and Mallick (1999, p. 120) suggest, for paper-based questionnaires, the use of high-quality paper if funding permits.

Layout can be a particular problem in Internet surveys where the screen size is much smaller than the length of a printed page.

Dillman *et al*. (1999, 2014) found that respondents tend to expect less of a form-filling task than is actually required. They expect to read a question, read the response, make a mark and move on to the next question, but in many questionnaires it is more complicated than this. The rule is simple: keep it as uncomplicated as possible.

It is important for respondents to be introduced to the purposes of each section of a questionnaire, so that they can become involved in it and maybe identify with it. If space permits, it is useful to tell the respondent the purposes and focuses of the sections/of the questionnaire, and the reasons for the inclusion of the items. Here Champagne (2014, p. 72) argues for specificity in stating the purposes, avoiding such generalized statements of purpose as 'this questionnaire will help us to improve the quality of our teaching' as this is little more than a statement of the obvious (why else would you be conducting the questionnaire on teaching?).

Clarity of wording and simplicity of design are essential. Clear instructions should guide respondents – 'Put a tick', for example, invites participation, whereas complicated instructions and complex procedures intimidate respondents. Putting ticks in boxes by way of answering a questionnaire is familiar to most respondents, whereas requests to circle pre-coded numbers at the right-hand side of the questionnaire can be a source of confusion and error. This is useful for paper-based questionnaires; with computer-based questionnaires, the use of radio buttons and check boxes renders making a choice very easy.

In some paper-based questionnaires it might also be useful to include an example of how to fill in the questionnaire (e.g. ticking a box, circling a statement), though, clearly, care must be exercised to avoid leading the respondents to answering questions in a particular way by dint of the example provided (e.g. by suggesting what might be a desired answer to the subsequent questions). Verma and Mallick (1999, p. 121) suggest the use of emboldening to draw the respondent's attention to significant features.

Ensure that short, clear instructions accompany each section of the questionnaire. Repeating instructions as often as necessary is good practice in a postal questionnaire. Since everything hinges on respondents knowing exactly what is required of them, clear, unambiguous instructions, boldly and attractively displayed, are essential.

Clarity and presentation also impact on the numbering of the questions. For example a four-page questionnaire might contain sixty questions, broken down into four sections. It might be off-putting to respondents to number each question (1–60) as the list will seem interminably long, whereas to number each section (1–4) makes the questionnaire look manageable. Hence it is useful, in the interests of clarity and logic, to break down the questionnaire into subsections with section headings, and group together similar items or topics. This will also indicate the overall logic and coherence of the questionnaire to the respondents, enabling them to 'find their way' through the questionnaire. It might be useful to preface each subsection with a brief introduction that tells them the purpose of that section. In an Internet questionnaire, numbering the questions may even become redundant, as the computer sets out the questions.

The practice of sectionalizing and sub-lettering questions (e.g. Q9 (a) (b) (c)…) is a useful technique for grouping together questions about a specific issue. It is also a way of making the questionnaire look smaller than it actually is!

The questionnaire designer (particularly in a paper-based questionnaire) must make it clear if respondents are exempted from completing certain questions or sections of the questionnaire (discussed earlier in the section on skips, branches and filters). If so, then it is vital that the sections or questions are numbered so that the respondent knows exactly where to move to next. Here the instruction might be, for example: 'if you have answered "yes" to question 10 please go to question 15, otherwise continue with question 11', or: 'if you are the school principal please answer this section, otherwise proceed to Section 3'.

Arrange the contents of the questionnaire in such a way as to maximize cooperation. For example, include questions that are likely to be of general interest. Make sure that questions which appear early in the format do not suggest to respondents that the enquiry is not intended for them. Intersperse attitude questions throughout the questionnaire to allow respondents to air their views rather than merely describe their behaviour. Such questions relieve boredom and frustration as well as providing valuable information in the process.

Coloured pages and screens can help to clarify the overall structure of the questionnaire and the use of different colours for instructions can assist respondents (this is easily done in an electronic questionnaire). Further, as we noted in Chapter 17, Diaz de Rada (2005) reports that the design, size and colour of the paper used affects response rates. For paper-based questionnaires, small-sized questionnaires were mostly returned by males and those under sixty-four years of age (p. 69), whilst larger-sized questionnaires were mostly returned by females and those over the age of sixty-five (p. 70). He recommends the use of paper size 14.85×21 cm (i.e. a sheet of A4-sized paper folded in half), with white paper and a cover page (p. 73). He reports that paper size has no effect on the quality of the responses.

It is important to include in the questionnaire, perhaps at the beginning, assurances of confidentiality, anonymity and non-traceability, for example by indicating that respondents need not give their name, that

the data will be aggregated, that individuals will not be able to be identified or traced through the use of categories or details of their location etc. (i.e. that it will not be possible to put together a traceable picture of the respondents through the combining of nominal, descriptive data about them). In some cases, however, the questionnaire might ask respondents to put their names so that they can be traced for follow-up interviews in the research (Verma and Mallick, 1999, p. 121); here the guarantee of eventual anonymity and non-traceability will still need to be given (and this applies also to data archiving, where identifying data are removed).

Redline *et al*. (2002) indicate that the placing of the response categories to the immediate right of the text increases the chance of it being answered (the visual *location*), and making the material more salient (e.g. through emboldening and capitalization) can increase the chances of it being addressed (the *visibility* issue). This is particularly important for branching questions and instructions.

They also note that questions placed at the bottom of a page tend to receive more non-response than questions placed further up on the page. Indeed they found that putting instructions at the bottom of the page, particularly if they apply to items on the next page, can easily lead to those instructions being overlooked. It is important, then, to consider what should go at the bottom of the page, perhaps the inclusion of less important items at that point. The authors suggest that questions with branching instructions should not be placed at the bottom of a page. Though Redline *et al*. wrote about paper-based questionnaires, their comments can also apply to Internet-based questionnaires and screen layout.

Finally, a brief note at the very end of the questionnaire can: (a) ask respondents to check that no answer has been inadvertently missed out; (b) solicit an early return of the completed schedule; (c) thank respondents for their participation and cooperation.

24.10 Covering letters/sheets and follow-up letters

The purpose of the covering letter/sheet is to indicate the aim of the research, to convey to respondents its importance, to assure them of confidentiality and to encourage their replies. The covering letter/sheet should:

- provide a title to the research;
- introduce the researcher, giving her/his name, address, organization, contact telephone/fax/email address, together with an invitation to feel free to contact the researcher for further clarification or details;
- indicate the purposes of the research;
- indicate the importance and benefits of the research;
- indicate why the respondent has been selected for receipt of the questionnaire;
- indicate any professional backing, endorsement or sponsorship of, or permission for, the research (e.g. university, professional associations, government departments). The use of a logo can be helpful here;
- set out how to return the questionnaire (e.g. in the accompanying stamped, addressed envelope, in a collection box in a particular institution, to a named person; whether the questionnaire will be collected – and when, where and by whom) (for an Internet questionnaire return might be automatic);
- indicate the address to which to return the questionnaire;
- indicate what to do if questions or uncertainties arise (e.g. a helpline);
- indicate a return-by/complete-by date;
- indicate any incentives for completing the questionnaire;
- provide assurances of confidentiality, anonymity and non-traceability;
- indicate how the results will and will not be disseminated, and to whom;
- thank respondents in advance for their cooperation.

Verma and Mallick (1999, p. 122) suggest that, where possible, it is useful to personalize the letter, avoiding 'Dear colleague', 'Dear Madam/Ms/Sir' etc., and replacing these with exact names.

With these intentions in mind, the following practices are recommended:

- The appeal in the covering letter must be tailored to suit the particular audience. Thus, a survey of teachers might stress the importance of the study to the profession as a whole.
- Neither the use of prestigious signatories, nor appeals to altruism, nor the addition of handwritten postscripts affects response levels to postal questionnaires.
- The name of the sponsor or the organization conducting the survey should appear on the letterhead as well as in the body of the covering letter.
- A direct reference should be made to the confidentiality of respondents' answers and the purposes of any serial numbers and codings should be explained.

- A pre-survey letter advising respondents of the forthcoming questionnaire has been shown to have a substantial effect on response rates (Dillman *et al*., 2014).
- A short covering letter is most effective; no more than one page. An example of a covering letter for teachers and senior staff is set out in Boxes 24.1 and 24.2.

For a further example of a questionnaire, see the accompanying website.

24.11 Piloting the questionnaire

The wording of questionnaires is of paramount importance and pre-testing is crucial to their success (cf. Krosnick and Presser, 2010; Dillman *et al*., 2014; Owen *et al*., 2016). A pilot has several functions, principally to increase the reliability, validity and practicability of the questionnaire (Oppenheim, 1992; Morrison, 1993; Wilson and McLean, 1994, p. 47; Verma and Mallick, 1999, p. 120; Krosnick and Presser, 2010; Dillman *et al*., 2014):

- to check the clarity of the questionnaire items, instructions and layout;
- to gain feedback on the validity of the questionnaire items, the operationalization of the constructs and the purposes of the research;
- to eliminate ambiguities or difficulties in wording;
- to check readability levels for the target audience;
- to gain feedback on the *type* of question and its format (e.g. rating scale, multiple choice, open, closed etc.);
- to gain feedback on response categories for closed questions and multiple-choice items, and for the appropriateness of specific questions or stems of questions;
- to identify omissions and redundant and irrelevant items;
- to gain feedback on leading questions;
- to gain feedback on the attractiveness and appearance of the questionnaire;
- to gain feedback on the layout, sectionalizing, numbering and itemization of the questionnaire;
- to check the time taken to complete the questionnaire;
- to check whether the questionnaire is too long or too short, too easy or too difficult;
- to generate categories from open-ended responses to use as categories for closed response modes (e.g. rating scale items);
- to identify how motivating/non-motivating/sensitive/threatening/intrusive/offensive items might be;
- to identify redundant questions, for example, those questions which consistently gain a total 'yes' or 'no' response, i.e. those questions with little discriminability;
- to identify which items are too easy, too difficult, too complex or too remote from the respondents' experience;

BOX 24.1 EXAMPLE OF A COVERING LETTER

Dear colleague,

IMPROVING SCHOOL EFFECTIVENESS

We are asking you to take part in a project to improve school effectiveness, by completing this short research questionnaire. The project is part of your school development, support management and monitoring of school effectiveness, and the project will facilitate a change management programme that will be tailor-made for the school. This questionnaire is seeking to identify the nature, strengths and weaknesses of different aspects of your school, particularly in respect of those aspects of the school over which the school itself has some control. It would be greatly appreciated if you would be involved in this process by completing the sheets attached, and returning them to me. Please ***be as truthful as possible*** in completing the questionnaire.

You do not need to write your name, and no individuals will be identified or traced from this, i.e. confidentiality and anonymity are assured. If you wish to discuss any aspects of the review or this document please do not hesitate to contact me. I hope that you will feel able to take part in this project.

Thank you.

Signed

Contact details (address, fax, telephone, email)

BOX 24.2 A SECOND EXAMPLE OF A COVERING LETTER

Dear colleague,

PROJECT ON CONDUCTING EDUCATIONAL RESEARCH

I am conducting a small-scale piece of research into issues facing researchers undertaking investigations in education. The topic is very much under-researched in education, and that is why I intend to explore the area.

I am asking you to be involved as you yourself have conducted empirical work as part of a Master's or doctorate degree. No one knows the practical problems facing the educational researcher better than you.

The enclosed questionnaire forms part of my investigation. May I invite you to spend a short time in its completion?

If you are willing to be involved, please complete the questionnaire and return it to XXX by the end of November. You may either place it in the collection box at the General Office at my institution or send it by post (stamped addressed envelope enclosed), or by fax or email attachment.

The questionnaire will take around fifteen minutes to complete. It employs rating scales and asks for your comments and a few personal details. You do not need to write your name, and you will not be able to be identified or traced. When completed, I intend to publish my results in an education journal.

If you wish to discuss any aspects of the study then please do not hesitate to contact me.

I very much hope that you will feel able to participate. May I thank you, in advance, for your valuable cooperation.

Yours sincerely,

Signed

Contact details (address, fax, telephone, email)

- to identify commonly misunderstood or non-completed items (e.g. by studying common patterns of unexpected response and non-response);
- to try out the coding/classification system for data analysis.

In short, as Oppenheim (1992, p. 48) remarks, *everything* about the questionnaire should be piloted; nothing should be excluded, not even the typeface or the quality of the paper (see also Krosnick and Presser, 2010).

The above outline describes a particular kind of pilot: one that does not focus on data, but on matters of coverage and format, gaining feedback from a limited number of respondents and experts on the items set out above.

There is a second type of pilot. This is one which starts with a long list of items and, through statistical analysis and feedback, reduces those items (Kgaile and Morrison, 2006). For example, a researcher may generate an initial list of, for example, 120 items to be included in a questionnaire, and wish to know which items to excise. A pilot is conducted on a sizeable and representative number of respondents (e.g. 50–100) and this generates real data – numerical responses – which can be analysed for:

a *reliability*: those items with low reliability can be removed (Cronbach's alpha for internal consistency: see Chapter 40);
b *collinearity*: if items correlate very strongly with others then a decision can be taken to remove one or more of them, provided, of course, that this does not result in the loss of important areas of the research (i.e. human judgement prevails over statistical analysis);
c *multiple regression*: those items with low betas (see Chapter 42) can be removed, provided, of course, that this does not result in the loss of important areas of the research (i.e. human judgement must prevail over statistical analysis);
d *factor analysis*: to identify clusters of key variables and to identify redundant items (see Chapter 43).

As a result of such analysis, the items for removal can be identified, and this can result in a questionnaire of manageable proportions. It is important to have a good-sized and representative sample here in order to generate reliable data for statistical analysis; too few respondents in this type of pilot may result in important items being excluded from the final questionnaire.

24.12 Practical considerations in questionnaire design

Drawing together the issues discussed so far in questionnaire design, a range of practical implications for designing a questionnaire can be highlighted (cf. Black, 1999; Krosnick and Presser, 2010; Abascal and Diaz de Rada, 2014; Champagne, 2014; Denscombe, 2014; Dillman *et al*., 2014; Hilton, 2017). Sellitz and her associates (1976) have provided a useful guide to researchers in constructing their questionnaires which we summarize in Box 24.3.

Operationalization

- Operationalize the purposes of the questionnaire carefully.
- Ensure that the data acquired will cover the topics and research questions comprehensively and answer the research questions, and that the information asked for is relevant, for example, facts, opinions, behaviour, events, attitudes etc.
- Ensure that every issue has been explored exhaustively; decide on the content and explore it in depth and breadth.
- Use several items to measure a specific attribute, concept or issue.

BOX 24.3 A GUIDE FOR QUESTIONNAIRE CONSTRUCTION

A Decisions about question content

1. Is the question necessary? Just how will it be useful?
2. Are several questions needed on the subject matter of this question?
3. Do respondents have the information necessary to answer the question?
4. Does the question need to be more concrete, specific and closely related to the respondent's personal experience?
5. Is the question content sufficiently general and free from spurious concreteness and specificity?
6. Do the replies express general attitudes and only seem to be as specific as they sound?
7. Is the question content biased or loaded in one direction, without accompanying questions to balance the emphasis?
8. Will the respondents give the information that is asked for?

B Decisions about question wording

1. Can the question be misunderstood? Does it contain difficult or unclear phraseology?
2. Does the question adequately express the alternative with respect to the point?
3. Is the question misleading because of unstated assumptions or unseen implications?
4. Is the wording biased? Is it emotionally loaded or slanted towards a particular kind of answer?
5. Is the question wording likely to be objectionable to the respondent in any way?
6. Would a more personalized wording of the question produce better results?
7. Can the question be better asked in a more direct or a more indirect form?

C Decisions about form of response to the question

1. Can the question best be asked in a form calling for a check answer (or short answer of a word or two, or a number), free answer or check answer with a follow-up answer?
2. If a check answer is used, which is the best type for this question – dichotomous, multiple-choice ('cafeteria' question) or scale?
3. If a checklist is used, does it cover adequately all the significant alternatives without overlapping and in a defensible order? Is it of reasonable length? Is the wording of items impartial and balanced?
4. Is the form of response easy, definite, uniform and adequate for the purpose?

D Decisions about the place of the question in the sequence

1. Is the answer to the question likely to be influenced by the content of preceding questions?
2. Is the question led up to in a natural way? Is it in correct psychological order?
3. Does the question come too early or too late from the point of view of arousing interest and receiving sufficient attention, avoiding resistance, and so on?

Source: Adapted from Sellitz *et al.* (1976)

Respondents

- Consider respondent effort and load: avoid overloading respondents with thinking, recalling, reading, responding; avoid placing too great a burden/demand on respondents in answering the question.
- Consider the reading, writing, listening and thinking abilities of the respondents.
- Consider respondent motivation and ability to answer.
- Consider the willingness of the respondent to answer the questions correctly, accurately and honestly, and whether the respondent will actually have the answer (e.g. to factual questions or to questions which require long-term memory). Remember that respondents may not know the answer or their recall may be faulty.
- Relevance: make sure that the questions included actually apply to the respondents.
- Ensure that the wording is comprehensible to the respondent (use easy words) and judge how the respondent will regard and feel about the question asked.

Ethics

- Address informed consent, right not to take part and to withdraw.
- Address privacy, confidentiality, anonymity, non-traceability.
- Do no harm.
- Address ethical issues in data archiving.
- Consider respondent reactions and effects on respondents.
- Bring beneficence.

Order

- Consider the order of the questions (they are not independent of each other, and the answer to one question may affect the answer to another in the respondent's mind, e.g. primacy, 'carry over' and 'anchoring' effects (Dillman *et al*., 2014, p. 235) (what comes first affects what comes later and respondents use the early questions as a standard against which they compare the later questions)).
- Make the order and organization of the questionnaire easy for the respondent to understand (subheadings in a written survey are useful here).
- Start with a question that is meaningful, interesting and salient to the respondents.
- Make the early questions interesting, able to be answered and easy to answer.
- Group together questions that cover similar topics, to make understanding easy, with subheadings in written surveys, to parallel what would naturally happen in a conversation (as, if respondents see two questions as similar, then they are likely to give similar answers).
- Put important questions in the first half of the questionnaire, and avoid putting them at the end of the survey (later responses may suffer from respondent fatigue, which leads to satisficing).
- Within each topic area, proceed from the general to the specific.
- Put sensitive questions later in the questionnaire in order to avoid creating a mental set in the mind of respondents, but not so late in the questionnaire that boredom and lack of concentration have set in.
- Intersperse sensitive questions with non-sensitive questions.
- If you are using branching questions, ask all the branching questions before asking the follow-up questions.

Question planning

- Ensure that the question actually applies to the respondent.
- Ensure that the question is necessary and relevant for the research purposes and research questions. Remove redundant items ruthlessly.
- Consider what the question is asking for, for example, factual answers; attitudes, perceptions and opinions; behaviours; events; and how to make these clear to the respondent.
- Do not assume that respondents know the answers, or have information to answer the questions, or will always tell the truth (wittingly or not). Include 'don't know', 'not applicable', 'unsure', 'neither agree not disagree' and 'not relevant' categories if appropriate.
- Remember that some factual information is easy (e.g. gender, age) but other data (e.g. attitudes, behaviours and those which rely on memory) may be less accurate.
- Remember that some factual personal questions may be sensitive, so place them at the end of the questionnaire.
- Ensure a balance of questions asking for facts and opinions.

Question type

- Decide on the most suitable and appropriate *type* of question, for example: (a) for *nominal variables*: dichotomous, multiple choice (single choice, restricted number of choices, e.g. three from a longer list, free number of choices); for *ordinal variables*: rating scales, ranking scales; (c) for *interval, ratio and continuous variables*: constant sum,

percentages, marks out of 10, open number (e.g. number of hours of study in a week); (d) for *non-numerical answers*: open questions.
- Frame questions with the data analysis in mind, plan so that the appropriate scales and kinds of data (e.g. nominal, ordinal, interval and ratio) are used.
- Ask more closed than open questions for ease of analysis (particularly with large samples).

Question construction and wording

- Consider the readability levels of the questionnaire and match them to the respondents.
- Use simple, clear language and syntax.
- Avoid jargon; use simple, factual, familiar and non-technical terms.
- Keep the questions (and instructions) simple, clear and short as possible, with as few words as possible, but no fewer.
- Make the wording as concrete, specific, precise, unambiguous and as clear as possible, so that the respondent understands exactly what is being asked for in the questionnaire.
- Avoid making the questions too hard.
- Ask only one thing at a time in a question.
- Use a single, complete, easily structured sentence per item wherever possible.
- Keep statements in the present tense wherever possible.
- Balance brevity with politeness.
- Avoid being offensive.
- Avoid leading questions (those which influence the response and indicate a desired response).
- Try to avoid threatening and embarrassing questions, or write them as neutrally as possible.
- Balance the number of negative questions with the number of positive questions.
- Avoid negatively worded items.
- Avoid double negatives.
- Ensure that the questions are accurate and that the metrics are appropriate (Kosnick and Presser (2010) give the example of a question which measured the height of a horse in feet, whereas it should be in 'hands' (units of four inches)).
- Ensure that the questions use the appropriate scales of measurement and scales (e.g. 1–5, −4 to +4, 'strongly disagree' to 'strongly agree').
- Decide whether to have a mid-point in scale items.
- Note that having a mid-point often leads to greater reliability.
- Note that the absence of a mid-point may force responses into unwelcome choices.
- Use large range scales if subsequent factor analysis is intended or if nuanced responses are required (NB scales higher than seven-point make little difference to the nuancing and may overwhelm respondents).
- Consider the ordering of the scales in each question (e.g. positive to negative; negative to positive, placing a low or high score on the left).
- Avoid double-barrelled questions (asking more than one thing in a single question).
- Take steps to reduce satisficing, acquiescence and social desirability in responses.
- Decide how to avoid falsification of responses (e.g. introduce a checking mechanism into the questionnaire responses to another question on the same topic or issue).

Response categories

- Include sufficient response categories and ensure that they are exhaustive, to fit the choices that participants will really want, i.e. to enable respondents to say what they want to say (which underlines the importance of running a pilot).
- Make response categories discrete (no overlaps), with not too many choices.
- Keep response categories simple and short.
- Consider including a mid-point.
- Clarify to respondents the kinds of responses required in open questions.
- Ensure that the respondent knows how to enter a reply to each question, for example, by underlining, circling, ticking, writing, checking a box.

Length

- Consider the length of the questionnaire; long questionnaires may suffer from respondent fatigue, which leads to satisficing.
- Balance comprehensiveness and exhaustive coverage of issues with the demotivating factor of having respondents complete several pages of a questionnaire.

Layout and instructions

- Make the layout of the questionnaire very clear, unambiguous and attractive.
- Avoid splitting an item over more than one page (or one screen in Internet questionnaires), as the respondent may think that the item from the previous page is finished.
- Avoid putting all the instructions at the start of the questionnaire.
- Keep the instructions close to the questions involved.
- Avoid putting instructions at the foot of a page (or, for electronic surveys, on a different screen from the question to which it applies).

- Provide instructions for introducing, completing and returning (or collection of) the questionnaire (provide a stamped addressed envelope if it is to be a postal questionnaire).

Response rate

- Be satisfied if you receive a 50 per cent response to the questionnaire (a very much lower response rate is probably going to be the case).
- Decide what you will do with missing data and what is the significance of the missing data (that might have implications for the strata of a stratified sample targeted in the questionnaire), and why the questionnaires have not been completed and returned (e.g. were the questions too threatening? Was the questionnaire too long? This might have been signalled in the pilot).
- Consider imputation methods for missing data (see Chapter 17).

Covering letter

- Include a covering letter (or screen, for electronic surveys) with explanation, thanking the potential respondent for anticipated cooperation, indicating the purposes of the research, how anonymity and confidentiality will be addressed, who you are and what position you hold, who will be party to the final report, and your contact details.

Administration

- Consider the medium of the administration and conduct, for example, postal service, email, face-to-face interview, website, telephone, i.e. the visual, oral and aural administration of the survey and who enters the responses (the respondent or the interviewer).
- Decide: whether you (the researcher) will be present when the questionnaire is being completed; whether it is advisable to have an interviewer/researcher present or absent, as the interviewer's/researcher's presence may bias the respondent, raising issues of the respondent's concern for (a) social desirability and (b) acquiescence, and acquiescence is a particular problem in questions which include 'agree', as there is a tendency to agree.
- If the questionnaire is going to be administered by someone other than the researcher, ensure that instructions for administration are provided and that they are clear.

Pre-piloting and piloting

- Be prepared to have a pre-pilot (often with open questions) to generate items for a pilot questionnaire, and then be ready to modify the pilot questionnaire for the final version.
- Pilot the questionnaire, using a group of respondents who are drawn from the possible sample but who will not receive the final, refined version.
- If the pilot includes many items, and the intention is to reduce the number of items through statistical analysis or feedback, then be prepared to have a second round of piloting, after the first pilot has been modified.

A key issue that permeates this lengthy list is for the reader to pay considerable attention to respondents, to see the questionnaire through their eyes and envisage how they will regard it (e.g. from hostility to suspicion to apathy to grudging compliance to welcome; from easy to difficult, from motivating to boring, from straightforward to complex etc.). Address 'brevity, simplicity and concreteness' (Hilton, 2017, p. 30).

24.13 Administering questionnaires

Questionnaires can be administered in several ways, including:

- self-administration
- post
- face-to-face interview (individual and group)
- telephone
- drop-off (see Chapter 17)
- Internet.

Here we discuss only self-administered and postal questionnaires. Chapter 25 covers administration by face-to-face interview and telephone, and administration by the Internet, and we also refer readers to Chapters 17 and 18 on surveys, both paper-based and Internet-based.

The setting in which the questionnaire is completed can also exert an influence on the results. Strange *et al*. (2003, p. 343) found that asking students to complete a questionnaire in silence in a classroom or in a hall set out in an examination style might be very challenging for some; some students did not want to complete a questionnaire 'on their own' and wanted clarification from other students, some wanted a less 'serious' atmosphere to prevail whilst completing the questionnaire, and some (often boys) simply did not complete a questionnaire in conditions that they did not like (p. 344). Researchers must consider how best to achieve reliability by taking into account the setting and preferences of the respondents, and, in the case of schools (p. 345), this includes:

- the timing of the completion;
- the school timetable;
- the space available;
- the layout of the room;
- the size of the school;
- the relationships between the students and the researchers;
- the culture of the school and classrooms;
- the duration of lessons.

Self-administered questionnaires

Self-administration questionnaires are widely used. There are two types here: those that are completed in the presence of the researcher and those that are filled in when the researcher is absent (e.g. at home, in the workplace). We recall the work of Krosnick and Presser (2010) earlier, in indicating the demands made upon respondents in terms of reading, understanding and interest in the question, searching their memories, integrating their information into a judgement and translating their judgement into a response. Self-administration brings all of these four points into sharp relief (Duckworth and Yeager, 2015, p. 240), particularly for some school students or low-achievers. Researchers must decide whether his or her presence is useful or counter-productive.

Self-administered questionnaires in the presence of the researcher

The presence of the researcher may be helpful in enabling any queries or uncertainties to be addressed immediately. Further, it typically ensures a good response rate (e.g. undertaken with teachers at a staff meeting or with students in one or more classes). It can also check that all the questions are completed (the researcher can check these before finally receiving the questionnaire) and filled in correctly (e.g. no rating scale items that have more than one entry per item, and no missed items). It means that the questionnaires are completed rapidly and on one occasion, i.e. it can gather data from many respondents simultaneously.

On the other hand, having the researcher present may be threatening and exert a sense of compulsion, where respondents may feel uncomfortable about completing the questionnaire, and may not wish to complete it or even start it. Respondents may also want extra time to think about and complete the questionnaire, maybe at home, and they are denied the opportunity to do this.

Having the researcher present also places pressure on the researcher to attend at an agreed time and in an agreed place, and this may be time-consuming and require the researcher to travel extensively, thereby extending the time frame for data collection. Travel costs for conducting the research with dispersed samples could also be expensive.

Self-administered questionnaires without the presence of the researcher

The absence of the researcher may be helpful in enabling respondents to complete the questionnaire in private, to devote as much time as they wish to its completion, to be in familiar surroundings and to avoid the potential threat or pressure to participate caused by the researcher's presence. It can be inexpensive to operate, and is more anonymous than having the researcher present. This latter point, in turn, can render the data more (or, indeed, less) honest: it is perhaps harder to tell lies or not to tell the whole truth in the presence of the researcher, and it is also easier to be honest and revealing about sensitive matters without the presence of the researcher.

The down side is that the researcher is not there to address any queries or problems that respondents may have, and respondents may omit items or give up rather than try to contact the researcher. They may wrongly interpret the question and, consequently, answer it inaccurately. They may present an untrue picture to the researcher, for example answering what they would like a situation to be rather than what the actual situation is, or painting a falsely negative or positive picture of the situation or themselves. The absence of the researcher means that the researcher has no control over the environment in which the questionnaire is completed, for example, time of day, noise distractions, presence of others with whom to discuss the questions and responses, seriousness given to the completion of the questionnaire, or even whether it is completed by the intended person.

Postal questionnaires

A postal questionnaire is useful in educational research. Take, for example, the researcher studying the adoption and use made of a new curriculum series of textbooks in secondary schools. An interview survey based upon some sampling of the population of schools would be both expensive and time-consuming. A postal questionnaire, on the other hand, has several distinct advantages. Moreover, given the usual constraints over finance and resources, it might well prove the only viable way of carrying through such an enquiry.

A number of myths about postal questionnaires are not borne out by the evidence (see Krosnick and Presser, 2010; Dillman *et al*., 2014). Response levels to postal surveys are not invariably lower than those obtained by interview procedures; frequently they

equal, and in some cases surpass, those achieved in interviews. Nor does the questionnaire necessarily have to be short in order to obtain a satisfactory response level. With sophisticated respondents, for example, a short questionnaire might appear to trivialize complex issues with which they are familiar. There are several factors in securing a good response rate to a postal questionnaire.

Initial mailing

- use good-quality envelopes, typed and addressed to a named person wherever possible;
- use rapid postage services, with stamped rather than franked envelopes wherever possible;
- enclose a stamped addressed envelope for the respondent's reply;
- in surveys of the general population, Thursday is the best day for mailing out; in surveys of organizations, Monday or Tuesday are recommended;
- avoid at all costs a December survey (questionnaires will be lost in the welter of Christmas postings in the western world).

Follow-up letter

In connection with maximizing response levels, the follow-up letter has been shown to be very effective. The following points should be borne in mind in preparing reminder letters:

- all of the rules that apply to the covering letter apply even more strongly to the follow-up letter;
- the follow-up should re-emphasize the importance of the study and the value of the respondents' participation;
- the use of the second person singular, the conveying of an air of polite disappointment at non-response and some surprise at non-cooperation have been shown to be effective ploys;
- nowhere should the follow-up give the impression that non-response is normal or that numerous non-responses have occurred in the particular study;
- the follow-up letter must be accompanied by a further copy of the questionnaire together with a stamped addressed envelope for its return;
- second and third reminder letters suffer from the law of diminishing returns, so how many follow-ups are recommended and what success rates do they achieve? It is difficult to generalize, but the following points are worth bearing in mind. A well-planned postal survey might obtain a 40 per cent response rate and with the judicious use of reminders, a 70 to 80 per cent response level. A preliminary pilot survey is invaluable in that it can indicate the general level of response to be expected. There is evidence that the use of three reminders can increase the original return by as much as 30 per cent in surveys of the general public. A typical pattern of responses to the three follow-ups is as follows:

Original despatch	40 per cent
First follow-up	+20 per cent
Second follow-up	+10 per cent
Third follow-up	+5 per cent
Total	75 per cent

Bailey (1994, pp. 163–9) shows that follow-ups can be both by mail and by telephone. If a follow-up letter is sent, then this should be around three weeks after the initial mailing. A second follow-up is also advisable (*ibid*.), and this should take place one week after the first follow-up. He reports research (p. 165) that indicates that a second follow-up can elicit up to a 95.6 per cent response rate compared to a 74.8 per cent response with no follow-up. A telephone call *in advance* of the questionnaire can also help in boosting response rates (by up to 8 per cent). More recently, Dillman *et al*. (2014) note that mixed mode questionnaires, particularly with advance notice and follow-up reminders, can be very effective in securing higher response rates.

Incentives

An important factor in maximizing response rates is the use of incentives. It can substantially reduce non-response rates, particularly when the chosen incentives accompany the initial mailing rather than being mailed subsequently as rewards for the return of completed schedules. The explanation of the effectiveness of this appears to lie in the sense of obligation that is created in the recipient. Care is needed in selecting the most appropriate type of incentive. It should clearly be seen as a token rather than a payment for the respondent's efforts and should be as neutral as possible. We refer the reader to discussion of incentives and increasing response rates in Chapter 17.

The preparation of a flow chart can help the researcher to plan the timing and the sequencing of the various parts of a postal survey. One such flow chart, suggested by Hoinville and Jowell (1978), is shown in Figure 24.2. The researcher might wish to add a chronological chart alongside it to help plan the exact timing of the events shown here.

Researchers have to consider, first, whether respondents who complete questionnaires do so accurately, and second, whether those who fail to return their questionnaires would have given the same distribution of

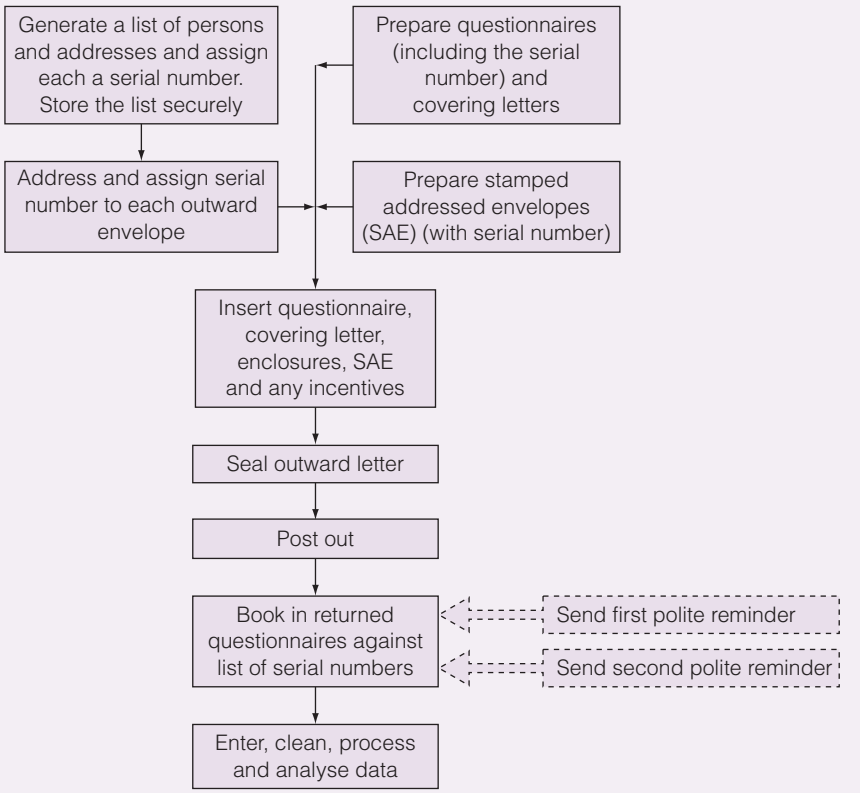

FIGURE 24.2 A flow chart for the planning of a postal questionnaire
Source: Adapted from Hoinville and Jowell (1978)

answers as did the returnees. We discuss the problem of non-response and how to reduce it in Chapter 17.

Further, we devote an entire chapter (Chapter 18) to Internet questionnaires, and we direct readers to this here.

20.14 Processing questionnaire data

Let us assume that researchers have followed the advice we have given about the planning, design and administration of questionnaires and have secured a high response rate to their surveys. Their task is now to reduce the mass of data they have obtained to a form suitable for analysis. Such 'data reduction' generally consists of coding data in preparation for analysis – by hand in the case of small surveys; by computers when the size is greater. First, however, prior to coding, the questionnaires have to be checked. This task is referred to as *editing*.

Editing questionnaires is intended to identify and eliminate errors made by respondents. Moser and Kalton (1977) point to three central tasks in editing:

1. *Completeness*: a check is made that there is an answer to every question. In most surveys, interviewers are required to record an answer to every question (a 'not applicable'/'don't know'/'decline to answer' or 'other' category always being available). Missing answers can sometimes be cross-checked from other sections of the survey. At worst, respondents can be contacted again to supply the missing information. Imputation methods (see Chapter 17) can also be used to compensate for missing data.
2. *Accuracy*: as far as is possible a check is made that all questions are answered accurately. Inaccuracies arise out of carelessness on the part of either interviewers or respondents. Sometimes a deliberate attempt is made to mislead. A tick in the wrong box, a ring round the wrong code, an error in simple arithmetic – all can reduce the validity of the data unless they are picked up in the editing process.
3. *Uniformity*: a check is made that interviewers have interpreted instructions and questions uniformly. Sometimes the failure to give explicit instructions

over the interpretation of respondents' replies leads to interviewers recording the same answer in a variety of answer codes instead of one. A check on uniformity can help eradicate such errors.

The primary task of data reduction is *coding*, that is, assigning a code number to each answer to a survey question. Of course, not all answers to survey questions can be reduced to code numbers (e.g. open-ended questions). Coding can be built into the construction of the questionnaire itself. In this case, we talk of pre-coded answers. Where coding is developed after the questionnaire has been administered and answered by respondents, we refer to post-coded answers. Pre-coding is appropriate for closed questions: male 1, female 2, for example; or single 1, married 2, separated 3, divorced 4. For questions such as those whose answer categories are known in advance, a coding frame is generally developed before the interviewing commences so that it can be printed into the questionnaire itself. It is vital to get coding frames right from the outset – extending them or making alterations at a later point in the study is both expensive and wearisome.

For open-ended, qualitative questions ('Why did you choose this particular in-service course rather than XYZ?'), we refer readers to the discussion of qualitative data analysis in Part 5.

There are several computer packages that will automatically process questionnaire data and return them in useable form (e.g. an Excel file, and SPSS file). At the time of writing some such are SurveyMonkey, FluidSurveys, SphinxSurvey, QuestionPro, SurveyGizmo, Zoho, Typeform, Survey Anyplace. Such packages assist researchers in the design, administration and processing of questionnaires, either for paper-based or for on-screen administration. Responses can be entered rapidly, and data can be examined automatically, producing graphs and tables, as well as a wide range of statistics.

Whilst coding is usually undertaken by the researcher, Sudman and Bradburn (1982, p. 149) also make the case for coding by the respondents themselves, to increase validity. This is particularly valuable in open-ended questionnaire items, though, of course, it does assume not only the willingness of respondents to become involved *post hoc* but also that the researcher can identify and trace the respondents, which, as was indicated earlier, is an ethical matter.

We address data analysis in Part 5.

For considering electronic/Internet questionnaires we refer the reader to Chapter 18.

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Interviews

CHAPTER 25

Interviews are a widely used instrument for data collection. This chapter sets out a range of key issues to be considered in planning, conducting and reporting interviews, including:

- conceptions of the interview
- purposes of the interview
- types of interview
- planning and conducting interviews
- group interviewing
- interviewing children
- interviewing minority and marginalized people
- focus groups
- non-directive, focused, problem-centred and in-depth interviews
- telephone interviewing
- online interviewing
- ethical issues in interviewing

This chapter indicates different kinds of interview, and argues for 'fitness for purpose' to be addressed in deciding which kind of interview and interview questions to employ.

25.1 Introduction

The use of the interview in research marks a move away from seeing human subjects as simply manipulable and data as somehow external to individuals, and towards regarding knowledge as generated between humans, often through conversations (Kvale, 1996, p. 11). Regarding an interview, as Kvale (p. 14) remarks, as an *inter-view*, an interchange of views between two or more people on a topic of mutual interest, sees the centrality of human interaction for knowledge production, and emphasizes the social situatedness of research data.

The interview is a social, interpersonal encounter, not merely a data-collection exercise. Kvale (1996) identifies two different approaches to interviews: the 'miner' who thinks that the interviewee has the information and who is concerned to extract the nuggets of precious material from the interviewee, and the 'traveller' who is concerned to travel with the interviewee as a partner into an unknown country. Whilst the former extracts information, the latter co-constructs knowledge, and this latter more clearly echoes Kvale's view of an interview as an *inter-view*.

As we suggested in Chapter 7, knowledge should be seen as constructed between participants, generating *data* – gifts – rather than *capta* (Laing, 1967, p. 53). As such, the interview is not exclusively either subjective or objective, it is intersubjective (p. 66). Interviews enable participants – interviewers and interviewees – to discuss their interpretations of the world in which they live, and to express how they regard situations from their own point of view. In these senses the interview is not simply concerned with collecting data about life: it is life itself; its human embeddedness is inescapable.

The interview is a flexible tool for data collection, enabling multi-sensory channels to be used: verbal, non-verbal, seen, spoken, heard and, indeed with online interviews, written. The order of the interview may be controlled whilst still giving space for spontaneity, and the interviewer can press not only for complete answers but for responses about complex and deep issues.

Hochschild (2009) notes that the interview can do what surveys cannot, which is to explore issues in depth, to see how and why people frame their ideas in the ways that they do, how and why they make connections between ideas, values, events, opinions, behaviours, etc. They can be used to cast further explanatory insight into survey data, or indeed to set up a survey. In short, the interview is a powerful tool for researchers. On the other hand, interviews are expensive in time, they are open to interviewer bias, they may be inconvenient for respondents, interviewee fatigue may hamper the interview and anonymity may be difficult. We explore these and other issues in this chapter.

An interview is not an ordinary, everyday conversation (Dyer, 1995, pp. 56–8). In contrast to an everyday conversation, it has a specific purpose (to gain evidence or data or information), it is often question-based, with the questions being asked by the interviewer; the interviewer may express ignorance (as may the interviewee), and the responses must be as explicit and as

detailed as possible. The interview is a constructed and usually a specifically planned event rather than a naturally occurring situation, and this renders it different from an everyday conversation; the researcher, therefore, has an obligation to set up, and abide by, the 'rules of the game' in an interview. Indeed Kvale (1996) notes that everyday conversation does not follow a prescripted set of questions, does not occur by appointment and does not have 'respondents' (pp. 30–1).

25.2 Conceptions of the interview

Kitwood (1977) lucidly contrasts three conceptions of an interview. The first conception is that of a potential means of pure information transfer. Here accurate data may be obtained if the interviewer establishes rapport, puts questions in an acceptable manner, and if the respondent is sincere and motivated to answer without lying or giving purely a socially desirable response.

A second conception of the interview is that of a transaction which inevitably has bias which must be recognized and controlled. Here Kitwood explains that each participant – interviewer and interviewee – will define the interview in a particular way. The interview is best understood in terms of a theory of motivation which recognizes a range of non-rational factors governing human behaviour, like emotions, unconscious needs and interpersonal influences. Kitwood points out that both these views of the interview regard inherent features of interpersonal transactions as potential obstructions to research, and, if possible, to be controlled or eliminated.

The third conception of the interview sees it as an encounter necessarily sharing many of the features of everyday life (e.g. Box 25.1). Kitwood suggests that what is required, according to this view, is not a technique for dealing with bias, but a theory of everyday life that takes account of the relevant features of interviews. These may include role-playing, stereotyping, perception and understanding. As Walford (2001, p. 90) remarks, 'interviewers and interviewees co-construct the interview'. As mentioned above, the interview is a social encounter, not simply a site for information exchange or capture, and interviewers should keep this in the forefront of their minds.

One of the strongest advocates of this latter viewpoint is Cicourel (1964), who lists five unavoidable features of the interview situation that would normally be regarded as problematic:

1. There are many factors which inevitably differ from one interview to another, such as mutual trust, social distance and the interviewer's control.
2. The respondent may well feel uneasy and adopt avoidance tactics if the questioning is too deep.
3. Both interviewer and respondent are bound to hold back part of what is in their power to state.
4. Many of the meanings which are clear to one will be relatively opaque to the other, even when the intention is genuine communication.
5. It is impossible, just as in everyday life, to bring every aspect of the encounter within rational control.

The message here is that no matter how hard an interviewer may try to be systematic and objective, the constraints of everyday life will be a part of whatever interpersonal transactions she initiates. Indeed Barker and Johnson (1998, p. 230) argue that the interview is a particular medium for enacting or displaying people's knowledge of cultural forms, as questions, far from being neutral, are couched in the cultural repertoires of all participants, indicating how people make sense of their social world and of each other.

BOX 25.1 ATTRIBUTES OF ETHNOGRAPHERS AS INTERVIEWERS

Trust: There would have to be a relationship between the interviewer and interviewee that transcended the research, promotes a bond of friendship, a feeling of togetherness and joint pursuit of a common mission rising above personal egos.

Curiosity: There would have to be a desire to know, to learn people's views and perceptions of the facts, to hear their stories, discover their feelings. This is the motive force that drives researchers to tackle and overcome the many difficulties involved in setting up and conducting successful interviews.

Naturalness: One endeavours to be unobtrusive in order to see events as they are, untainted by one's presence and actions, so the aim is to secure what is within the minds of interviewees, uncoloured and unaffected by the interviewer.

Source: Adapted from Woods (1986)

25.3 Purposes of the interview

The purposes of the interview are many and varied, for example:

- to understand, evaluate or assess a person, situation or event(s) in some respect;
- to select or promote an employee;
- to effect therapeutic change (e.g. the psychiatric interview);
- to test or develop hypotheses;
- to develop a research instrument such as a survey (as in cognitive interviews (Priede *et al*., 2014));
- to gather data, as in surveys, experimental situations and case studies;
- to sample respondents' opinions.

Although in each of these situations the respective roles of the interviewer and interviewee may vary and the motives for taking part may differ, a common denominator is the transaction that takes place between seeking information on the part of one and supplying information on the part of the other.

As a distinctive research technique, the interview may serve three purposes. First, it may be used as the principal means of gathering information to serve the research objectives, acquiring information on what a person is thinking, knows, likes, values and believes (Tuckman, 1972). Second, it may be used to test hypotheses or to suggest new ones; or to be an explanatory device to help identify variables and relationships. And third, the interview may be used in conjunction with other methods in a research undertaking. In this connection, Kerlinger (1970) suggests that it might be used to follow up unexpected or survey results, for example, or to validate other methods, or to go deeper into the motivations of respondents and their reasons for responding as they do.

Interviews as a research tool range from the formal interview in which set questions are asked and the answers recorded on a standardized schedule through less formal interviews in which the interviewer is free to modify the sequence of questions, change the wording, explain them or add to them, to the completely informal interview where the interviewer may have a number of key issues which she raises in conversational style instead of having a set questionnaire. Beyond this point is located the non-directive interview in which the interviewer takes on a subordinate role.

The research interview has been defined as a conversation between two people which is designed to obtain research data to meet objectives of research which concern 'systematic description, prediction or explanation' (Cannell and Kahn, 1968, p. 527). It involves the gathering of data through direct verbal interaction between individuals and, in this sense, it differs from the questionnaire where the respondent is required to record in some way her responses to set questions (though online written interviews blur these differences).

As the interview has some things in common with the self-administered questionnaire, it is frequently compared with it. Each has advantages over the other in certain respects. The advantages of the questionnaire, for instance, are: it tends to be more reliable because it is anonymous (though this is attenuated in an online interview); it encourages greater honesty; and it is more economical than the interview in terms of time and money (e.g. it can be mailed). Its disadvantages, on the other hand, are: poor response rate; unlike a questionnaire, the interviewer can answer questions concerning both the purpose of the interview and any misunderstandings experienced by the interviewee, as the same questions have different meanings for different people; if only closed items are used, the questionnaire will be subject to the weaknesses discussed in Chapter 24; if only open items are used, respondents may be unwilling to write their answers for one reason or another; questionnaires present problems to people of limited literacy. With the rise of the online interview, some of these distinctions are blurred, and we discuss this below.

We illustrate the relative merits of the interview and the questionnaire in Table 25.1. The direct interaction in the interview is the source of both its advantages and disadvantages as a research technique (Borg, 1963). One advantage, for example, is that it allows for greater depth than is the case with other methods of data collection. A disadvantage, on the other hand, is that it is prone to subjectivity and bias on the part of the interviewer and interviewee.

Oppenheim (1992, pp. 81–2) suggests that interviews have a higher response rate than questionnaires because respondents become more involved and, hence, motivated; they enable more to be said about the research than is usually mentioned in a covering letter to a questionnaire, and they are better than questionnaires for handling more difficult and open-ended questions.

25.4 Types of interview

The number of types of interview is frequently a function of the sources one reads. For example, LeCompte and Preissle (1993) give six types: (i) standardized interviews; (ii) in-depth interviews; (iii) ethnographic

TABLE 25.1 SUMMARY OF RELATIVE MERITS OF INTERVIEW VERSUS QUESTIONNAIRE

Consideration	*Interview*	*Questionnaire*
1 Personal need to collect data	Requires interviewers	Requires a secretary
2 Major expense	Payment to interviewers	Postage and printing
3 Opportunities for response-keying (personalization)	Extensive	Limited
4 Opportunities for asking	Extensive	Limited
5 Opportunities for probing	Possible	Difficult
6 Relative magnitude of data reduction	Great (because of coding)	Mainly limited to rostering
7 Typically, the number of respondents who can be reached	Limited	Extensive
8 Rate of return	Good	Poor
9 Sources of error	Interviewer, instrument, coding, sample	Limited to instrument and sample
10 Overall reliability	Quite limited	Fair
11 Emphasis on writing skill	Limited	Extensive

Source: Tuckman (1972)

interviews; (iv) elite interviews; (v) life history interviews; (vi) focus groups. Bogdan and Biklen (1992) add to this: (vii) semi-structured interviews; (viii) group interviews. Lincoln and Guba (1985) add: (ix) structured interviews; and Oppenheim (1992, p. 65) adds: (x) exploratory interviews. Patton (1980, p. 206) outlines four types: (xi) informal conversational interviews; (xii) interview guide approaches; (xiii) standardized open-ended interviews; (xiv) closed quantitative interviews. Patton sets these out as shown in Table 25.2.

How is the researcher to comprehend the range of these various types? Kvale (1996, pp. 126–7) sets the several forms of interview along a series of continua, arguing that interviews differ in the openness of their purpose, their degree of structure, the extent to which they are exploratory or hypothesis-testing, whether they seek description or interpretation, or whether they are largely cognitive-focused or emotion-focused. A major difference appears to lie in the degree of structure in the interview (cf. Wellington, 2015, p. 141), which itself reflects the purposes of the interview, for example, to generate numbers of responses about a given issue or to indicate unique, alternative feelings about a particular matter. Lincoln and Guba (1985, p. 269) suggest that the structured interview is useful when the researcher is aware of what she does not know and therefore is in a position to frame questions that will supply the knowledge required, whereas the unstructured interview is useful when the researcher is not aware of what she does not know, and therefore relies on the respondents to tell her.

The issue here is of 'fitness for purpose': the more one wishes to gain comparable data – across people, across sites – the more standardized and quantitative one's interview tends to become; the more one wishes to acquire unique, non-standardized, personalized information about how individuals view the world, the more one veers towards qualitative, open-ended, unstructured interviews. This is true not simply of interviews but of their written counterpart – questionnaires. Oppenheim (1992, p. 86) indicates that standardization should refer to *stimulus equivalence*, i.e. that every respondent should *understand* the interview question in the same way, rather than replicating the exact wording, as some respondents might have difficulty with particular questions, or interpret them very differently and perhaps irrelevantly (though he adds that, as soon as the wording of a question is altered, however minimally, it becomes, in effect, a different question).

Oppenheim (1992, p. 65) suggests that *exploratory* interviews are designed to be essentially heuristic and seek to develop hypotheses rather than to collect facts and numbers. He notes that these may cover emotionally loaded topics and, hence, require skill on the part of the interviewer to handle the interview situation, enabling respondents to talk freely and emotionally, with candour, richness, depth, authenticity and honesty in their comments.

Morrison (1993, pp. 34–6) sets out five continua of different ways of conceptualizing interviews. At one end of the first continuum are numbers, statistics, objective facts and quantitative data; at the other end are transcripts of conversations, comments, subjective accounts, essentially word-based qualitative data.

At one end of the second continuum are closed questions, multiple-choice questions where respondents

TABLE 25.2 STRENGTHS AND WEAKNESSES OF DIFFERENT TYPES OF INTERVIEW

Type of interview	*Characteristics*	*Strengths*	*Weaknesses*
1 Informal conversational interview	Questions emerge from the immediate context and are asked in the natural course of things; there is no predetermination of question topics or wording.	Increases the salience and relevance of questions; interviews are built on and emerge from observations; the interview can be matched to individuals and circumstances.	Different information collected from different people with different questions. Less systematic and comprehensive if certain questions don't arise 'naturally'. Data organization and analysis can be quite difficult.
2 Interview guide approach	Topics and issues to be covered are specified in advance, in outline form; interviewer decides sequence and working of questions in the course of the interview.	The outline increases the comprehensiveness of the data and makes data collection somewhat systematic for each respondent. Logical gaps in data can be anticipated and closed. Interviews remain fairly conversational and situational.	Important and salient topics may be inadvertently omitted. Interviewer flexibility in sequencing and wording questions can result in substantially different responses, thus reducing the comparability of responses.
3 Standardized open-ended interviews	The exact wording and sequence of questions are determined in advance. All interviewees are asked the same basic questions in the same order.	Respondents answer the same questions, thus increasing comparability of responses; data are complete for each person on the topics addressed in the interview. Reduces interviewer effects and bias when several interviewers are used. Permits decision makers to see and review the instrumentation used in the evaluation. Facilitates organization and analysis of the data.	Little flexibility in relating the interview to particular individuals and circumstances; standardized wording of questions may constrain and limit naturalness and relevance of questions and answers.
4 Closed quantitative interviews	Questions and response categories are determined in advance. Responses are fixed; respondent chooses from among these fixed responses.	Data analysis is simple; responses can be directly compared and easily aggregated; many short questions can be asked in a short time.	Respondents must fit their experiences and feelings into the researcher's categories; may be perceived as impersonal, irrelevant and mechanistic. Can distort what respondents really mean or experienced by so completely limiting their response choices.

Source: Patton (1980, p. 206)

have to select from a given, predetermined range of responses the particular response which most accurately represents what they wish to have recorded for them; at the other end of the continuum are much more open-ended questions which do not require the selection from a given range of responses, and respondents can answer the questions in their own way and in their own words, i.e. the research is responsive to participants' own frames of reference and response.

At one end of the third continuum is a desire to measure responses, to compare one set of responses with another, to correlate responses, to see how many people said this, how many rated a particular item as such-and-such; at the other end of the continuum is a desire to capture the uniqueness of a particular situation, person or programme – what makes it/them different from others, i.e. to record the quality of a situation or response.

At one end of the fourth continuum is a desire for formality and the precision of numbers and prescribed categories of response where the researcher knows in advance what is being sought; at the other end is a more

responsive, informal intent where what is being sought is more uncertain and indeterminate: we only know what we are looking for when we have found it! The researcher goes into the situation and responds to what emerges.

At one end of the fifth continuum is the attempt to find regularities – of response, opinions etc. – in order to begin to make generalizations from the data, to describe what is happening; at the other end is the attempt to portray and catch uniqueness, the quality of a response, the complexity of a situation, to understand why respondents say what they say, and all of this in their own terms.

One can cluster the sets of poles of the five continua thus:

Quantitative approaches	*Qualitative approaches*
numbers	words
predetermined, given	open-ended, responsive
measuring	capturing uniqueness
short-term, intermittent	long-term, continuous
comparing	capturing particularity
correlating	valuing quality
frequencies	individuality
formality	informality
looking at	looking for
regularities	uniqueness
description	explanation
objective facts	subjective facts
describing	interpreting
looking in from the outside	looking from the inside
structured	unstructured
statistical	ethnographic, illuminative

The left-hand column is much more formal and pre-planned to a high level of detail, whilst the right-hand column is far less formal and the fine detail only emerges once the researcher is *in situ*. Interviews in the left-hand column are front-loaded, that is, they require all the categories and multiple-choice questions to be worked out in advance. This usually requires a pilot to try out the material and refine it. Once the detail of this planning is completed the analysis of the data is relatively straightforward because the categories for analysing the data have been worked out in advance, hence data analysis is rapid.

The right-hand column is much more end-loaded, that is, it is quicker to commence and gather data because the categories do not have to be worked out in advance; they emerge once the data have been collected. However, in order to discover the issues that emerge and to organize the data presentation, the analysis of the data takes considerably longer.

Kvale (1996, p. 30) sets out key characteristics of qualitative research interviews, namely that they should:

- engage, understand and interpret the key feature of the lifeworlds of the participants;
- use natural language to gather and understand qualitative knowledge;
- be able to reveal and explore the nuanced descriptions of the lifeworlds of the participants;
- elicit descriptions of specific situations and actions, rather than generalities;
- adopt a deliberate openness to new data and phenomena, rather than being too pre-structured;
- focus on specific ideas and themes, i.e. have direction, but avoid being too tightly structured;
- accept the ambiguity and contradictions of situations where they occur in participants, if this is a fair reflection of the ambiguous and contradictory situation in which they find themselves;
- accept that the interview may provoke new insights and changes in the participants themselves;
- regard interviews as an interpersonal encounter, with all that this entails;
- be a positive and enriching experience for all participants.

Here we focus on five main kinds of interview that may be used specifically as research tools: (i) the structured interview; (ii) the semi-structured interview; (iii) the unstructured interview; (iv) the non-directive interview; and (v) the focused interview.

In the structured interview the content and procedures are organized in advance, the sequence and wording of the questions are determined by means of a schedule and the interviewer is left little freedom to make modifications. Where some leeway is possible, it, too, is specified in advance. It is characterized by being a closed situation.

In the semi-structured interview, the topics and questions are given, but the questions are open-ended and the wording and sequence may be tailored to each individual interviewee and the responses given, with prompts and probes (discussed below).

The unstructured interview is an open situation, having greater flexibility and freedom. As Kerlinger (1970) notes, although the research purposes govern the questions asked, their content, sequence and wording are entirely in the hands of the interviewer. This does not mean, however, that the unstructured interview is a more casual affair, for in its own way it also has to be carefully planned.

The non-directive interview as a research technique derives from the therapeutic or psychiatric interview.

The principal features of it are the minimal direction or control exhibited by the interviewer and the freedom the respondent has to express her subjective feelings as fully and as spontaneously as she chooses or is able. Moser and Kalton (1977, p. 297) argue that respondents should be encouraged to talk about the subject under investigation (e.g. themselves) and to be free to guide the interview, with few set questions or prefigured frameworks. The interviewer should prompt and probe, pressing for clarity and elucidation, rephrasing and summarizing where necessary and checking for confirmation of his/her understanding of the issue, particularly if the issues are complex or vague.

The need to introduce more interviewer control into the non-directive situation led to the development of the focused interview. The distinctive feature of this type is that it focuses on a respondent's subjective responses to a known situation in which she has been involved and which has been analysed by the interviewer prior to the interview. She is thereby able to use the data from the interview to substantiate or reject previously formulated hypotheses. Here, as Merton and Kendall (1946) explain, 'the interviewer can, when expedient, play a more active role: he can introduce more explicit verbal cues to the stimulus pattern or even *represent* it' (p. 542). It evokes concrete responses by participants.

We examine both the non-directive interview and the focused interview in more detail later in the chapter.

25.5 Planning and conducting interviews

Planning an interview involves sampling, question type, the design of the interview and who is being interviewed. 'How many interviews do I need to conduct?' is a frequent question of novice researchers, asking both about the numbers of people and the number of interviews with each person. Our advice here echoes that of Kvale (1996, p. 101), namely, one conducts interviews with as many people as necessary in order to gain the information sought. There is no simple rule of thumb, as this depends on the purpose of the interview, for example, to make generalizations, to provide in-depth, individual data, to gain a range of responses etc. (see Chapter 12 on sampling for fuller treatment of these matters). The issue here is that the interviewer must ensure that the interviewees selected will be able to furnish the researcher with the information, i.e. that participants actually possess the information.

Kvale (1996, p. 88) sets out several stages in the planning of an interview investigation: thematizing; designing; interviewing; transcribing; analysing; verifying; and reporting. We extend these to a ten-stage sequence to structure our comments here about the planning of interview-based research.

Stage 1: thematizing

The preliminary stage of an interview study is where the purpose of the research is decided. It may begin by outlining the theoretical basis of the study, its broad aims, its practical value and the reasons why the interview approach was chosen. There then follows the translation of the general goals of the research into more detailed and specific objectives and research questions. This is the most important step, for only careful formulation of objectives at this point will eventually produce the right kind of data necessary for satisfactory answers to the research problem.

Stage 2: designing

There follows the preparation of the interview schedule itself. This involves translating the research objectives and research questions into the actual questions that make up the main body of the schedule. This needs to be done in such a way that the questions adequately reflect what the researcher is trying to find out. One can begin this task by writing down the variables to be dealt with in the study (Tuckman, 1972).

Before the actual interview items are prepared, it is important to consider the question format and the response mode. The choice of question format, for instance, depends on a consideration of one or more of the following factors:

- the objectives of the interview;
- the nature of the subject matter;
- whether the interviewer is dealing in facts, opinions or attitudes;
- whether specificity and/or depth is sought;
- the respondent's likely level of understanding;
- the kind of information he or she can be expected to have;
- whether or not the interviewee's thought needs to be structured;
- some assessment of the interviewee's motivational level;
- the extent of the interviewer's own insight into the respondent's situation;
- the kind of relationship the interviewer can expect to develop with the respondent.

From these, the researcher is in a position to decide the kind of interview to adopt, whether to use open and/or closed questions, direct and/or indirect questions, specific and/or non-specific questions, and so on.

Stage 3: construction of schedules

As discussed in detail in Chapter 24, there are several types of question that can be asked: open ended, closed, dichotomous, multiple choice (single response, constrained response – a limited number of choices – and free choice; rank ordering, rating scales, ratio data). We refer the reader to that chapter.

Three main kinds of items are used in the construction of schedules in research interviews (Kerlinger, 1970). First, 'fixed-alternative items' allow the respondent to choose from two or more alternatives, for example, the dichotomous item which offers two alternatives only: 'yes–no' or 'agree–disagree', and sometimes a third alternative such as 'undecided' or 'don't know' is also offered. Kerlinger notes that 'fixed-alternative items' have the advantage of achieving greater uniformity of measurement and therefore greater reliability; of making the respondents answer in a manner fitting the response category; and of being more easily coded. Disadvantages include: their superficiality; the possibility of irritating those respondents who find none of the alternatives suitable; and the possibility of forcing inappropriate responses, either because the alternative chosen conceals ignorance on the part of the respondent or because she may choose an alternative that does not accurately represent the true facts. These weaknesses can be overcome, however, if the items are written with care, mixed with open-ended items and used in conjunction with probes by the interviewer.

Second, 'open-ended items' have been succinctly defined by Kerlinger (1970) as those which provide a frame of reference for respondents' answers, but which put little restraint on the kinds and contents of answers and how they can be expressed, for example, 'What kind of Internet areas do you most search?' Here, other than the subject of the question, which is determined by the nature of the issue under investigation, there are no other restrictions on either the content or the manner of the interviewee's reply.

Open-ended questions have a number of advantages: they are flexible; they allow the interviewer to probe so that she may go into more depth if she chooses, or to clear up any misunderstandings; they enable the interviewer to test the limits of the respondent's knowledge; they encourage cooperation and help to establish rapport; and they allow the interviewer to make a truer assessment of what the respondent really believes. Open-ended situations can also produce unexpected or unanticipated answers which may suggest hitherto unthought-of relationships or hypotheses.

A particular kind of open-ended question is the 'funnel' which, as in questionnaires, starts with a broad question or statement and then narrows down to more specific ones. Kerlinger (1970) quotes an example from the study by Sears *et al*. (1957):

> All babies cry, of course. Some mothers feel that if you pick up a baby every time it cries, you will spoil it. Others think you should never let a baby cry for very long. How do you feel about this? What did you do about it? How about the middle of the night?
>
> (Sears *et al*., 1957, p. 157)

Third, the 'scale' (rating scales) is a set of verbal items to each of which the interviewee responds by indicating degrees of agreement or disagreement (or other anchor statements for response), i.e. the individual's response is located on a scale of fixed alternatives. The use of this technique along with open-ended questions enables scale scores to be checked against data elicited by open-ended questions. It is possible to use one of a number of scales in this context: attitude scales, rank order scales, rating scales, and so on (see also Chapter 24). We touch upon this subject again below.

In devising questions for the interview, Arksey and Knight (1999, pp. 93–5) suggest that attention has to be given to:

- the vocabulary to be used (keeping it simple);
- avoiding prejudicial language;
- avoiding ambiguity and imprecision;
- leading questions (a decision has to be taken whether it is justified to use them);
- avoiding double-barrelled questions (asking more than one point at a time);
- questions which make assumptions (e.g. 'do you go to work in your car?');
- hypothetical or speculative questions;
- sensitive or personal questions (whether to ask or avoid them);
- avoiding assuming that the respondent has the required knowledge/information;
- recall (how easy it will be for the respondent to recall events etc.).

Prompts and probes

The framing of questions for a semi-structured interview can also consider *prompts* and *probes* (Morrison, 1993, p. 66). Prompts enable the interviewer to clarify topics or questions, particularly if the interviewee seems not to have understood, or to have misunderstood, or wishes to ask for clarification or more guidance from the interviewer. The interviewer can, for example, rephrase or repeat the question, or give an example (Denscombe, 2014, p. 193). These have to be

used with caution, as they may falsely assume that the interviewee has not understood the question.

Probes enable the interviewer to ask respondents to extend, elaborate, add to, exemplify, provide detail for, clarify or qualify their response, thereby addressing richness, depth of response, comprehensiveness and honesty that are some of the hallmarks of successful interviewing (see also Patton, 1980, p. 238; Wellington, 2015, p. 147), and they enable the researcher to understand more the thought processes of the interviewee (Priede *et al*., 2014). A probe may be simply the follow-up 'why'/'how' questions or 'can you give me an example of this?'. It could comprise simply repeating the question, repeating the answer in a questioning tone, showing interest and understanding, asking for clarification or an example or further explication, or indeed simply pausing as if to give the interviewee the opportunity to add more.

Aldridge and Levine (2001, p. 119) suggest two types of probe: one in which more detailed factual information is sought, and another in which the respondent is encouraged to elaborate on accounts that they have given or opinions that they hold. Patton (1990) gives three types of probe: detail-oriented probes; elaboration probes; and clarification probes. Beatty and Willis (2007) identify four types of probe (p. 300):

- *anticipated probes*: pre-scripted probes to follow up on an initial question (see also Conrad and Blair's (2009) 'discretionary probes');
- *spontaneous probes*: not pre-scripted, where the interviewer decides on the spur of the moment what to probe, which is not based on a particular response from the interviewee;
- *conditional probes*: pre-scripted probes which are only used if the respondent answers in a particular way or hesitates (see also Conrad and Blair, 2009);
- *emergent probes*: not pre-scripted, where the interviewer decides to probe in response to what the interviewee says, for example, an apparent problem.

Priede *et al*. (2014, p. 560) add three further types:

- *cognitive probes*: focusing on the interviewee's understandings and interpretations of the question, what they drew on and time frames they referred to when answering the question, and how easy or difficult they found the question;
- *confirmatory probes*: 'to check that the information given by the respondent is thus far correct' (p. 560);
- *expansive probes*: seeking further information and details from the interviewees.

Probes can range from the less intrusive (e.g. pausing for the respondent to say more, or making a sound such as 'mmm' to indicate that the interviewer is following closely) to the more intrusive (e.g. repeating a phrase or idea that the respondent said and then following it up with a request for further information, or summarizing ('am I right in thinking that you were saying…', or 'can I just check that I have understood correctly?') and then questioning, or asking for an example or instance, or asking for clarification, or even politely and respectfully challenging, or checking (cf. Aldridge and Levine, 2001, p. 120)).

Fowler (2009, p. 139) offers a cautionary note, suggesting that the more the interviewer prompts and probes, the greater is the chance of bias entering the interview. His argument favours standardized wording, with the possibility of further explanation if respondents are unclear. Wellington (2015, p. 147) advises caution in having too many prompts or probes which ask for depth ('over probing'), as this may provoke resentment or bias.

An interview schedule for a semi-structured interview (i.e. where topics and open-ended questions are written but the exact sequence and wording does not have to be followed with each respondent) might include:

- the topic to be discussed;
- the specific possible questions to be put for each topic;
- the issues within each topic to be discussed, together with possible questions for each issue;
- a series of prompts and probes for each topic, issue and question.

Stage 4: question formats

We now look at the kinds of questions and modes of response in interviewing. First, the matter of question format (cf. Wilson, 1996): how is a question to be phrased or organized? Tuckman (1972) listed four possible formats. For example, questions may take a direct or indirect form. Thus an interviewer could ask a teacher whether she likes teaching: this would be a direct question. Or else she could adopt an indirect approach by asking for the respondent's views on education in general and the ways schools function. From the answers proffered, the interviewer could make inferences about the teacher's opinions concerning her job. Tuckman suggests that by making the purpose of questions less obvious, the indirect approach is more likely to produce frank and open responses.

Second, there are questions which deal with either a general or specific issue. To ask a child what she

thought of the teaching methods of the staff as a whole would be a general or non-specific question. To ask her what she thought of her teacher as a teacher would be a specific question. There is also the sequence of questions, for example, the funnel, in which the movement is from the general and non-specific to the more specific. Tuckman comments that the interviewer must be careful in being too specific too soon, as such direct questions could make the respondent cautious, reticent and avoid an honest answer; rather, coming at an issue more indirectly could produce a more honest response without causing alarm.

Third, a further distinction is made between questions inviting factual answers and those inviting opinions. To ask a person what political party she supports is a factual question. To ask her what she thinks of the current government's foreign policy is an opinion question. Both fact and opinion questions can yield less than the truth, however: the former do not always produce factual answers, nor do the latter necessarily elicit honest opinions. In both instances, inaccuracy and bias may be minimized by careful wording and sequencing of the questions.

There are several ways of categorizing questions, for example (Spradley, 1979; Patton, 1980):

- descriptive questions;
- experience questions;
- behaviour questions;
- knowledge questions;
- construct-forming questions;
- contrast questions (asking respondents to contrast one thing with another);
- feeling questions;
- sensory questions;
- background questions;
- demographic questions.

These concern the *substance* of the question. Kvale (1996, pp. 133–5) adds to these what might be termed *process* questions, i.e. those which:

- introduce a topic or interview;
- follow up on a topic or idea;
- probe for further information or response;
- ask respondents to specify and provide examples;
- directly ask for information;
- indirectly ask for information;
- interpret respondents' replies.

An interviewee may be presented with either a question or a statement. In the case of the latter she will be asked for her response to it in one form or another.

Example question: Do you think homework should be compulsory for all children between nine and twelve years old?

Example statement: Homework should be compulsory for all children between nine and twelve years old.

Agree Disagree Don't know

Stylianou (2008) discusses the 'interview control question'. In experimental and survey designs, variables are often controlled, i.e. held 'constant and unvarying so that one can see the true effects of other variables' after the effects of others have been neutralized (controlled out) (Morrison, 2009, p. 65), i.e. what effects remain after all the other variables have been controlled out. Controlling for the effects of other variables can be undertaken, inter alia, through randomization and random allocation (see Chapter 20), and isolation and control of independent variables other than those in which the researcher is interested (e.g. holding them constant). Controlling for the effects of other variables enables the researcher to see the true effect(s) of a single independent variable in which she or he is interested, i.e. what is left after other variables have been controlled out of the situation. Stylianou (2008) suggests that the same can be done in interviews, i.e. by isolating and controlling out the effects of other variables, the researcher can see the true effect of a particular variable in which she or he is interested, i.e. when the effects of others have been removed. Interview control questions are a form of a probe.

Let us give an example of an interview control question in an imaginary interview concerning a parent who expresses a negative attitude towards mixed ability classes in a primary school:

1. *Interviewer*: Why are you not in favour of mixed ability classes in the school?
2. *Respondent*: The less able students will slow down the more able students in the class, and the teacher will have to work very hard to keep up with the wide range of different abilities in the class.
3. *Interviewer*: But we know that many more capable students slow down anyway, for two reasons: firstly, if they finish work quickly then they are given more work to do, and they want an easy life, and secondly, many of the more able students don't want to stand out as being exceptional in their class, so they slow down. And anyway, the teacher has to work hard, as she has a range of tasks to do as part of her daily work. In fact the teacher can

have a classroom assistant to work with students of different abilities.

4 *Respondent*: But having a classroom assistant still doesn't ensure that all the students get their fair share of the teacher's attention – only the less able and more able children get the extra attention from the classroom assistant.

5 *Interviewer*: But that's the case anyway, as not all the students get the same amount of attention by the teacher, regardless of their abilities, as some students prefer to work quietly on their own without the teacher. Students have to work by themselves anyway, for example, in their mathematics lessons only they can do the work and the teacher cannot do it for them. And, anyway, it's important for students to learn to work by themselves; isn't that a good thing?

6 *Respondent*: But some students aren't good at working by themselves and they may need the teacher's help at critical moments, and having so many mixed abilities will prevent the teacher from being there at critical moments.

7 *Interviewer*: But the teacher will be there to help them at critical moments anyway, that's part of their job, and they are trained to recognize critical moments. Teachers have to be present at critical moments in a student's thinking, prompting them to take the next step in their thinking or learning.

8 *Respondent*: But some students will want to have an easy life, so they won't let the teacher know that they need help or prompting, and they will ask their friend to help them.

9 *Interviewer*: But students do that anyway, as they often help each other; surely that's a good thing, to work collaboratively and help each other, and students learn well from each other.

10 *Respondent*: Look, I just don't want my child to have to work with less able children, and that's all.

In the example, the interviewer is carefully stripping away the possible causes of the parent's attitude: (a) slowing down the more capable students (paras. 2 and 3); (b) students having fair access to adult help (paras. 4 and 5); (c) students having to learn by themselves (paras. 5 and 6); (d) the presence of teachers at critical moments (paras. 6 and 7); (e) students working with friends (paras. 8 and 9). The interviewer, even though being somewhat confrontational (the repeated use of the word 'but'), is raising alternative applications of each of the possible causes, i.e.:

- there are reasons other than the one given here as to why the teacher has to work hard anyway (i.e. not only a matter of having the more and less able students in the same class), and why the more able students may slow down their rate of learning, not only the presence of less able students;
- there are reasons other than the one given here as to why having a classroom assistant will not help to solve the problem of students' access to the teacher's attention (i.e. there are other things that a classroom assistant has to do);
- there are reasons other than the one given here as to why students work by themselves, not only a matter of having or not having the teacher's attention;
- there are reasons other than the one given here as to why the teacher may be present at critical moments;
- there are reasons other than the one given here as to why students work together.

The interviewer is finding that the reasons that the respondent gives for objecting to mixed ability classes operate in other contexts as well, and not solely mixed ability contexts, and so they have to be controlled out: teacher working hard; access to teacher's attention; students working on their own; teacher's non-presence at critical moments; students working collaboratively.

In para. 10, the respondent, having had a range of variables controlled (neutralized) here, becomes exasperated and ends the interview. The researcher might conclude here that the parent is simply prejudiced, other key variables having been removed (controlled) from the reasoning, indeed Stylianou (2008, p. 244) suggests that this kind of probing is useful for studying attitudes and prejudice. Here the interview control question assumes that the variables are dichotomous (e.g. the presence or absence of a variable are the only options); however, within that limitation, the interview control question is useful for identifying possible causal factors in an interviewee's responses.

Stage 5: response modes

Just as there are varied ways of asking questions, so there are several ways in which they may be answered. Here we refer the reader again to Chapter 24 on the several types of question that can be asked and the response modes that accompany them: open-ended, closed, dichotomous, multiple choice (single response, constrained response – a limited number of choices – and free choice); rank ordering, rating scales, ratio data.

As a general rule, the kind of information sought, the means of its acquisition and the kinds of question asked will determine the choice of response mode. The choice of response mode must ensure that the interviewer can be confident that the data will serve her

purposes and analysis of them can be duly prepared. Table 25.3 summarizes the relationship between response mode and type of data.

It is important to bear in mind that more than one question format and more than one response mode can be employed when building up a schedule. The final mixture will depend on the kinds of factors mentioned earlier – the objectives of the research, and so on.

Where an interview schedule is to be used as part of a field survey in which a number of trained interviewers are to be used, it will be necessary to include appropriate instructions for both interviewer and interviewees.

Stage 6: conducting the interview

Setting up and conducting the interview make up the next stage in the procedure. This includes, for example, consideration of the people involved, the location, time and timing of the interview (Mills, 2001), the nature of the interview and the actual conduct of the interview – what happens in it.

Where the interviewer is initiating the research herself, she will clearly select her own respondents; where she is engaged by another agent then she will probably be given a list of people to contact. The interviewer should inform the participant of the nature or purpose of the interview, being honest yet without risking biasing responses (Tuckman, 1972). The interviewer should introduce herself/himself and explain the purposes and conduct of the interview (what happens, and how, and the structure and organization of the interview), how responses may be recorded (and seek permission if this is to happen), and these procedures should be observed throughout (cf. Fowler, 2009, p. 140). The sequence of the question needs careful planning, grouping together similar topics or questions. There are several kinds of question (Kvale, 1996), for example:

- introductory questions (to introduce the topic of that part of the interview, e.g. 'can you tell me about…?');
- follow-up questions (e.g. 'can you tell me a little more about…?'; 'can you give me an example of…?');
- direct questions (e.g. with a 'yes/no' answer);
- indirect questions (to try to obtain the interviewee's real opinion);
- probing questions (to go deeper into a topic);
- specifying questions (e.g. 'what happened next?');
- structuring questions (those that move the interview on to the next topic);
- interpreting questions (to check your understanding, e.g. 'do you mean that…?'; 'Am I right in thinking that…?');
- silence (indicating that you are giving the interviewee the opportunity to expand on a topic or answer).

During the interview the biases and values of the interviewer should not be revealed, and the interviewer must be neutral and avoid being judgemental. The interviewer may have to steer respondents if they are rambling off the point, without being impolite. Aldridge and Levine (2001, p. 119) suggest that factual, personal data should be kept until later in the interview, or at the end, rather than at the beginning of the interview.

The interview, as a social encounter, also requires: clear guidance (however tacit) on when to speak and when to be silent (Mills, 2001, p. 204); tolerance of inattention or lack of clarity; carefully planned greeting and parting; if possible, the topic should put the interviewees at ease (p. 295). In this respect one has to bear in mind that different socio-cultural contexts exert different influences on an interview (not least the linguistic factor in which the researcher may be conducting

TABLE 25.3 THE SELECTION OF RESPONSE MODE

Response mode	*Type of data*	*Chief advantages*	*Chief disadvantages*
Fill-in	Nominal	Less biasing; greater response flexibility	More difficult to score
Scaled	Interval	Easy to score	Time-consuming; can be biasing
Ranking	Ordinal	Easy to score; forces discrimination	Difficult to complete
Checklist or Categorical	Nominal (may be interval when totalled)	Easy to score; easy to respond	Provides less data and fewer options

Source: Tuckman (1972)

the interview in a language that is not his/her first language or the respondent's first language). Miltiades (2008) notes that in some cultures, the influence of culture manifests itself in having not only the presence of other members of an extended family at the interview (p. 281), but those other members actively participating in the interview, giving answers, censoring information (p. 282), interrupting, preventing information from being spoken, and passing comments, i.e. adopting a gate-keeping role (p. 283). As she remarks (p. 282), in some cultures the self is a 'we-self' (rather than an 'I-self') in a collective family, and indeed she notes that the Bengali language has no word for 'private'. Just as the researcher brings his or her own cultural background to the interview, so do the respondents (p. 278), and this might affect the nature, substance and amount of data given, the possible biases towards social desirability of answers (the tendency of respondents to give what they believe will be a socially desirable response, or indeed to self-censor) (p. 283), and indeed in some cultures, the tendency for elders – as authority figures – to give answers rather than the initially targeted interviewees (p. 278). As she remarks (p. 281), in some cultures, the interview becomes a social event.

As the interview, as mentioned already, is a social encounter, a speech act (Austin, 1962), Kvale (1996, p. 125) suggests that an interview follows an unwritten script for interactions, the rules for which only surface if they are transgressed. Hence the interviewer must be at pains to conduct the interview carefully, sensitively and with delicacy (Mills, 2001, p. 286). Kvale (1996, p. 147) adds that, as the researcher is the research instrument, the effective interviewer is not only knowledgeable about the subject matter but is also an expert in interaction and communication. The interviewer will need to establish an appropriate atmosphere such that the participant can feel secure to talk freely. This operates at several levels.

For example, there is the need to address the *cognitive* aspect of the interview, ensuring that the interviewer is sufficiently knowledgeable about the subject matter so that she or he can conduct the interview in an informed manner, and that the interviewee does not feel threatened by lack of knowledge. That this is a particular problem when interviewing children has been documented by Simons (1982) and Lewis (1992), who indicate that children will tend to say anything rather than nothing at all, thereby limiting the possible reliability of the data. The interviewer must also be vigilant to the fact that respondents may not always be what they seem; they may be providing misinformation, telling lies, evading the issue, putting on a front (Walford, 2001, p. 91), settling scores and being malicious. By contrast, it is also an issue in interviewing powerful people (Chapter 13), where the interviewer must be well informed of the subject in question.

Further, the ethical dimension of the interview must be borne in mind, ensuring, for example, informed consent, guarantees of confidentiality, beneficence and non-maleficence (i.e. the interview may be to the advantage of the respondent and will not harm her). Ethics also needs to take account of what is to count as data. For example, it is often after the recorder or video camera has been switched off that the 'gems' of the interview are revealed, or people may wish to say something 'off the record'; the status of this kind of information needs to be clarified before the interview commences. The ethical aspects of interviewing are discussed later in the chapter.

Then there is a need to address the *interpersonal, interactional, communicative and emotional* aspects of the interview. For example, the interviewer and interviewee communicate non-verbally, by facial and bodily expression. Something as slight as a shift in position on a chair might convey whether the researcher is interested, angry, bored, uncomfortable with talking about the issue, agreeing, disagreeing and so on, so the interviewer has to be adept at 'active listening'. We note later in the chapter the challenges and benefits of telephone and online interviewing in depriving participants of visual clues.

Further, the onus is on the interviewer to establish and maintain a good rapport with the interviewee. This concerns being clear, polite, non-threatening, friendly and personable, to the point without being too assertive. It also involves being respectful, for example, some respondents may or may not wish to be called by their first name, family name or title; being dressed too casually may not inspire confidence. Rapport also requires the interviewer to communicate very clearly and positively the purpose, likely duration, nature and conduct and contents of the interview, to give the respondent the opportunity to ask questions, to be sensitive to any emotions in the respondent, to avoid giving any signs of annoyance, criticism or impatience, and to leave the respondent feeling better than, or at least no worse than, she or he felt at the start of the interview. The interviewer must put himself/herself in the shoes of the respondent, and be sensitive to how it must feel to be interviewed. Rapport also means establishing trust, for example, about confidentiality, privacy, anonymity, non-traceability and honesty. It does not mean 'liking' the respondent (Dyer, 1995, p. 62); it means handling the situation sensitively, professionally and ethically.

The interviewer is also responsible for considering the *dynamics* of the situation, for example, how to keep the conversation going, how to motivate participants to discuss their thoughts, feelings and experiences, how to overcome the problems of the likely asymmetries of power in the interview (where the interviewer typically defines the situation, the topic, the conduct, the introduction, the course of the interview and the closing of the interview) (Kvale, 1996, p. 126). As Kvale suggests, the interview is not usually a reciprocal interaction between two equal participants. It is important to keep the interview moving forward, and the interviewer must anticipate and plan for how to achieve this, for example by being clear on what she wishes to find out, asking questions that will elicit the kinds of data sought, giving appropriate verbal and non-verbal feedback to the respondent during the interview. It extends even to considering when the interviewer should keep silent (1996, p. 135).

The 'directiveness' of the interviewer has been scaled by Whyte (1982), where a six-point scale of directiveness and responding was devised (1 = the least directive and 6 = the most directive):

1. Making encouraging noises.
2. Reflecting on remarks made by the informant.
3. Probing on the last remark made by the informant.
4. Probing an idea preceding the last remark by the informant.
5. Probing an idea expressed earlier in the interview.
6. Introducing a new topic.

This is not to say that the interviewer should avoid being too directive or not directive enough; indeed on occasions a confrontational style might yield much more useful data than a non-confrontational style. Further, it may be in the interests of the research if the interview is sometimes quite tightly controlled, as this might facilitate the subsequent analysis of the data. For example, if the subsequent analysis seeks to categorize and classify the responses, then it might be useful for the interviewer to clarify meaning and even suggest classifications during the interview (see Kvale, 1996, p. 130).

Patton (1980, p. 210) suggests that it is important to maintain the interviewee's motivation and interest; hence the interviewer must keep boredom at bay, for example, by keeping to a minimum any demographic and background questions. The issue of the *interpersonal* and *interactional* elements reaches further, for the language of all speakers has to be considered, for example, translating the academic language of the researcher into the everyday, more easy-going and colloquial language of the interviewee, in order to generate rich descriptions and authentic data. Patton goes on to underline the importance of clarity in questioning, and this entails the interviewer finding out what terms the interviewees use about the matter in hand, what terms they use among themselves, and avoiding the use of academic jargon (p. 225). The issue here is not only that the language of the interviewer must be understandable to interviewees but that it must be part of their frame of reference, such that they feel comfortable with it.

Further, the age, gender, race, class, dress, language of the interviewers and interviewees all exert an influence on the interview itself. As Mills (2001, p. 296) remarks, consideration should be given to the potential differentiation of power brought about by the characteristics of the interviewer (e.g. age, profession, social class). Bailey (1994, p. 183) reports that survey interviewers may be female, middle-class white-collar workers, yet those they interview may have none of these characteristics. He reports that having women interviewers elicited a greater percentage of honest responses than having male interviewers (p. 182), that having white interviewers interviewing black respondents yielded different results from having black interviewers interview black respondents (pp. 180–1). He also suggests that interviewers should avoid having specific identity with particular groups or countercultures in their dress (p. 185) as this can bias the interview; rather some unobtrusive clothing should be worn so as to legitimize the role of the interviewer by fitting in with the respondents' expectations of an interviewer's appearance. One can add here that people in power may expect to be interviewed by interviewers in powerful positions and it is more likely that an interview with a powerful person may be granted to a higher-status interviewer (discussed fully in Chapter 13).

The issue extends to consideration of who the interviewer is: an insider or an outsider. Lee (2016) notes that, in some circumstances, for example, members of a particular linguistic, social, cultural or ethnic group, that is, having a natural affinity with the group, may enable greater access and rapport to be obtained than if one is a 'social intruder' (p. 40).

The *sequence* and *framing* of the interview questions will also need to be considered, for example, ensuring that easier and less threatening, non-controversial questions are addressed earlier in the interview in order to put respondents at their ease (see Patton, 1980, pp. 210–11). This might mean that the 'what' questions precede the more searching and difficult 'how' and 'why' questions (though, as Patton reminds us (p. 211), knowledge questions – 'what'-type questions – can be threatening). The interviewer's

questions should be straightforward and brief, even though the responses need not be (Kvale, 1996, p. 132). The interviewer will also need to consider the *kinds* of questions to be put to interviewees, discussed earlier.

There are several problems in the actual conduct of an interview that can be anticipated and, possibly, prevented, ensuring that the interview proceeds comfortably, for example:

- avoiding interruptions from outside (e.g. telephone calls, people knocking on the door);
- minimizing distractions;
- minimizing the risk of 'stage fright' in interviewees and interviewers;
- avoiding asking embarrassing or awkward questions;
- jumping from one topic to another;
- giving advice or opinions (rather than active listening);
- summarizing too early or closing off an interview too soon;
- being too superficial;
- handling sensitive matters (e.g. legal, personal, emotional matters).

Arksey and Knight (1999, p. 53) suggest that the interviewer should:

- appear to be interested;
- keep to the interview schedule in a structured interview;
- avoid giving signs of approval or disapproval of responses received;
- be prepared to repeat questions at the respondent's request;
- be prepared to move on to another question without irritation, if the respondent indicates unwillingness or inability to answer the question;
- ensure that he/she (the interviewer) understands a response, checking if necessary (e.g. 'am I right in thinking that you mean …?');
- if a response is inadequate, but the interviewer feels that the respondent may have more to say, thank the respondent and add 'and could you please tell me …';
- give the respondent time to answer (i.e. avoid answering the question for the respondent).

Gadd (2004, p. 397) reports the importance of how the interviewer responds to the interviewee, as an unsupportive, unsympathetic or negative response (even if not intended) could discourage a respondent from proceeding.

In preparing for the interview, the interviewer must become familiar with the topic in hand, consider the structure and sequence of the interview, plan clear questions that can be put in as few words as possible, plan how to respond (both to the people *qua* people and to what they say), plan how to steer the interview and keep it on track and plan how to balance the different areas of the interview, for example, factual, opinions, feelings, values, background/contextual matters.

There is also the issue of how to record the interview. For example, an audio recorder might be unobtrusive but might constrain the respondent; a video recorder might yield more accurate data but might be even more constraining, with its connotation of surveillance. It might be less threatening not to have any recording, in which case the reliability of the data might rely on the memory of the interviewer (though, as Gadd (2004, p. 384) remarks, memory is *motivated* in nature, and may be subject to selective recall). An alternative might be to have the interviewer make notes *during* the interview, but this could be highly off-putting for some respondents. The issue here is that there is a trade-off between the need to catch as much data as possible and yet to avoid having so threatening an environment that it impedes the potential of the interview situation.

The 'ideal' interview, then, meets several 'quality criteria' (Kvale, 1996, p. 145):

- the extent of spontaneous, rich, specific and relevant answers from the interviewee;
- the shorter the interviewer's questions and the longer the subject's answers, the better;
- the degree to which the interviewer follows up and clarifies the meanings of the relevant aspects of the answers;
- the ideal interview is to a large extent interpreted throughout the interview;
- the interviewer attempts to verify his or her interpretations of the subject's answers in the course of the interview;
- the interview is 'self-communicating' – it is a story contained in itself that hardly requires much extra descriptions and explanations.

People may refuse to be interviewed (Bailey, 1994, pp. 186–7; Cooper and Schindler, 2001, p. 301); they might:

- not give a reason for refusing;
- be hostile to what they see as intrusion;
- hold anti-authoritarian feelings;
- feel that it is a waste of time;
- speak a foreign language;

- take an instant dislike to the interviewer;
- say that they are too busy;
- feel embarrassed or ignorant;
- dislike or feel uncomfortable with the topic under review;
- be afraid of the consequences of participating;
- feel inadequate or that they do not know the right answer.

The onus is on the interviewer to try to overcome these factors, whilst recognizing, of course, that they may be legitimate, in which case no further attempt can be made to conduct the interview. It is important for the interviewer to render the interview as a positive, pleasant and beneficial experience, and to convince the participant of their own worth and the importance of the topic (cf. Solberg (2014) discussing interviewing children). If there is a significant difference between the interviewer and the respondent (e.g. gender, age, ethnicity, race, social status, colour, class), it might be advisable to have another interviewer try to conduct the interview (Morrison, 2013a).

So far the assumption has been that there is only one interviewer present at the interview. There is an argument for having more than one interviewer present, so that one can transcribe or observe features that might be overlooked by the other interviewer whilst the other is engaging the respondent (and these roles have to be signalled clearly to the respondent at the interview), and also to share the interviewing. Joint interviews can provide two versions of the interview – a cross-check – and one can complement the other with additional points, leading to a more complete and reliable record. It also enables one interviewer to observe non-verbal features such as the power and status differentials and social dynamics, and, if there is more than one respondent present at the interview, the relationships between the respondents, for example, how they support, influence, complement, agree and disagree with each other, or indeed contradict each other, the power plays at work, and so on.

On the other hand, having more than one interviewer present is not without its difficulties. For example, the roles of the two interviewers may be unclear to the respondents (and it is the job of the interviewers to make this clear), or it may be intimidating to have more than one interviewer present. Researchers will need to weigh carefully the strengths and weaknesses of having more than one interviewer present, and what their roles will be.

We give readers a list of guidelines for conduct during the interview in Box 25.2.

BOX 25.2 GUIDELINES FOR THE CONDUCT OF INTERVIEWS

- Interviews are an interpersonal matter, a social event.
- Avoid saying 'I want to know …'; the interviewee is doing you a favour, not being interrogated.
- How to follow up on questions/answers.
- How to keep people on track and how to keep the interview moving forward.
- How to show respect.
- How to divide your attention as interviewer and to share out the interviewees' responses – giving them all a chance to speak in a group interview.
- Do you ask everyone in a group interview to give a response to a question?
- If there is more than one interviewer, what are the roles of the 'silent' interviewer, and do the interviewees know the roles of the interviewers?
- Who is looking at whom.
- If you need to look at your watch then maybe comment on this publicly.
- Try not to refer to your interview schedule; if you need to refer to it then comment on this publicly (e.g. 'let me just check that I have covered the points that I wanted').
- Avoid using your pen as a threatening weapon, pointing it at the interviewee.
- Consider your non-verbal communication, eye contact, signs of anxiety, showing respect.
- Give people time to think – don't interrupt yourself if there is silence.
- How to pass over from one interviewer to another and from one interviewee to another if there is more than one interviewer or interviewee.
- How to give feedback and acceptance to the interviewees.
- Should you write responses down – what messages does this give?
- Put yourself in the shoes of the interviewee.

continued

continued

- What are the effects of losing eye contact or of maintaining it for too long?
- Think of your body posture – not too laid-back and not too menacing.
- How to interpret and handle silence.
- Avoid looking away from the respondent if possible.
- Avoid interrupting the respondent.
- Avoid judging the respondent or his/her response.
- The interviewer should summarize and crystallize issues and build on them – that is a way of showing respect.
- How to give signs of acceptance of what people are saying, and how to avoid being judgemental.
- Take care of timing – not too long to be boring.
- Give interviewees the final chance to add any comments, and thank them at the end.
- Plan how to hand over the questions to the next interviewer.
- How to arrange the chairs and tables – do you have tables (they may be a barrier or a protection)?
- Identify who controls the data, and when the control of the data passes from the interviewee to the interviewer.
- What to do with 'off the record' data.
- Take time to 'manage' the interview and keep interviewees aware of what is happening and where it is going.
- Vary the volume/tone of your voice.
- Avoid giving your own view or opinion; be neutral.
- Who is working harder – the interviewer or the interviewee?
- Who is saying more – the interviewer or the interviewee?
- If there is more than one interviewer, how to avoid one interviewer undermining another.
- Think of prompts and probes.
- How to respond to people who say little.
- Consider the social (and physical) distance between the interviewer and interviewee(s).
- Consider the layout of the furniture – circle/oval/straight line or what?
- Have a clear introduction which makes it plain how the interview will be conducted and how the interviewees can respond (e.g. turn-taking).
- Make sure you summarize and crystallize every so often.
- How to handle interviewees who know more about the topic than you do.
- Do you have males interviewing females and vice versa (think of age/gender/race etc. of interviewers and interviewees)?
- Give some feedback to respondents every so often.
- What is the interview doing that cannot be done in a questionnaire?
- If there are status differentials then don't try to alter them in the space of an interview.
- Plan what to do if the interviewee 'turns the tables' and tries to be the interviewer.
- Plan what to do with aggressive or angry interviewees.
- Plan what to do if powerful interviewees don't answer your questions (maybe you need to admit that you haven't understood very well, and ask for clarification, i.e. that it is your fault).
- Be very prepared, so that you don't need to look at your schedule.
- Know your subject matter well.
- If people speak fast then try to slow down everything.
- As an interviewer, you have the responsibility for making sure the interview runs well.

Denscombe (2014, pp. 192–4) provides helpful advice for interviews, noting that a 'good' interviewer must be: attentive and sensitive to the interviewees and their feelings; able to tolerate silences; non-judgemental; effective in the use of prompts, probes and checks; and an effective facilitator in group interviews/focus groups.

Interviewers have to be sensitive to their own effect on the interview. For example, they may fail to secure full cooperation or keep to procedures, they may establish an inappropriate environment (physical, cognitive, emotional, interpersonal), they may be exerting undue influence or pressure on the respondent, or they may be

selective in recording the data; we consider the issue of reliability in Chapter 14.

It is important for the interviewer to explain to the respondent the purpose, scope, nature and conduct of the interview, the use to be made of the data, ethical issues, the likely duration of the interview, i.e. to explain fully the 'rules of the game' so that the interviewee is left in no doubt as to what will happen during and after the interview. The interviewer must introduce herself/himself properly and fully to the respondent (maybe even providing identification). The interviewer has to set the scene appropriately, for example, to say that there are no right and wrong answers, that some of the topics may be deep but that they are not designed to be a test, to invite questions and interruptions, and to clear permission for recording. During the interview it is important, also, for the interviewee to speak more than the interviewer, for the interviewer to listen attentively and to be seen by the respondent to be listening attentively, and for the interviewer to be seen to be at ease with the interview.

What is being suggested here is that the interview, as a social encounter, as a series of speech acts, has to take account of, and plan for, the whole range of other possibly non-cognitive factors that form part of everyday conduct.

Stage 7: transcribing

This is a crucial step in interviewing, for there is the potential for massive data loss, distortion and the reduction of complexity. It has been suggested throughout this chapter that the interview is a social encounter, not merely a data-collection exercise; the problem with much transcription is that it becomes solely a record of data rather than a record of a social encounter. As Powney and Watts (1987) remark:

> Talk is dynamic – a quality it loses as soon as it is collected in any way. It is somewhat … like catching rain in a bucket for later display. What you end up with is water, which is only a little like rain.
>
> (Powney and Watts, 1987, p. 16)

Indeed this problem might have begun at the data-collection stage, for example an audio recording is selective, it filters out important contextual factors, neglecting the visual and non-verbal aspects of the interview (Mishler, 1986) (see also the comments below on online and telephone interviewing). Moreover, frequently non-verbal communication gives important information additional to the verbal communication. Morrison (1993, p. 63) recounts the incident of an autocratic headteacher extolling the virtues of collegiality and democratic decision making whilst shaking her head vigorously from side to side and pressing the flat of her hand in a downwards motion away from herself as if to silence discussion and dismiss any other views. To replace audio recording with video recording might make for richer data and catch non-verbal communication, but this is time-consuming to analyse.

Transcriptions inevitably lose data from the original encounter as it represents the translation from one set of rule systems (oral and interpersonal) to another remote rule system (written language). As Kvale (1996, p. 166) suggests, the prefix *trans* indicates a change of state or form; transcription is selective transformation. Therefore it is unrealistic to pretend that the data on transcripts are anything but *already interpreted* data. As Kvale (p. 167) remarks, the transcript can become an opaque screen between the researcher and the original live interview situation.

Because of these difficulties, there can be no single 'correct' transcription; rather the issue becomes whether, how and how much a transcription is useful. Transcriptions are decontextualized, abstracted from time and space, from the dynamics of the situation, from the live form, and from the social, interactive, dynamic and fluid dimensions of their source; they are frozen.

The words in transcripts are not necessarily as solid as they were in the social setting of the interview. Mishler (1991, p. 260) suggests that data and the relationship between meaning and language are contextually situated; they are unstable, changing and capable of endless reinterpretation.

We are not arguing against transcriptions, rather we are cautioning the researcher against believing that they catch everything that happened in the interview. The researcher might need to ensure that different *kinds* of data are recorded in the transcript of the recording, for example:

- what was being said;
- the tone of voice of the speaker(s) (e.g. harsh, kindly, encouraging);
- the inflection of the voice (e.g. rising or falling, a question or a statement, a cadence or a pause, a summarizing or exploratory tone, opening or closing a line of enquiry);
- emphases placed by the speaker;
- pauses (short to long) and silences (short to long);
- interruptions;
- the mood of the speaker(s) (e.g. excited, angry, resigned, bored, uncomfortable, enthusiastic, committed, happy, grudging);
- the speed of the talk (fast to slow, hurried or unhurried, hesitant to confident);

- how many people were speaking simultaneously;
- whether a speaker was speaking continuously or in short phrases;
- who is speaking to whom;
- indecipherable speech;
- any other events that were taking place at the same time that the researcher can recall.

If the transcript is of a video recording, then this enables the researcher to comment on all of the non-verbal communication that was taking place in addition to the words spoken. The issue here is that it is often inadequate to transcribe only spoken words; other data are important. Of course, as soon as other data are noted, this becomes a matter of interpretation (what is a long pause, what is a short pause, was the respondent happy or was it just a 'front', what gave rise to such-and-such a question or response, why did the speaker suddenly burst into tears?). As Kvale (1996, p. 183) notes, interviewees' statements are not simply collected by the interviewer, they are, in reality, co-authored.

Stage 8: analysing

Once data from the interview have been collected, the next stage involves analysing them, for example, by some form of coding, scoring or content analysis. In qualitative data the analysis is almost inevitably interpretive, hence the data analysis is less a completely accurate representation (as in the numerical, positivist tradition) and more a reflexive, reactive interaction between the researcher and the decontextualized data that are already interpretations of a social encounter.

The researcher has to consider whether to focus on those items which the participant mentions or reiterates the most, or whether to deem important those items that arise when the participant wanders from the point or changes the subject, or – in the case of two respondents – whether they actually mean the same even if they are using the same words to describe similar experiences or the same experience (Gadd, 2004, p. 385). At issue here is the unavoidable integration of analysis and interpretation.

The great tension in data analysis is between maintaining a sense of the holism of the interview and the tendency for analysis to atomize and fragment the data, to separate them into constituent elements, thereby losing the synergy of the whole, and in interviews often the whole is greater than the sum of the parts. There are several stages in analysis, for example:

- generating natural units of meaning;
- classifying, categorizing and ordering these units of meaning;
- structuring narratives to describe the interview contents;
- interpreting the interview data.

These are comparatively generalized stages. Miles and Huberman (1994) suggest several tactics for generating meaning from transcribed and interview data:

- counting frequencies of occurrence (of ideas, themes, pieces of data, words);
- noting patterns and themes (Gestalts), which may stem from repeated themes and causes or explanations or constructs;
- seeing plausibility: trying to make sense of data, using informed intuition to reach a conclusion;
- clustering: setting items into categories, types, behaviours and classifications;
- making metaphors: using figurative and connotative language rather than literal and denotative language, bringing data to life, thereby reducing data, making patterns, decentring the data and connecting data with theory;
- splitting variables to elaborate, differentiate and 'unpack' ideas, i.e. to move away from the drive towards integration and the blurring of data;
- subsuming particulars into the general (akin to Glaser's (1978) notion of 'constant comparison', discussed in Chapter 37 of this volume): a move towards clarifying key concepts;
- factoring: bringing a large number of variables under a smaller number of (frequently) unobserved hypothetical variables;
- identifying and noting relations between variables;
- finding intervening variables: looking for other variables that appear to be 'getting in the way' of accounting for what one would expect to be strong relationships between variables;
- building a logical chain of evidence: noting causality and making inferences;
- making conceptual/theoretical coherence: moving from metaphors to constructs to theories to explain the phenomena.

This progression, though perhaps positivist in its tone, is a useful way of moving from the specific to the general in data analysis. Running through the suggestions from Miles and Huberman (1994) is the importance that they attach to coding, partially as a way of reducing what is typically data overload in qualitative data. They suggest that analysis through coding can be performed both within-site and cross-site, enabling causal chains, networks and matrices to be established, all of these addressing what they see as the

major issue of reducing data overload through careful data display.

Coding has been defined by Kerlinger (1970) as the translation of question responses and respondent information to specific categories for the purpose of analysis. As we have seen, many questions are pre-coded, that is, each response can be immediately and directly converted into a score in an objective way. Rating scales and checklists are examples of pre-coded questions. Coding is the ascription of a category label to a piece of data, with the category label either decided in advance or in response to the data that have been collected.

We discuss coding more fully in Chapter 34, and we refer the reader to that discussion, including the advantages and disadvantages of coding.

Content analysis involves reading and judgement; Brenner *et al.* (1985) set out several sequential steps in undertaking a content analysis of open-ended data:

1. Briefing (understanding the problem and its context in detail).
2. Sampling (of people, including the types of sample sought; see Chapter 12).
3. Associating (with other work that has been done).
4. Hypothesis development.
5. Hypothesis testing.
6. Immersion (in the data collected, to pick up all the clues).
7. Categorizing (in which the categories and their labels must: (a) reflect the purpose of the research; (b) be exhaustive; (c) be mutually exclusive).
8. Incubation (e.g. reflecting on data and developing interpretations and meanings).
9. Synthesis (involving a review of the rationale for coding and an identification of the emerging patterns and themes).
10. Culling (condensing, excising and even reinterpreting the data so that they can be written up intelligibly).
11. Interpretation (making meaning of the data).
12. Writing (including: giving clear guidance on the incidence of occurrence; proving an indication of direction and intentionality of feelings; being aware of what is not said as well as what it said – silences; indicating salience to the readers and respondents).
13. Rethinking.

This process, Brenner *et al*. suggest (1985, p. 144), requires researchers to:

- understand the research brief thoroughly;
- evaluate the relevance of the sample for the research project;
- associate their own experiences with the problem, looking for clues from the past;
- develop testable hypotheses as the basis for the content analysis (the authors name this the 'Concept Book');
- test the hypotheses throughout the interviewing and analysis process;
- stay immersed in the data throughout the study;
- categorize the data in the Concept Book, creating labels and codes;
- incubate the data before writing up;
- synthesize the data in the Concept Book, looking for key concepts;
- cull the data – being selective is important because it is impossible to report everything that happened;
- interpret the data, identifying its meaning and implication;
- write up the report;
- rethink and rewrite: have the research objectives been met?

We discuss content analysis fully in Chapter 34.

Hycner (1985) sets out procedures that can be followed when analysing interview data phenomenologically. We saw in Chapters 1 and 15 that the phenomenologist advocates the study of direct experience taken at face value and sees behaviour as determined by the phenomena of experience rather than by external, objective and physically described reality. In addressing this, Hycner's summary guidelines are as follows:

1. *Transcription*: transcribe the interview recording, noting not only the literal statements but also non-verbal and paralinguistic communication.
2. *Bracketing and phenomenological reduction*: enter the world of the unique individual being interviewed, suspending as far as possible the researcher's own meaning and interpretations.
3. *Listening to the interview for a sense of the whole*: listen to the entire recording several times and read the transcription a number of times in order to provide a context for the emergence of specific units of meaning and themes later on.
4. *Delineating units of general meaning*: thoroughly scrutinize both verbal and non-verbal gestures to elicit the participant's meaning, to crystallize and condense what the respondent has said, using, as far as possible, the interviewee's own words.
5. *Delineating units of meaning relevant to the research question*: once the units of general meaning have been noted, reduce them to units of meaning relevant to the research question.

6 *Training independent judges to verify the units of relevant meaning*: have other researchers carry out the above procedures.
7 *Eliminating redundancies*: check the lists of relevant meaning and eliminate those clearly redundant to others previously listed.
8 *Clustering units of relevant meaning*: determine if any of the units of relevant meaning naturally cluster together; whether there seems to be some common theme or essence that unites several discrete units of relevant meaning.
9 *Determining themes from clusters of meaning*: examine all the clusters of meaning to determine if there is/are one (or more) central theme(s) which expresses the essence of these clusters.
10 *Writing a summary of each individual interview*: go back to the interview transcription and write up a summary of it, incorporating the themes elicited from the data.
11 *Return to the participant with the summary and themes, conducting a second interview*: check to see whether the essence of the first interview has been accurately and fully captured.
12 *Modifying themes and summary*: with the new data from the second interview, look at all the data as a whole and modify or add themes as necessary.
13 *Identifying general and unique themes for all the interviews*: look for the themes common to most or all of the interviews as well as the individual variations: (a) noting if there are themes common to all or most of the interviews; then (b) noting when there are themes unique to a single interview or a minority of the interviews.
14 *Contextualization of themes*: place these themes back within the overall contexts or horizons from which these themes emerged.
15 *Composite summary*: write up a composite summary of all the interviews which accurately capture the essence of the phenomenon being investigated, as experienced by the participants, noting, where relevant, individual differences.

We also refer readers to the chapters on analysing qualitative data in Chapters 32 to 37.

Stage 9: verifying

Chapter 14 discusses at length the issues of reliability, validity and generalizability of the data from interviews, and so these issues are not repeated here. Kvale (1996, p. 237) notes that validation must take place at all stages of the interview-based investigation, set out above. For example: (a) the theoretical foundation of the research must be rigorous and there must be a logical link between such theory and the research questions; (b) all aspects of the research design must be sound and rigorous; (c) the data must be accurate, reliable and valid (with consistency and reliability checks undertaken); (d) the translation of the data from an oral to a written medium must demonstrate fidelity to the key features of the interview situation; (e) data analysis must demonstrate fidelity to the data; (f) validation procedures should be in place and used; (g) the reporting should be fair and seen to be fair by readers.

Here there is no single canon of validity; rather fitness for purpose within an ethically defensible framework should be adopted, giving rise to different kinds of validity for different kinds of interview-based research (e.g. structured to unstructured, qualitative to quantitative, nomothetic to idiographic, generalizable to unique, descriptive to explanatory, positivist to ethnographic, pre-ordinate to responsive).

Stage 10: reporting

The nature of the reporting will be decided to some extent by the nature of the interviewing and the audience. For example, a standardized, structured interview may yield numerical data which may be reported succinctly in tables and graphs, whilst a qualitative, word-based, open-ended interview will yield word-based accounts that take up considerably more space.

Kvale (1996, pp. 263–6) suggests several elements of a report: (i) an introduction that includes the main themes and contents; (ii) an outline of the methodology and methods (from designing to interviewing, transcription and analysis); (iii) the results (the data analysis, interpretation and verification); (iv) a discussion (including possible explanations for the findings).

Figures and tables appear in a typical quantitative report; if the interview is more faithfully represented in words rather than numbers then this presents the researcher with the issue of how to present particular quotations. Here Kvale (p. 266) suggests that direct quotations should: (a) illuminate and relate to the general text whilst maintaining a balance with the main text; (b) be contextualized and be accompanied by a commentary and interpretation; (c) be particularly clear, useful and the 'best' of the data (the 'gems'!); (d) include an indication of how they have been edited; and (e) be incorporated into a natural written style of the report.

For sample interview data, see the accompanying website.

25.6 Group interviewing

One technique of interviewing is that of group interviewing. Watts and Ebbutt (1987) and Leshem (2012), for example, have considered the advantages and disadvantages of group interviewing as a means of collecting data in educational research. The group interview can be cost-efficient, time-efficient, generate a wider range of responses than in individual interviews. Bogdan and Biklen (1992, p. 100) add that group interviews can be useful for gaining an insight into what might be pursued in subsequent individual interviews. There are practical and organizational advantages, too. Pre-arranged groups can be used by teachers with minimum disruption. Group interviews are often more time-saving than individual interviews. The group interview can also bring together people with varied opinions, or as representatives of different collectivities.

Arksey and Knight (1999, p. 76) suggest that having more than one interviewee present can provide two versions of events – a cross-check – and one can complement the other with additional points, leading to a more complete and reliable record. It is also possible to detect how the participants support, influence, complement, agree and disagree with each other, and the relationships between them. On the other hand, one respondent may dominate the interview (p. 76). Further, Arksey and Knight suggest that antagonisms may be stirred up at the interview, individuals may be reticent in front of others, particularly if they are colleagues or if the matter is sensitive. They also suggest that a 'public line' may be offered instead of a more honest, personal response, and indeed participants may collude in withholding information.

Watts and Ebbutt (1987) note that group interviews may be of little use in allowing personal matters to emerge, or where the researcher has to aim a series of follow-up questions at one specific member of the group. As they explain, the dynamics at work among the members of the group may deny access to various personal types of data. Group interviews may produce 'group think', discouraging individuals who hold a different view from speaking out in front of the other group members; they may be 'apprehensive, self-conscious and stressed' (Leshem, 2012, p. 3). Leshem reports that 'the group interview is an intensive social encounter that weaves a complex web of communication styles that may convey ambiguous messages' as interviewers and interviewees bring their own personalities, cultures, values, beliefs and backgrounds to the situation, which 'inevitably affect the way they perform in a constrained reality' (2012, p. 6). As Scheurich (1997) remarks, both interviewers and interviewees bring their own 'conscious and unconscious baggage' to an interview (p. 73).

Further, Lewis (1992) comments on the problem of coding the responses of group interviews. For further guidance on this topic and the procedures involved, we refer the reader to Simons (1982), Arksey and Knight (1999) and Part 5 on qualitative data analysis.

Several issues have to be addressed in the conduct of a group interview, for example:

1. How to divide your attention as interviewer and to share out the interviewees' responses, giving them all a chance to speak in a group interview?
2. Do you ask everyone in a group interview to give a response to a question?
3. How to handle people who are too quiet, too noisy, who monopolize the conversation, who argue and disagree with each other?
4. What happens if people become angry with you or with each other?
5. How to make people be quiet/stop talking whilst being polite?
6. How to handle differences in how talkative people are?
7. How to arrange turn-taking (if appropriate)?
8. Do you ask named individuals questions?
9. How can you have individuals answer without forcing them?
10. How to handle a range of very different responses to the same question?
11. Why have you brought together the particular people in the group?
12. Do you want people to answer in a particular sequence?
13. How to handle different ages, ethnicities, genders, status positions etc. within the group of interviewees?
14. What to do if the more experienced or senior people always answer first in a group interview?
15. As an interviewer, how to be vigilant to pick up on people who are trying to speak?

When conducting group interviews the unit of analysis is the view of the whole group and not the individual member; a collective group response is being sought, even if there are individual differences or a range of responses within the group. This ensures that no individual is either unnecessarily marginalized or subject to blame or being ostracized for holding a different view.

Group interviews are also very useful when interviewing children, and it is to this that we now turn.

25.7 Interviewing children

Children have been regarded as 'the best sources of information about themselves' (Docherty and Sandelowski, 1999, p. 177), but it is important for the interviewer to be able to enter their world and childhood culture and to see the situation through their eyes (p. 177). It is important to understand the world of children through their own eyes rather than the lens of the adult. Children differ from adults in cognitive and linguistic development, attention and concentration span, ability to recall, life experiences, what they consider to be important, status and power (Arksey and Knight, 1999, p. 116). All of these have a bearing on the interview.

Jansen (2015) notes that some children may relish an interview and are eager to participate as it takes them seriously and values their views, experiences and stories, which they do not normally have the opportunity to express in their daily lives, and that the interview is non-evaluative and non-judgemental in nature. Indeed Morrison (2013a) reports a study in which the children left the interview encounter feeling very positive about themselves and the interview, even though it had been an unfamiliar experience.

The interview accords children agency and competency which is sometimes denied in their lives (Jansen, 2015, p. 34). Children are seen as a respected resource, not a problem, and their knowledge is seen by all parties as essential for the research (p. 37). Indeed Solberg (2014) notes, not only with children but more widely, that the interview must respect the point that interviewees have ideas, opinions, information and experiences that the researcher wishes to understand (which also requires the interview to clarify to participants the purposes of the interview) (p. 244).

The interview, as we have mentioned before, is a non-naturally occurring social encounter, a series of speech acts; this is acutely important to keep in mind when interviewing children, as the task is to engage children in a safe context, not to interrogate them or pump them for information. Here the ethical issue of *primum non nocere* – 'first, do no harm' – is paramount (Jansen, 2015). An interview is likely to be an unfamiliar situation for many children, and Morrison (2013a) comments that the task of the interviewer, in a reversal of Blumer's (1969) dictum of 'making the familiar strange', is to 'make the strange familiar'. Morrison (2013a) notes several deliberate actions that the interviewer can take to address this, including, in a situation in which group interviewing with children is conducted in school time and on the school premises:

- have a familiar location (a school classroom with complete privacy and no risk of interruption);
- have the interviewers seen around the school before the interviews;
- ensure a good fit between the culture of the interview and the culture and ethos of the school;
- ensure informed consent;
- guarantee anonymity, privacy, confidentiality and non-traceability;
- put the children at their ease at the start of the interview;
- make the interviews serious yet very good natured, easy, enjoyable and positive;
- create a relaxed, friendly and, at times, humorous atmosphere;
- indicate how important the children are in the research;
- take care with clothing, to respect the children rather than to frighten or over-awe them;
- if the lead interviewer is much older than the children, have a much younger research assistant who deliberately dresses down to be more akin to the children;
- have the interviewers use question-and-answer techniques that the children are well used to in class, i.e. the children have expectations of the adults, and the adults deliberately try to fit those expectations to some extent;
- use the language, genre and register of the children wherever possible;
- take care with question structure, sequence and wording, making them easy to understand, clear, concrete and specific, with one-word answers at first, moving to open-ended answers later in the interview;
- take great care with proxemics, personal space and non-verbal communication, and scrupulously avoid intrusion into personal space;
- give positive feedback on, and thanks for, comments received;
- include voting on various items by the group;
- be acutely alert to hesitancies, non-verbal communication and silences, the emotional and social dimensions of the interview and respond appropriately.

Arksey and Knight (1999, pp. 116–18) indicate that it is important to establish trust with children (cf. Solberg's (2014) comments that the interview is a 'co-production' between children and interviewer, even in a guided interview (p. 244)), to put the child at ease quickly and to help him/her to feel confident, to avoid over-reacting (e.g. if the child is distracted). Putting children at ease extends to the choice of venue and time

(Morrison, 2013a; Leeson, 2014). Conducting an interview in the family home or in school sends signals to children; a child in an abusive family might find school an easier venue than the family home, and a child who has problems at school might prefer a neutral venue. Sometimes the school environment might exert a very positive influence on how seriously the child takes an interview on, say, a school-related matter (Morrison, 2013a), although, of course, it may elicit a perceived socially or institutionally desirable response.

Researchers must also make the interview non-threatening and enjoyable, and avoid making the children feel that they have to explain themselves (Leeson, 2014). Solberg (2104) comments that adults must indicate to the children that they are not like 'ordinary' adults (e.g. in the sense of exerting power over the children) but rather that they (adults) lack the knowledge that the children possess and that they (adults) can learn from the children's experiences, opinions and ideas (p. 244).

Interviewers must use straightforward language and child's language (Danby *et al*., 2011) and ask questions that are appropriate for the age of the child (e.g. keep to the 'here and now' and avoid using 'why', 'when' and 'how' questions with very young children (e.g. below five years old), and ensure that children can understand abstract questions (e.g. with older children)). Krähenbühl and Blades (2006) note the need for questions to be very clear, uncomplicated, concrete, specific and straightforward (see also Wilson and Powell, 2001). The researcher must be mindful, too, that some children will choose to respond orally, whilst others may respond in non-verbal communication (Solberg, 2014, p. 246).

In short, interviewers with children must guide the interviews in such a way as to 'invite rather than overrule the informants' (Solberg, 2014, p. 234). All of these require the researcher to give children time to think, and to combine methods and activities in an interview, for example, drawing, playing, writing, speaking, playing a game, using pictures, doing an enjoyable task (Houssart and Evens, 2011), using newspapers, toys or photographs (cf. Leeson, 2014).

Group interviewing can be useful with children, as well as being economical on researcher time, and it encourages interaction between the group rather than simply a response to an adult's question. Group interviews of children might also be less intimidating for them than individual interviews (Greig and Taylor, 1999, p. 132). Eder and Fingerson (2003, p. 34) suggest that a power and status dynamic is heavily implicated in interviewing children; they have little in comparison to the adult. Indeed, Thorne (1994) uses the term 'kids' rather than 'children', as the former is the term used by the children themselves, whereas 'children', she argues, is a term used exclusively by adults, denoting subordinacy (cf. Eder and Fingerson, 2003, p. 34). Mayall (1999) suggests regarding children as a 'minority group', in that they lack power and control over their own lives. If this is the case, then it is important to take steps to ensure that children are given a voice and an interview setting in which they feel comfortable (cf. Maguire, 2005). Group interviewing is such a setting, taking place in as close to a natural surrounding as possible (Greig and Taylor, 1999, p. 131); indeed Eder and Fingerson (2003, p. 45) report the successful use of a high-status child as the interviewer with a group of children.

Group interviewing with children enables them to reach a consensus or, indeed, to challenge each other and participate in a way that may not happen in a one-to-one, adult–child interview, using language that the children themselves use (Houssart and Evens, 2011, p. 65). For example, Lewis (1992) found that ten-year-olds' understanding of severe learning difficulties was enhanced in group interview situations, the children challenging and extending each other's ideas and introducing new ideas into the discussion. Further, interviewing a group of children together can equalize more the power differentials between interviewer and children (Houssart and Evens, 2011).

Having the interview as part of a routine, everyday activity can also help to make it less unnatural, as can making the interview more like a game (e.g. by using props such as toys and pictures). For example, it could be part of a 'show and tell' or 'circle time' session, or part of group discussion time. The issue here is to try to make the interview as informal as possible. Of course, sometimes it may be more useful to formalize the interview, so that children have a sense of how important the situation is, and they can respond to this positively. It can be respectful to have an informal or, indeed, a formal interview; the former maybe for younger children and the latter for older children (cf. Morrison, 2013a).

Whilst group interviews may be useful with many children, individual interviews with children are also valuable. For example, Eder and Fingerson (2003, pp. 43–4) report the value of individual interviews with adolescents, particularly about sensitive matters, for example, relationships, family, body issues, sexuality, love. Indeed they report examples where individual interviews yielded different results from group interviews with the same people about the same topics, and where the individuals valued greatly the opportunity for a one-to-one conversation.

Interviews with children should try to employ open-ended questions, to avoid a single-answer type of

response (Greig and Taylor, 1999; Wright and Powell, 2006; Powell, 2007), as answers to open-ended questions are usually more accurate than answers to closed questions (Wright and Powell, 2006, p. 317), being respondent-driven and respondent-focused, and they can take greater account of children with limited linguistic or cognitive abilities. Closed questions can lead to response bias in that children may provide answers without thinking (p. 317). Waterman *et al*. (2001) report that children gave clear answers to 'yes/no' closed questions even when such question types were deliberately given in respect of unanswerable questions (i.e. where insufficient information had been given for the question to be answered), in other words the format of the question artificially skewed the response. Clearly, however, specific questions may be needed to elicit specific (e.g. factual) details (Wright and Powell, 2006, p. 320).

Another strategy for interviewing children is to use a projection technique. Here, instead of asking direct questions, the interviewer can show a picture or set of pictures, and then ask the children for their responses to it/them (cf. Greig and Taylor, 1999, pp. 132–3; Dalli and Stephenson, 2010; Hurworth, 2012; Leeson, 2014). For example, a child may first comment on the people's colour in the pictures, followed by their gender, suggesting that colour may be more important in their mind than their gender. This avoids a direct question and may reduce the possibility of a biased answer – where the respondent may be looking for cues as to how to respond. Other projection techniques include the use of dolls or puppets, vignettes, drawings by the interviewees, photographs of a particular scene which the respondents have to comment upon (e.g. what is happening? What should be done here?) (cf. Hurworth, 2012), and the 'guess who' technique (i.e. which people might fit a particular description) (Wragg, 2002, p. 157; see also Dalli and Stephenson, 2010; Hurworth, 2012).

Simons (1982), Lewis (1992), Bailey (1994, pp. 447–9), Breakwell (2000, pp. 245–6), Breakwell *et al*. (2006, pp. 245–6), Brenner (2006), Danby *et al*. (2011), Hurworth (2012) and Leeson (2014) chart some challenges in interviewing children, for example, how to:

- overcome children being easily distracted (e.g. some interviewers provide toys or pictures, or children may be fascinated by something as simple as the researcher's pen, or there may be a passing vehicle outside, and these distract the children);
- avoid the researcher being seen as an authority figure (e.g. a teacher, a parent or an adult in a powerful position);
- understand what children mean and what they say (particularly with very young children);
- gather a lot of information in a short time, children's attention span being limited;
- have children reveal what they really think and feel rather than what they think the researcher wants to hear;
- avoid the interview being seen by the child as a test;
- keep the interview relevant;
- overcome young children's unwillingness to contradict an adult or assert themselves, or, in the case of adolescents, deliberately being oppositional in their views;
- interview inarticulate, hesitant and nervous children;
- get the children's teacher away from the children;
- respond to the child who says something then immediately wishes she hadn't said it;
- elicit genuine responses from children rather than simply responses to the interview situation;
- get beyond the institutional, headteacher's or 'expected' response;
- avoid receiving a socially desirable response;
- ensure that the child is giving a true opinion;
- keep children to the point;
- avoid children being too extreme or destructive of each other's views;
- pitch language at the appropriate level;
- overcome the children taking a question too literally (particularly young children), hence avoid metaphors, similes or analogies;
- enable the children to see a situation through other people's eyes;
- avoid the interview being an arduous bore;
- overcome children's poor memories;
- avoid children being too focused on particular features or situations;
- avoid the situation where the child will say 'yes' to anything addressed (an 'acquiescence bias'), for example, by avoiding 'yes/no' questions in favour of open-ended questions;
- overcome the situation of the child saying anything in order to please, or rather than feel they do not have 'the answer';
- overcome the proclivity of some children to say that they 'don't know' (for a variety of reasons, e.g. they are not interested, they genuinely don't know, they don't understand the question, they think that the interviewer might expect them not to know, they are unwilling to disclose what they do know, they are too shy to speak, they cannot explain themselves very well), or simply to shrug their shoulders and remain silent;

- overcome the problem that some children dominate the conversation in a group interview;
- avoid the problem of children feeling very exposed in front of their friends in a group interview;
- avoid children feeling uncomfortable or threatened (addressed, perhaps, by placing children with their friends);
- avoid children telling lies.

Clearly these problems are not exclusive to children; they apply equally well to adult group interviews. Group interviews require skilful chairing and attention to the physical layout of the room so that everyone can see everyone else and has personal space (which varies in different cultures). Group size is also an issue; too few and it can put pressure on individuals, too large and the group fragments and loses focus. Lewis (1992) indicates that a group of around six or seven is an optimum size, though it can be smaller for younger children. The duration of an interview may not be for longer than around fifteen minutes, and it is important to ensure that distractions are kept to a minimum. Simple language to the point and without ambiguity (e.g. avoiding metaphors) is also important. It is crucial to keep in mind that an interview is a social encounter, and children may be very sensitive to the social dynamics and social context of the interview (Morison *et al*., 2000), and not only its cognitive element (Maguire (2005, p. 4) suggests that 'children have good social radar').

Children will be sensitive to the gender and ethnicity of the interviewer, in fact to many features of the interviewer ('interviewer effects'; Denscombe, 2014, p. 191); the very fact that the interviewer is an adult will affect the interview (Morison *et al*., 2000, p. 113), as power inequalities inhere in adult–child relationships (Solberg, 2014). For further information, we refer the reader to Wilson and Powell (2001) and Mukerji and Albon (2010).

25.8 Interviewing minority and marginalized people

Not all the methods of interviewing set out so far will apply to interviewing marginalized people, i.e. those who are 'on the edge' of society (Barron, 1999), for example, economically, socially or politically, or who are 'invisible': stigmatized groups, the unemployed, the elderly, refugees, asylum seekers, travellers, those with special needs, those with a low status in society, those with limited linguistic, cognitive or intellectual abilities, those whose first language is a minority language, the disabled, the chronically ill, children with cerebral palsy, victims of crime, the oppressed, the subordinate, and so on. Parker and Lynn (2002, p. 13) argue that much educational research has ignored marginalized groups by not addressing their concerns or including them as areas of research, or it regards them as minorities who do not merit research, or, if research is conducted with/on them, it uses culturally inappropriate methods of investigation (p. 13). Similarly, Kelly (2007, p. 22) argues that researchers can no longer 'exclude learning disabled children' from research on the grounds that they pose challenges to conventional research methods.

In interviewing marginalized groups, the interviewer will need to consider greater use of informal, open-ended interviews (which follow the train of thought and response of the respondent and which use age-appropriate and context-appropriate language) rather than highly structured interviews (Swain *et al*., 1998, p. 26). The authors recommend the use of narrative, qualitative and in-depth interviews (discussed later), enabling self-disclosure (both by the interviewer and the interviewee) (Swain *et al*., 1998, p. 26), wherein participants 'tell their stories' in their own words (Barron, 1999, p. 38) and recount their subjective experiences and feelings. This gives them a 'voice', where otherwise they would either not be heard or listened to (see also Swain *et al*., 1998; Leeson, 2014; Solberg, 2014). This accords with the emancipatory potential or intent of research that was set out as a key feature of critical educational research in Chapter 3 (see also Barron, 1999, pp. 40, 44–6). Barron suggests that it is important for the interviewee to feel safe, secure, supported, close to the interviewer, and to know that he/she has the undivided attention of the interviewer (1999, p. 41) and a non-judgmental and non-evaluative stance by the interviewer, with built-in opportunities for respondent validation and clearance (interviewees may wish, upon reflection, to withdraw comments initially made at interview).

The researcher must take care not to exploit what are likely to be (perceived) asymmetries of power in the interview (where the researcher may be regarded as having more power than the respondent) (Swain *et al*., 1998, p. 26). Indeed Swain *et al*. (1998, p. 25) remind researchers that the interviews and research on marginalized groups should bring benefit to them, for example, they do not continue to be exploited or marginalized: the issue of reciprocity.

An interview is a communicative encounter, and, for some marginalized groups (e.g. the physically disabled or those with communication difficulties), this is precisely the challenge to be faced by researchers: how to communicate with those who cannot communicate

easily or at all (e.g. those who cannot speak, elective mutes, the deaf, children with degrees of autism, children with Down's syndrome or attention deficit disorder). Here Kelly (2007, pp. 25–6) notes the use of communication cards, pictorial cards (e.g. which indicate feelings), drawing frames, picture books, toys, puppets, photographs of familiar people or places, respecting and working with – and in – the language used by the participant and keeping within their frame of reference, considering the greater use of 'yes/no' questions than open questions (e.g. for students who cannot speak but who can point). She also advocates the use of projection techniques (p. 28) such as 'three wishes', asking participants to draw a picture to represent the matter in hand and the use of 'feeling cards' (cards with pictures of feelings).

Kelly (2007, p. 24) comments that gaining access to marginalized groups may be difficult, and that in the case of those with disabilities, it is likely to be necessary to gain access through gatekeepers, for example, parents, social workers, health team members, carers and suchlike, and indeed to have them present during the interview or to speak on their behalf (e.g. to protect the respondents' rights directly or to act as proxies/advocates). This is important, as Kelly (p. 23) reports the dangers of 'suggestibility' of participants in interviews, which leads to her comment that skilful and sensitive questioning are essential, drawing on participants' actual experiences and taking care not to project the researcher's own interests. Bourne-Day and Treweek (2008) also indicate that issues of privacy and identity may be significant in researching marginalized groups.

In conducting interviews, Kelly (2007) notes that it may be necessary to hold several short interviews rather than a single long interview, in order for the participants to be able to concentrate, retain their attention (p. 25) and not become tired. She also emphasizes the importance of waiting longer for an answer to be given, and to be alert to different ways in which children can communicate other than through speech (p. 28), for example, facial expression, writing, signing, gestures and non-verbal communication, symbols (see also Mitchell and Sloper, 2008, p. 11), drawing and game playing. There has to be a shift, Kelly avers, away from a deficit model in which children cannot speak, and towards a positive model of how they can communicate through other means.

Morgan (1996) suggests that interviewing marginalized groups can be addressed usefully through group interviewing and with focus groups, and it is to focus groups that we turn now.

25.9 Focus groups

Focus groups are a form of group interview in which reliance is placed on the interaction within the group, which discusses a topic supplied by the researcher (Morgan, 1988, p. 9), yielding a collective rather than an individual view. Here the participants interact with each other rather than with the interviewer, such that the views of the participants can emerge – the participants' rather than the researcher's agenda can predominate. It is from the *interaction* of the group that the data emerge, hence the dynamics of the groups are important (Denscombe, 2014, p. 189). Focus groups are contrived settings, bringing together a specifically chosen sector of the population, often previously unknown to each other (Hydén and Bülow, 2003), to discuss a particular given theme or topic, where the interaction with the group leads to data and outcomes (Smithson, 2000; Hydén and Bülow, 2003). Typically a moderator/facilitator is present to lead the discussion, steer the group as necessary and keep them to the focus of the discussion. The 'contrived' nature of focus groups is both their strength and their weakness: they are unnatural settings yet they are structured and very focused on a particular issue and, therefore, will yield insights that might not otherwise have been gained from a straightforward interview; they are economical on time, often producing a large amount of data in a short period, but they tend to produce less data than interviews with the same number of individuals on a one-to-one basis. Focus groups have the attraction of synergy, with several people stimulating discussion and working together on the issue in hand.

Focus groups (Morgan, 1988; Krueger, 1988; Bailey, 1994, pp. 192–3; Robson, 2002, pp. 284–5; Gibbs, 2012) are useful for:

- orientation to a particular field of focus;
- developing themes, topic and schedules flexibly for subsequent interviews and/or questionnaires;
- generating hypotheses that derive from the insights and data from the group;
- generating and evaluating data from different subgroups of a population;
- gathering qualitative data;
- generating data quickly and at low cost;
- gathering data on attitudes, values, perceptions, viewpoints and opinions;
- empowering participants to speak out, and in their own words;
- encouraging groups, rather than individuals, to voice opinions;
- encouraging non-literate participants;

- providing greater coverage of issues than would be possible in a survey;
- gathering feedback from previous studies.

Focus groups might be useful to triangulate with other forms of interviewing, questionnaire, observation etc. There are several issues to be addressed in running focus groups (Morgan, 1988, pp. 41–8; Gibbs, 2012), for example:

- deciding the number of focus groups for a single topic (one group may be insufficient, as the researcher will be unable to know whether the outcome is unique to the behaviour of the group);
- deciding the size of the group (too small and intra-group dynamics exert a disproportionate effect, too large and the group becomes unwieldy and hard to manage; it fragments). Morgan (1998, p. 43) suggests between four and twelve people per group, whilst Fowler (2009, p. 117) suggests between six and eight people;
- how to allow for people not 'turning up' on the day. Morgan (1998, p. 44) suggests the need to over-recruit by as much as 20 per cent;
- taking extreme care with the sampling, so that *every* participant is the bearer of the particular characteristic required or that the group has homogeneity of background in the required area, otherwise the discussion will lose focus or become unrepresentative; sampling is a major key to the success of focus groups;
- ensuring that participants have something to say and feel comfortable enough to say it;
- chairing the meeting so that a balance is struck between being too directive and veering off the point, i.e. keeping the meeting open-ended but to the point;
- having an effective and well-briefed facilitator to set the ground rules, clarify, probe, question, keep to the point, reflect back, summarize and manage group dynamics etc.;
- how to address confidentiality and informed consent (and indeed other ethical issues), disagreements, conflicts, strong feelings, silence, non-verbal communication and complex responses.

Newby (2010, pp. 350–1) and Gibbs (2012) indicate that focus groups should be clear on the agenda and the focus, take place in a setting that is conducive to discussion, have a skilled moderator (facilitator) who can prompt people to speak, promote thinking and reflection, and should have a record kept.

Unlike group interviewing with children, discussed earlier, focus groups operate more successfully if they are composed of relative strangers rather than friends, unless friendship is an important criterion for the focus (e.g. the group will discuss something that is usually only discussed among friends).

Focus groups are not without their drawbacks. For example, they tend not to yield numerical, quantifiable or generalizable data; the data may be difficult to analyse succinctly; they may yield less information than a survey; the group dynamics may lead to non-participation by some members and dominance by others (e.g. status differentials may operate); the number of topics to be covered may be limited; intra-group disagreement and even conflicts may arise; inarticulate members may be denied a voice; the data may lack overall reliability. Further, Smithson (2000) suggests that there is a problem of only one voice being heard, particularly if there is a dominant member of the group, and for the group dynamics to suppress dissenting voices or different views on controversial topics, even though the group moderator may try to prevent this. Focus groups require skilful facilitation and management by the researcher. Many of the points raised earlier about group interviewing apply to focus groups, and we refer readers to this.

25.10 Non-directive, focused, problem-centred and in-depth interviews

The non-directive interview

Originating from the psychiatric and therapeutic fields with which it is most readily associated, the non-directive interview is characterized as a situation in which the respondent is responsible for initiating and directing the course of the encounter and for the attitudes she expresses in it (in contrast to the structured or research interview, where the dominating role assumed by the interviewer results in differentials of power and commitment (Kitwood, 1977)). It has been shown to be a particularly valuable technique because it reaches the deeper attitudes and perceptions of the person being interviewed in such a way as to leave them free from interviewer bias. We examine here, if briefly, the characteristics of the therapeutic interview and then consider its usefulness as a research tool in the social and educational sciences.

The non-directive interview as it is currently understood grew out of the pioneering work of Freud and subsequent modifications to his approach by later analysts. His basic discovery was that if one can arrange a special set of conditions and have a patient talk about his or her difficulties in a certain way, behaviour changes of many kinds can be accomplished. The

technique developed was used to elicit highly personal data from patients in such a way as to increase their self-awareness and improve their skills in self-analysis. By these means they became better able to help themselves. As Madge (1965) observed, these techniques have greatly influenced interviewing techniques, especially those of a more penetrating and less quantitative kind.

The therapeutic interview has its most persuasive advocate in Carl Rogers, who testified to its efficacy. Basing his analysis on his own clinical studies, he identified a sequence of characteristic stages in the therapeutic process, beginning with the client's decision to seek help. He/she is met by a counsellor who is friendly and receptive, but not didactic. The next stage is signalled when the client begins to give vent to hostile, critical and destructive feelings, which the counsellor accepts, recognizes and clarifies. Subsequently, and invariably, these antagonistic impulses are used up and give way to the first expressions of positive feeling. The counsellor likewise accepts these until suddenly and spontaneously 'insight and self-understanding come bubbling through' (Rogers, 1942, p. 40). With insight comes the realization of possible courses of action and also the power to make decisions. It is in translating these into practical terms that the client frees himself/herself from dependence on the counsellor.

Rogers (1945) subsequently identified a number of qualities in the interviewer which he deemed essential: that she bases her work on attitudes of acceptance and permissiveness; that she respects the client's responsibility for his own situation; that she permits the client to explain his problem in his own way; and that she does nothing that would in any way arouse the client's defences.

What of the usefulness of the non-directive interview as a research technique in educational contexts? There are several features of the therapeutic interview which are peculiar to it and may well be inappropriate in other settings, for example: the interview is initiated by the respondent; his/her motivation is to obtain relief from a particular symptom; the interviewer is primarily a source of help, not a procurer of information; the interview is part of a therapeutic experience; the purpose of the interview is to change the behaviour and inner life of the person and its success is defined in these terms; and there is no restriction on topics discussed.

The focused interview

What appear as advantages in a therapeutic context may be decided limitations when the technique is used for research purposes, even though the interviewer may be sympathetic to the spirit of the non-directive interview. For example, the research interview is less concerned with therapy and 'curing' and having the interviewee control the interview to a great extent, and more concerned with obtaining data. One attempt to meet the need for the research application of the non-directive interview is the *focused interview* (Merton and Kendall, 1946; Flick, 2009). While seeking to follow closely the principle of non-direction, the method introduces rather more interviewer control in the kinds of questions used and seeks also to limit the discussion to certain parts of the respondent's experience.

The focused interview differs from other types of research interview in certain respects (Merton and Kendall, 1946):

- The persons interviewed are known to have been involved in a particular situation: they may, for example, have watched a film; or read a book or article; or have been a participant in a social situation.
- By means of the techniques of content analysis, elements in the situation which the researcher deems significant have previously been analysed by her. She has thus arrived at a set of hypotheses relating to the meaning and effects of the specified elements.
- Using her analysis as a basis, the investigator constructs an interview guide. This identifies the major areas of enquiry and the hypotheses which determine the relevant data to be obtained in the interview.
- The actual interview is focused on the subjective experiences of the people who have been exposed to the situation. Their responses enable the researcher both to test the validity of her hypotheses, and to ascertain unanticipated responses to the situation, thus giving rise to further hypotheses.

The distinctive feature of the focused interview is the prior analysis by the researcher of the situation in which subjects have been involved. The advantages of this procedure have been cogently explained by Merton and Kendall (1946):

> Foreknowledge of the situation obviously reduces the task confronting the investigator, since the interview need not be devoted to discovering the objective nature of the situation. Equipped in advance with a content analysis, the interviewer can readily distinguish the objective facts of the case from the subjective definitions of the situation. He thus becomes alert to the entire field of 'selective

> response'. When the interviewer, through his familiarity with the objective situation, is able to recognize symbolic or functional silences, 'distortions', avoidances, or blockings, he is the more prepared to explore their implications.
>
> (Merton and Kendall, 1946, p. 541)

In the quest for what Merton and Kendall term 'significant data', the interviewer must develop the ability to evaluate continuously the interview while it is in progress. To this end, they established a set of criteria by which productive and unproductive interview material can be distinguished (see also Flick, 2009). Briefly, these are:

- *non-direction*: interviewer guidance should be minimal;
- *specificity*: respondents' definitions of the situation should find full and specific expression;
- *range and scope*: the interview should maximize the range of evocative stimuli and responses reported by the subject;
- *depth and personal context*: the interview should bring out the affective and value-laden implications of the subjects' responses, to determine whether the experience has central or peripheral significance. It should elicit the relevant personal context, the idiosyncratic associations, beliefs and ideas.

The problem-centred interview

Witzel (2000) advocates the use of the *problem-centred interview* for gathering objective evidence on human behaviour and subjective views on social phenomena. He indicates three principles underpinning the problem-centred interview:

- a 'problem-centred orientation' towards socially relevant problems (p. 2);
- methodological flexibility (e.g. group interviews, individual interviews, the biographical interview, structured and less structured interviews) in the 'object-orientation', in order to address different kinds of problem (p. 3);
- a 'process orientation', i.e. attempting to reconstruct the actions and orientations of the participant (p. 3).

The problem-centred interview, Witzel avers, can use: (a) a structured, *short questionnaire* at interview in order to gather factual data about the participants (e.g. age, sex, occupation, education); (b) an *interview schedule* (guidelines) in order to structure the interview, with lead questions; (c) *recording equipment* to ensure accuracy of the account and to avoid the interviewer having to take notes (i.e. able to concentrate on the discussion); and (d) a *postscript* (pp. 3–4), written directly after the interview, to contain reflections, key points, observations and interpretations. Flick (2009), like Witzel, advocates the preparation of an interview guide in the problem-centred interview, consideration of how to manage 'conversational entry' (p. 163) prompting (general and specific: deep) and being prepared to raise ad hoc questions and to challenge the interviewee on contradictions and inconsistencies in statements made.

The in-depth interview

The in-depth interview, as its name suggests, is conducted to explore issues, personal biographies, what is meaningful to, or valued by, participants, what they know about a topic, what they have experienced, how they feel about particular issues, how they look at particular issues, their attitudes, opinions and emotions (cf. Newby, 2010, pp. 243–4; Mears, 2012). They tend to be semi-structured, to enable the course of the respondents' responses to dictate the direction of the interview, though the researcher also has an interview schedule to keep an interview on track, and may operate probes to inquire further into issues. They may feature in case studies, action research and, as the work of Ball (1990, 1994a, 1994b), Bowe *et al*. (1992) and Flick (2009) testifies, they may feature in interviewing powerful people and policy makers. They may also be useful in gathering data from marginalized or stigmatized groups in society (Newby, 2010, pp. 243–4). Given the intensive and extensive nature of these interviews, gaining access and permission may be difficult, not least as they may take time to conduct.

25.11 Telephone interviewing

We advise the reader to take this section in conjunction with Chapter 17 on telephone interviews in surveys. The use of telephone interviewing has long been recognized as an important method of data collection and is common practice in survey research. Arksey and Knight (1999, p. 79) note that telephone interviews do not feel like interviews, as both parties are deprived of several channels of communication and the establishment of a positive relationship (e.g. non-verbal). Similarly, Lechuga (2012) notes that telephone interviews are often used in tandem with face-to-face interviews, though in survey research they can be the principal means of data collection.

Dicker and Gilbert (1988), Nias (1991), Oppenheim (1992), Borg and Gall (1996), Shaughnessy *et al*. (2003), Shuy (2003), Lechuga (2012) and Kee and

Browning (2013) suggest several attractions to telephone interviewing:

- it is sometimes cheaper and quicker than face-to-face interviewing;
- it enables researchers to select respondents from a much more dispersed population than if they have to travel to meet the interviewees;
- travel costs are omitted;
- interviews can be conducted at a time to suit the interviewee, and can reduce interruptions;
- it is particularly useful for brief surveys;
- it can protect the privacy, anonymity and confidentiality of respondents, and this can improve the quality of responses, according them safety;
- it is useful for gaining rapid responses to a structured questionnaire;
- monitoring and quality control are undertaken more easily since interviews are undertaken and administered centrally, indeed there are greater guarantees that the researcher actually carries out the interview as required;
- interviewer effects are reduced;
- there is greater uniformity in the conduct of the interview and the standardization of questions;
- there is greater interviewer control of the interview;
- the results tend to be quantitative (e.g. with standardized interview questions), giving a degree of consistency/control to the interview;
- telephone interviews are quicker to administer than face-to-face interviews because respondents will only usually be prepared to speak on the telephone for, at most, ten to fifteen minutes;
- call-back costs are so slight as to enable frequent call-backs, enhancing reliability and contact;
- many groups, particularly of busy people, can be reached at times more convenient to them than if a visit were to be made;
- it can reach marginalized or minority groups;
- it can neutralize power differentials between interviewer and interviewee;
- it can increase disclosure by interviewees in comparison to face-to-face interviews, and can be used to collect sensitive data, as possible feelings of threat of face-to-face questions about awkward, embarrassing or difficult matters are absent;
- it is safer to undertake than, for example, having to visit dangerous neighbourhoods;
- it does not rely on the literacy of the respondent (as, for example, in questionnaires);
- it may put a little pressure on the respondent to respond, and it is usually the interviewer rather than the interviewee who terminates the call;
- response rate is higher than, for example, questionnaires.

Smartphones are useful in interviewing (Raento *et al*., 2009), as so many people carry them around and hence can be contacted easily, regardless of their location (though it relies on the interviewer knowing the smartphone number). Further, with increasing additional functionality, the smartphone offers a potentially powerful tool for researchers. Smartphones, Raento *et al*. aver (2009, p. 428), have the attraction of flexibility, with many uses and computer-like functions on a single smartphone, for example, video and image recording and cost-efficiency; they enable easy access and relatively unobtrusive data collection as data can be collected in real time or stored; and they enable high granularity of data to be gathered (p. 442). We refer the reader to the discussion of online interviews later in this chapter.

Telephone interviewing is not as cut-and-dried as the claims made for it, as there are several potential problems with it, for example (e.g. Lechuga, 2012):

- it is very easy for respondents simply to hang up on the caller;
- motivation to participate may be lower than for a personal interview;
- there is a chance of skewed sampling, as not all of the population have a telephone (perhaps the very people that the researcher wishes to target) or can hear (e.g. the old and second-language-speakers in addition to those with hearing difficulties);
- there is a lower response rate at weekends;
- the lack of visual, non-verbal and contextual cues and data may cause problems for both parties;
- the standardized format of telephone interviews may prevent thoughtful or deep answers from being provided;
- some people may have a deep dislike of telephones that sometimes extends to a phobia, and this inhibits their responses or willingness to participate;
- respondents may not disclose information because of uncertainty about actual (even though promised) confidentiality;
- respondents may come to snap judgements without the adequate or deeper reflection necessary for a full answer to serious issues;
- respondents may not wish to spend a long time on the telephone, so telephone interviews tend to be briefer than other forms of interview;
- concentration spans are shorter than in a face-to-face interview;
- the interviewer has to remain bright and focused, listen very carefully and respond, which is tiring;

- questions tend to be closed, fixed and simple and there is a limit on the complexity of the questions that can be put;
- the quality of the data may be inferior than face-to-face interview data because of shortage of time, lack of visual and non-verbal cues and limited emotional feedback;
- the limits placed on emotional feedback from the interviewer may prevent the interviewee from disclosing sensitive information;
- response categories must be very simple or else respondents will forget what they are;
- many respondents may be 'ex-directory' or numbers will not be available (e.g. in telephone directories), particularly for cellphones;
- respondents may withhold important information or tell lies, as the non-verbal behaviour that frequently accompanies this is not witnessed by the interviewer;
- it is often more difficult for complete strangers to communicate by telephone than face-to-face, particularly as non-verbal cues are absent;
- respondents are naturally suspicious (e.g. of the caller trying to sell a product);
- one telephone might be shared by several people;
- some telephone service providers screen out callers;
- some respondents feel that telephone interviews afford less opportunity for interviewees to question or rebut the points made by the interviewer;
- there may be distractions for the respondent (e.g. a television may be switched on in the background, children may be crying, others may be present);
- responses are difficult to write down or record during the interview.

Harvey (1988), Oppenheim (1992), Miller (1995) and Lechuga (2012) consider that: (a) telephone interviews need careful arrangements for timing and duration (as they are typically shorter and quicker than face-to-face interviews) – a preliminary call may be necessary to fix a time for a longer call to be made; (b) the interviewer will need to have ready careful prompts and probes, including more than usual closed questions and less complex questions, in case the respondent 'dries up' on the telephone; (c) both interviewer and interviewee need to be prepared in advance of the interview if its potential is to be realized; and (d) sampling requires careful consideration, using, for example, random sampling or some form of stratified sample. In general, however, many of the issues from 'standard' forms of interviewing apply equally well to telephone interviewing. Further, Houtkoop-Steenstra and van den Bergh (2000) report that an agenda-based introduction (in which interviewers formulate their own introductions based on a small number of keywords) is more effective in securing higher response rates than standardized, scripted introductions.

Kee and Browning (2013, pp. 12–16) note that interviewers can use different ways to persuade interviewees to take part in a telephone interview, for example: persuasion by association (at the end of one interview the interviewer asks the interviewee to recommend other people for interview); persuasion by specificity (being specific on what the interview will cover); persuasion by trust: the interviewer assures the interviewee that the data will not be abused or misused or cause problems for the interviewee (i.e. non-maleficence); persuasion by kindness/goodwill (interviewees agree to be kind and helpful); persuasion by opportunity (e.g. to take part in an important piece of research); persuasion by personalization (a personal invitation); persuasion by flexibility (the interviewer can call at the interviewee's convenience); and persuasion by sequence (an email is followed by the telephone call).

Face-to-face interviews may be more suitable than telephone interviews (Weisberg *et al*., 1996, p. 122; Shuy, 2003, pp. 179–82; Kee and Browning, 2013) where: (a) the interviewer wishes to address complex issues or sensitive questions (though these authors also note that telephone interviewing may be particularly useful for exploring sensitive issues because of the lack of a face-to-face presence); (b) a natural context might yield greater accuracy; (c) deeper and self-generated answers are sought, i.e. where the question does not frame the answer too strongly; (d) issues requiring probing, deep reflection and, thereby, a longer time is sought; (e) greater equality of power between interviewer and respondent is sought; (f) older, second-language-speakers and hearing-impaired respondents are being interviewed; (g) marginalized respondents are being sought.

In conducting the telephone interview, the interviewer should strive to put the participant at ease, introduce himself/herself and to clarify any uncertainties (Kee and Browning, 2013), obtain consent and build trust. It may also be necessary for the interviewer to clarify ('customize') pre-scripted questions (p. 20). Further, in a telephone interview, as in face-to-face interviews, the interviewer's personality and skill are important factors in success, as both parties – interviewer and interviewee – are striving to define the attitudes, nature and personality of the other (Lechuga, 2012).

It is not uncommon for telephone interviewing to be outsourced; this can be an advantage or a disadvantage. On the one hand, it takes pressure off the researcher, not only because of the time involved but also because a fifteen-minute telephone interview might be more

exhausting than a fifteen-minute face-to-face interview, there being more social and non-verbal cues in face-to-face interaction. On the other hand, in outsourced telephone interviews care has to be taken on standardization of the conduct of the interview, the content of questions, the entry of responses, the personality and demeanour of the interviewer, and indeed to check that the interviews have been done and responses not simply fabricated.

In conducting telephone interviews it is important to consider several issues:

- Will the people have the information that you require? Who will you need to speak to on the telephone? If the person answering the call is not the most suitable person then you need to talk to somebody else.
- There is a need to pilot the interview schedule and to prepare and train the telephonists, to discover the difficult/sensitive/annoying/personal questions, the questions over which the respondents hesitate and answer very easily, the questions that will need prompts and explanations.
- Keep to the same, simple response categories for several questions, so that the respondents become used to these and keep in the same mindset for responding.
- Keep personal details, if any, until the end of the interview, in order to reduce any sense of threat.
- Keep to no more than, at the most, thirty questions, and take no longer than, at the most, fifteen minutes, and preferably ten minutes.
- Be clear with the respondents at the start of the interview that they have the time to answer and that they have the information sought (i.e. that they are suitable respondents). If they are not the most suitable respondents, then ask if there is someone present who can answer the questions, or try to arrange call-back times when the most suitable person can be reached. Ask to speak to the most suitable person.
- Keep the terminology simple and to the point, avoiding jargon and confusion.
- You should be able to tell the gender of the respondent by his or her voice, i.e. there may be no need to ask a particular question.
- Keep the response categories very simple and use them consistently (e.g. a mark out of ten, 'strongly agree' to 'strongly disagree', a 1–5 scale etc.).
- Rather than asking direct personal questions (unless you are confident of an answer), for example, about age or income, ask about categories such as which age group or income group they fall into (and give the age groups or income brackets).

25.12 Online interviewing

Online interviewing, interviewing in the virtual world, takes several forms, for example:

- text-based only (chat rooms, social networking sites, discussion forums, blogs, email, SMS);
- a combination of text and visuals (e.g. social networking sites, discussion boards, instant messaging);
- audio only (e.g. WeChat, WhatsApp, conferencing);
- audio and visual interviews (e.g. Skype, net meetings and conferences);

Some of these are synchronous – real-time – messaging (e.g. chat rooms and services, SMS, instant messaging, Skype, online meetings); others are asynchronous (e.g. email, discussion boards, blogs, WeChat, WhatsApp). Some online interviews take place through private contact (e.g. emails), others through public sites (e.g. blogs), and researchers need to consider the issue of privacy.

What they have in common is that they all involve versions of online interviewing. Different kinds have different advantages and disadvantages; we explore these below and we also advise readers to review Chapter 18. However, all of these presume access to the Internet, smartphone or relevant equipment/hardware, and the ability to download and use relevant software, and these latter might be problematic, even for more experienced and competent IT users. Researchers are advised to avoid uncommonly used, difficult-to-use software and software which requires complicated registration, and to opt for commonly used software.

A great attraction of these methods is that time and location present few or no challenges, as there is great flexibility in contact times, and both parties do not necessarily have to be present at the same time for some of these methods. Contact can be made with complete strangers, anonymity can be preserved in some of these methods, and, for non-visual methods, the absence of a face might encourage more sensitive areas to be addressed (as with the comments earlier about telephone interviewing). Further, the potential differentials of power between interviewer and interviewee can be reduced (James, 2015, 2016).

In synchronous, text-based interviews, the speed of the interview can depend on speed of connection, typing and reading, whilst in asynchronous methods the interviewers have the flexibility and convenience of different contact times and response times, the opportunity to think about, and reflect on, questions and previous answers, and to consider carefully their answers.

Some text-based methods can be both synchronous and asynchronous, depending on the wishes and availability of the users (e.g. email, chat rooms, SMS).

On the other hand, the interviewer has no control over the circumstances of the interviewee, who may be distracted, indeed who may not be the person intended – an identity problem – and who may not have the level of motivation or interest to participate (and it is often easier to decline an online interview than a face-to-face interview). Some interviewees may not wish to read/write/type in text-based interviews, or be less competent in doing so, and text-based interviews deprive both parties of the benefits of visual clues and non-verbal communication (as with telephone interviewing). Additionally, research using online interviews, particularly if they are text-based only, must avoid 'flaming' (overreacting with aggressive, insulting, attacking, derogatory or hostile remarks).

The considerations for interviews already set out in this chapter and Chapters 12, 17 and 18 apply to online interviews, for example:

- sampling and representativeness;
- whether to have individual or group interviews;
- the need to have interview questions prepared;
- the need to plan the content, structure, sequence and type of questions;
- the need to plan and consider probes and follow-ups;
- the need to build relationships, rapport and trust;
- how to overcome lack of visual/non-verbal cues;
- the need to observe research and interview ethics;
- the need to avoid risks of bias and socially desirable answers;
- the need to choose language, genre and register very carefully.

James and Busher (2007) and James (2007, 2015, 2016) writing about emails, and Hinchcliffe and Gavin (2008), Kazmer and Xie (2008) and Pearce *et al*. (2014) writing about instant messaging, argue for the power of email/messaging interviewing as a qualitative method in educational research, as it enables the researcher to contact hard-to-reach groups or individuals, for example, by virtue of practical constraints such as time and availability of both parties to meet face-to-face, location and travelling, geographical dispersion, disability and language or communication (James, 2007, 2015, 2016; see also Bampton and Cowton, 2002).

Whilst email typically has a time delay (which can be very short indeed: a matter of a few seconds), instant messaging is, as its name suggests, instant, i.e. synchronous. Instant messaging can also be aural. Pearce *et al*. (2014) suggest that instant messaging (which now includes visual functions) trumps email for research purposes even though it requires prior arrangements to be made for the interview to be synchronous. However, James and Busher (2007, p. 405) argue that email interviews, by virtue of their ability to be non-synchronous, can generate fuller, richer, more reflective, thoughtful and longer answers than telephone interviewing, and James (2016) notes that emails afford the researcher the opportunity to probe the interviewee for further or richer information.

Email interviews also reduce transcription time as the email is already transcribed, and the interviewee, therefore, has the opportunity to check what data are being given, thereby overcoming the possibility of respondents in a face-to-face interview saying something they later wish to withdraw (Bampton and Cowton, 2002, p. 4). Whether or not the absence of face-to-face contact, the visibility of the participants and the absence of non-verbal cues increases or reduces reliability is a moot point (James, 2007, p. 969). Similarly, the researcher will need to make continual efforts to ensure that the respondent:

- keeps to the point;
- fully understands the nature, focus and purpose of the interview;
- knows the number of questions that will be asked (particularly if there are several email exchanges);
- knows that they should not delete previous emails that are part of the interview;
- knows the time frame in which to reply to an email (cf. James and Busher, 2006, pp. 407–9).

Email interviews can be conducted synchronously, in real time, or asynchronously (James, 2007, 2015, 2016). The latter can afford the interviewee some time to consider his/her responses (Bampton and Cowton, 2002, p. 3), and the 'silences' (James, 2015, 2016) between question, answer and the subsequent question/follow-up can be useful pauses to think, even when such silences span week or months. Email interviewing can 'democratise narrative exchanges' – as equals – between the interviewer and the interviewee (James, 2007, p. 970) (though James and Busher (2007, p. 416) contest this latter point). However, Bampton and Cowton (2002, p. 5) caution against bombarding the interviewee with too many questions in a single interview; rather, they suggest, the questions could be spaced over more than one email. Further, they indicate the need to signal to the respondent when the email interview is nearing its close.

Online interviewing is susceptible to technological problems (e.g. unstable connectivity, slow connections (particularly in video-conferencing), mailbox being full), and these must be explored before the online interview is conducted.

Skype, as an instant, face-to-face audio-visual method, has all the benefits and drawbacks of the face-to-face interview, and it can also include instantaneous text-based messaging. Both the researcher and interviewee have to agree the time for the interview, and each party might not know if there are any other parties present in the location.

Researchers will need to consider whether it is preferable to use text-based-only methods for online interviewing, for example, with the advantages of 'opaqueness', anonymity and confidentiality that might be highly suited to sensitive topics and provide the opportunity for reflection and review (Pearce *et al*., 2014) or whether to include visual methods which have the attractions of seeing body language and facial response. In both cases there are risks of bias. This is akin to the argument for and against face-to-face versus telephone interviewing, played out this time on a virtual plane.

We sum up the different forms of administering interviews in Figure 25.1.

25.13 Ethical issues in interviewing

Interviews have an ethical dimension; they concern interpersonal interaction and produce information about the human condition. Though one can identify several main areas of ethical issues here – informed consent, beneficence, do no harm, confidentiality and the consequences of the interviews – these need to be 'unpacked' a little, as each is problematic (Kvale, 1996, pp. 111–20). For instance, who should give the informed consent (e.g. participants, their superiors), and for whom and what? How much information should be given, and to whom? What is legitimate private and public knowledge? How might the research help or harm the interviewees? Does the interviewer have a duty to point out the possible harmful consequences of the research data or will this illegitimately steer the interview? How will the interviewers and interviewees both benefit from/gain something from the interview (cf. Mills, 2001)?

It is difficult to lay down hard and fast ethical rules, as ethical matters are situated, contestable and context-based. Nevertheless it is possible to raise some ethical questions to which answers need to be given before the interviews commence:

- Has the informed consent of the interviewees been gained?
- Has this been obtained in writing or orally?
- How much information should be given in advance of the study?
- How can adequate information be provided if the study is exploratory?
- Have the possible consequences of the research been made clear to the participants?
- Has care been taken to prevent any harmful effects of the research to the participants (and to others)?
- To what extent do any potential benefits outweigh the potential harm done by the research, and how justifiable is this for conducting the research?
- How will the research benefit the participants?
- Who will benefit from the research?
- How much reciprocity is there between what participants give to and receive from the research?
- Have confidentiality, anonymity, non-identifiability and non-traceability been guaranteed? Should participants' identities be disguised?
- How do Data Protection Acts and laws operate in interview situations?
- Who will have access to the data?
- What has been done to ensure that the interview is conducted in an appropriate, non-stressful, non-threatening manner?
- How will the data and transcriptions be verified, and by whom?

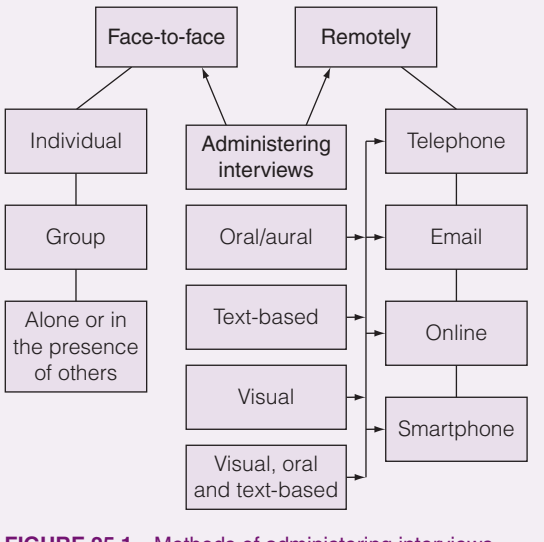

FIGURE 25.1 Methods of administering interviews

- Who will see the results of the research? Will some parts be withheld? Who owns the data? At what stage does ownership of the data pass from interviewees to interviewers? Are there rights of veto for what appears? To whom should sensitive data be made available (e.g. should interview data on child abuse or drug-taking be made available with or without consent of parents and the police)?
- How far should the researcher's own agenda and views predominate? What if the researcher makes a different interpretation from the interviewee? Should the interviewees be told, even if they have not asked for these interpretations?

These issues, by no means an exhaustive list, are not exclusive to the research interview, though they are applicable here. For further reading on ethical issues, we refer readers to Chapters 7 and 8. The personal safety of interviewers must also be addressed: it may be important, for example, for the interviewer to be accompanied, to leave details of where he or she is going, to take a friend, to show identification, to take a mobile phone, to reconnoitre the neighbourhood, to learn how to behave with fierce dogs or people, to use the most suitable transport. It is perhaps a sad indictment on society that these considerations have to be addressed, but they do.

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Observation

CHAPTER 26

Observation takes many forms. This chapter addresses several different kinds of observation and how to plan, conduct and report them, and we address:

- structured observation
- the need to practise structured observation
- analysing data from structured observations
- critical incidents
- naturalistic and participant observation
- data analysis for unstructured observations
- natural and artificial settings for observation
- video observations
- timing and causality with observational data
- ethical considerations
- reliability and validity in observations

This chapter can also be read with Chapters 15 and 31.

26.1 Introduction

Observation is more than just looking. It is looking (often systematically) and noting systematically people, events, behaviours, settings, artefacts, routines, and so on (Simpson and Tuson, 2003, p. 2; Marshall and Rossman, 2016). It can be systematic and structured or take some less structured form such as participant observation (Denscombe, 2014, p. 205).

The distinctive feature of observation as a research process is that it offers an investigator the opportunity to gather first-hand, 'live' data *in situ* from naturally occurring social situations rather than, for example, reported data (Wellington, 2015, p. 247) and second-hand accounts (Creswell, 2012, p. 213). The use of observation as a principal mode of research has the potential to yield more valid or authentic data than would otherwise be the case with mediated or inferential methods. This is observation's unique strength. Observation is strong on face validity; it can provide rich contextual information, enable first-hand data to be collected, reveal mundane routines and activities, and can offer an opportunity for documenting those aspects of lifeworlds that are verbal, non-verbal and physical (Clark *et al*., 2009).

There are other attractions to observation: as Robson says (2002, p. 310), what people do may differ from what they say they do, and observation provides a reality check. Observation also enables a researcher to look afresh at everyday behaviour that otherwise might be taken for granted, expected or go unnoticed (Cooper and Schindler, 2001, p. 374), and the approach, with its carefully prepared recording schedules, avoids problems such as selective or faulty memory caused when there is a time gap between the act of observation and the recording of the event. On a procedural point, some participants may prefer the presence of an observer to an intrusive, time-consuming interview or questionnaire.

Observation can be of *facts*, for example: the number of books in a classroom; the number of students who visit the school library in a given period. It can also focus on *events* as they happen in a classroom, for example: the amount of teacher and student talk; the amount of off-task conversation. It can focus on *behaviours* or qualities, for example: the friendliness of the teacher; the extent of cooperative behaviour among students.

There is a continuum from the observation of uncontestable facts to the researcher's interpretation and judgement of situations, which are then recorded as observations. What counts as evidence immediately becomes cloudy in observation, because what we observe depends on when, where and for how long we look, how many observers there are and how we look. Indeed the post-positivists argue that there is no neutral, theory-free observation and that our observations are driven by our theories (conscious or not, implicit or explicit), experiences, prior concepts, preferences, values, beliefs, purposes, assumptions, foci, perceptions and intentions (Denscombe, 2014, p. 206; Pring, 2015, p. 48; Wellington, 2015, p. 248). Observations are theory-laden and experience-laden (Barrett and Mills, 2009). Whilst reflexivity tries to address this, it only exposes rather than solves the problem.

What we observe also depends on what is taken to be evidence of, or a proxy for, an underlying, latent construct. What counts as acceptable evidence requires an operational definition that is valid and reliable.

Observers need to decide 'what is the observation evidence', for example: is the degree of wear and tear on a book in the school library an indication of its popularity, or carelessness by its readers, or of destructive behaviour by students? It is dangerous to infer cause from effect, intention from observation, stimulus from response.

Observational data are sensitive to context and require strong ecological validity (Moyles, 2002) to understand the context of programmes, to be open-ended and inductive, to see things that might otherwise be unconsciously missed, to discover things that participants might not freely talk about in interview situations, to move beyond perception-based data (e.g. opinions in interviews) and to access personal knowledge. Because observed incidents are less predictable there is freshness in this form of data collection that is often denied in other forms, for example, a questionnaire or a test.

Observation can enable the researcher to access interactions in a social context and to yield systematic records of these in many forms and contexts, to complement other kinds of data (Simpson and Tuson, 2003, p. 17). Observations (Morrison, 1993, p. 80) enable the researcher to gather data on:

- the *physical setting* (e.g. the physical environment and its organization);
- the *human setting* (e.g. the organization of people, the characteristics and make-up of the groups or individuals being observed, for instance, gender, class);
- the *interactional setting* (e.g. interactions that are taking place, formal, informal, planned, unplanned, verbal, non-verbal etc.);
- the *programme setting* (e.g. resources and their organization, pedagogic styles, curricula and their organization).

Additionally, observational data may be useful for recording non-verbal behaviour, behaviour in natural or contrived settings, and longitudinal analysis (Bailey, 1994, p. 244). On the other hand, the lack of control in observing in natural settings may render observation less useful, coupled with difficulties in measurement, problems of small samples, difficulties of gaining access and negotiating entry, and difficulties in maintaining anonymity (pp. 245–6). Observation can be a powerful research tool, but it is not without its difficulties, and this chapter identifies and addresses these.

Patton (1990, p. 202) suggests that observational data should enable the researcher to enter and understand the situation that is being described. The kind of observations available to the researcher lies on a continuum from unstructured to structured, responsive to pre-ordinate. A *highly structured* observation will know in advance what it is looking for (i.e. pre-ordinate observation) and will have its observation categories worked out in advance (e.g. Heath *et al*., 2010). A *semi-structured observation* will have an agenda of issues but will gather data to illuminate these issues in a far less predetermined or systematic manner (e.g. responsive to what is observed). An *unstructured observation* will be far less clear on what it is looking for and will therefore have to go into a situation and observe what is taking place before deciding on its significance for the research. In a nutshell, a structured observation will already have its hypotheses decided in advance and will use the observational data to confirm or refute these hypotheses. On the other hand, a semi-structured and, more particularly, an unstructured observation will be hypothesis-generating rather than hypothesis-testing. Semi-structured and unstructured observations will review observational data before suggesting an explanation for the phenomena being observed.

There is a well-known classification of researcher roles in observation, which lie on a continuum:

- the *complete participant*: a member of the group who conceals her/his role as an observer, whose knowledge of the group/situation may be intimate and who may gain 'insider knowledge', but who may be viewed with suspicion or resentment by the other members when his/her true role comes to light and who may lack the necessary objectivity to observe reliably;
- the *participant-as-observer*: a member of the group who reveals her/his role as an observer, whose knowledge of the group/situation may be intimate and who may gain 'insider knowledge', but who may lack the necessary objectivity to observe reliably and with whom confidences and confidential data may not be shared or given respectively;
- the *observer-as-participant*: not a member of the group, but who may participate a little or peripherally in the group's activities, and whose role as researcher is clear and overt, as unobtrusive as possible, without those being observed always knowing who is the researcher, and whose access to information and people may be incomplete or restricted;
- the *complete observer*: who only observes (overt or covert) and is detached from the group, for example, an outside observer, or where the observer is not covert but whose presence is unnoticed by the group, for example, an observer in a crowded location.

The move is from complete participation to complete detachment. The mid-points of this continuum strive to balance involvement with detachment, closeness with distance, familiarity with strangeness. The role of the complete observer is typified in the two-way mirror, the video recording and the photograph, whilst complete participation involves researchers taking on membership roles (overt or covert).

Traditionally, observation has been characterized as non-interventionist (Adler and Adler, 1994, p. 378), where researchers do not seek to manipulate the situation or subjects, they do not pose questions for the subjects, nor do they deliberately create 'new provocations' (p. 378). Quantitative research tends to have a small field of focus, fragmenting the observed into minute chunks that can subsequently be aggregated into a variable. Qualitative research, on the other hand, draws the researcher into the phenomenological complexity of participants' worlds; here situations unfold, and connections, causes and correlations can be observed as they occur over time. The qualitative researcher aims to catch the dynamic nature of events, to see intentionality and maybe to seek trends and patterns over time.

If we know in advance what we wish to observe, if the observation is concerned to chart the *incidence*, *presence* and *frequency* of elements and wishes to compare one situation with another, then it may be efficient in terms of time to go into a situation with a prepared observation schedule. If, on the other hand, we want to go into a situation and let the elements of the situation speak for themselves, perhaps with no concern for how one situation compares with another, then it may be more appropriate to opt for a less structured observation.

The former, structured observation, can take much time to prepare but the data analysis is fairly rapid, the categories having already been established, whilst the latter, less structured approach, is quicker to prepare but the data take much longer to analyse. The former approach operates within the agenda of the researcher and hence might neglect aspects of settings if they do not appear on the observation schedule, i.e. it looks selectively at situations. By contrast, the latter operates within the agenda of the participants, i.e. it is responsive to what it finds and therefore, by definition, is faithful to the situation as it unfolds. Here selectivity derives from the *situation* rather than from the *researcher* in the sense that the key issues which emerge follow from the observation rather than the researcher knowing in advance what those key issues will be. Structured observation is useful for testing hypotheses, whilst unstructured observation provides a rich description of a situation which, in turn, can lead to the subsequent generation and testing of hypotheses.

Flick (1998, p. 137) suggests that observation can be considered along five dimensions:

- structured, systematic and quantitative observation versus unstructured and unsystematic and qualitative observation;
- participant observation versus non-participant observation;
- overt versus covert observation;
- observation in natural settings versus observation in unnatural, artificial settings (e.g. a 'laboratory' or contrived situation);
- self-observation versus observation of others.

Cooper and Schindler (2001, p. 375) suggest that observation can be considered along three dimensions:

- whether the observation is direct or indirect (the former requiring the presence of the observer; the latter requiring recording devices, e.g. video cameras);
- whether the presence of the observer is known or unknown (overt or covert research, whether the researcher is concealed (e.g. through a two-way mirror or hidden camera) or partially concealed, i.e. the researcher is seen but not known to be a researcher, e.g. the researcher takes up a visible role in the school);
- the role taken by the observer (participant to non-participant observation, discussed below).

We address these throughout the chapter, and present these dimensions and others in Figure 26.1.

Observation, in general, is not only time-consuming but prone to bias in terms of what, why, when, where, whom and how the observer is observing. Observations are inevitably selective, and, in part, depend as much on the observer's attention and opportunity to observe as they do on the observational instruments and data-collection techniques used. Hence great caution and reflexivity are requisites for this form of data collection. As with other forms of data collection, observational data must enable the research questions to be answered. Indeed Simpson and Tuson (2003, chapter 2) and Hamilton and Corbett-Whittier (2013, p. 99) suggest that observers need to consider:

- the focus of the observation(s);
- why they are observing (e.g. looking for regularities, similarities, evolution of a situation, irregularities, patterns, key features etc.);

FIGURE 26.1 Continua of observation

- the research questions that the observational data will address;
- the boundaries of the observation (what to include and exclude);
- how to record the observations;
- what observer role to take;
- where to observe (e.g. key social places);
- what to observe (e.g. significant objects, setting; events, people etc.);
- whom to observe (e.g. key people, everyday participants, marginalized people);
- how many people, events, settings to observe (i.e. sampling);
- how many observations and series of observations to make;
- how systematic, structured, descriptive to be;
- what is the 'unit' of observation (e.g. a teacher, a student, a pair, a small group, a class);
- what resources are necessary (e.g. human observers, video cameras);
- problems that might be encountered;
- additional information that may be needed to complement the observational record;
- the processing and analysis of observational data;
- how to link observations with other kinds of data.

There is also the need to consider who the observer will be, as observation (particularly participant observation) can be affected by the gender, ethnicity, class, appearance, age, language, personality, temperament, attitude, interpersonal behaviour, familiarity with the situation, involvement and concern etc. of the observer (cf. Kawulich, 2005, p. 7).

On a practical level the researcher has to decide fundamental matters such as whether to stand or sit, whether to move around a setting (e.g. in order to track a student), and where to stand or sit. If a researcher is located too close he/she might be intrusive or inhibiting, or the researcher might lose the observation if a student moves away; if the researcher is too far away he/she might miss the detail of what is happening (cf. Simpson and Tuson, 2003, pp. 54–5).

26.2 Structured observation

A structured, systematic observation enables the researcher to generate numerical data from the observations. Numerical data, in turn, facilitate the making of comparisons between settings and situations, and enable frequencies, patterns and trends to be noted or calculated. The observer adopts a passive, non-intrusive role, simply noting down the incidence of the factors being studied. Observations are entered onto an observational schedule. An example of this is shown in Table 26.1. This is an example of a schedule used to monitor student and teacher conversations over a ten-minute period. The upper seven categories indicate who is speaking to whom, whilst the lower four categories indicate the nature of the talk. Looking at the example of the observation schedule, several points can be noted:

- the categories for the observation are discrete, i.e. there is no overlap between them; for this to be the case a pilot has to be developed and tested in order to iron out any problems of overlap of categories;
- each column represents a 30-second time interval, i.e. the movement from left to right represents the chronology of the sequence, and the researcher has to enter data in the appropriate cell of the matrix every thirty seconds (see section below on 'instantaneous sampling');
- because there are so many categories which must be scanned at speed (every thirty seconds), the

TABLE 26.1 A STRUCTURED OBSERVATION SCHEDULE

/ = participants in the conversation
✓ = nature of the conversation.

researcher will need to practise completing the schedule until he or she becomes proficient and consistent in entering data so that the observed behaviours, settings etc. are entered into the same categories consistently, achieving reliability. This can be done either through practising with video material or through practising in a live situation with participants who will not subsequently be included in the research. If there is to be more than one researcher then it may be necessary to provide training sessions so that the team of researchers proficiently, efficiently and consistently enter the same sort of data in the same categories, i.e. that there is inter-rater reliability;

- the researcher will need to decide what entry is to be made in the appropriate category, for example: a tick (✓), a forward slash (/), a backward slash (\), a figure (1, 2, 3 etc.), a letter (a, b, c etc.), a tally mark (|). Whatever code or set of codes is used, it must be understood by all the researchers (if there is a team) and must be simple and quick to enter (i.e. symbols rather than words), and the researcher will need to become proficient in fast and accurate data entry of the appropriate codes.

The need to pilot a structured observation schedule cannot be overemphasized. Categories must be mutually exclusive, comprehensive, complete, relevant, observable, unambiguous, self-evident and easy to record (cf. Denscombe, 2014, p. 208; Webster, 2015, p. 994). The researcher, then, will need to decide:

- the foci of the observation (e.g. people, events etc.);
- the frequency of the observations (e.g. every thirty seconds, every minute, every two minutes);
- the length of the observation period (e.g. one hour, twenty minutes);
- what counts as evidence (e.g. how a behaviour is defined and operationalized);
- the nature of the entry (the coding system).

The criterion of 'fitness for purpose' is used for making decisions on these five matters. Structured observation will take much time in preparation but the analysis of the data should be rapid as the categories for analysis will have been built into the schedule itself. If close, detailed scrutiny is required then the time intervals will be very short, and if less detail is required then the intervals may be longer.

Dyer (1995, pp. 181–4) suggests that structured observation must address several key matters:

- the choice of the environment (such that there will be opportunities for the behaviour to be observed to actually occur – the availability and frequency of the behaviour of interest to the observer: a key feature if unusual or special behaviour is sought);
- the need for clear and unambiguous measures and proxy measures (particularly if a latent characteristic or construct is being operationalized);
- a manageable number of variables (a sufficient number for validity to be demonstrated, yet not so many as to render data entry unreliable);
- overt or covert observation;
- continuous, time series or random observation;
- the different categories of behaviour to be observed;

- the number of people to be observed;
- the number of variables on which data must be gathered;
- the kind of observation schedule to be used.

Dyer (1995, p. 186) provides a checklist for planning a structured observation, shown in Box 26.1.

We introduce here five principal ways of entering data onto a structured observation schedule: event sampling; instantaneous sampling; interval recording; rating scales; and duration recording.

Event sampling

Event sampling, also known as a sign system, requires a tally mark to be entered against each statement each time it is observed, for example:

teacher shouts at the child	/////
child shouts at the teacher	///
parent shouts at the teacher	//
teacher shouts at the parent	//

The researcher will need to devise statements that yield the data which answer the research questions. This method is useful for calculating the frequencies or incidence of observed situations or behaviours, so that comparisons can be made; we can tell, for example, that the teacher does most shouting and that the parent shouts least of all. However, whilst these data enable us to chart the incidence of observed situations or behaviours, the difficulty here is that we are unable to

BOX 26.1 NON-PARTICIPANT OBSERVATION: A CHECKLIST OF DESIGN TASKS

1 The preliminary tasks

Have you

- Clearly described the research problem?
- Stated the precise aim of the research?
- Developed an explanation which either links your research to a theory or says why the observations should be made?
- Stated the hypotheses (if any) to be tested?
- Identified the appropriate test statistic (if needed)?

2 The observational system

Have you

- Identified the type(s) of behaviour to be observed?
- Developed clear and objective definitions of each category of behaviour?
- Checked that the categories are complete, and cover all the target behaviours?
- Checked that each category is clearly distinct from the others?
- Checked that the differences between each category are easily seen in the observing situation?

3 The observational process

Have you

- Identified an appropriate location to make your observations?
- Decided which data sampling procedure to use?
- Decided whether to use overt or covert observation?
- Decided whether to use one or more observers to collect information?

4 And finally …

Have you

- Designed the data collection sheet?
- Reviewed the ethical standards of the investigation?
- Run a pilot study and made any necessary amendments to the observation system, or procedure?
- If more than one observer has been used, made a preliminary assessment of inter-observer reliability?

Source: Dyer (1995, p. 186)

determine the *sequence* in which they occurred. For example, two different stories could be told from these data if the sequence of events were known. One story could be seen as follows, where the numbers 1–7 are the different periods over time (e.g. every thirty seconds):

	1	2	3	4	5	6	7
teacher shouts at the child		/	/	/	/		/
child shouts at the teacher	/	/				/	
parent shouts at the teacher		/			/		
teacher shouts at the parent					/	/	

Imagine the scene: a parent and his child arrive late for school one morning and the child slips into the classroom; an event quickly occurs which prompts the child to shout at the teacher, the exasperated teacher is very cross when thus provoked by the child; the teacher shouts at the child who then brings in the parent (who has not yet left the premises); the parent shouts at the teacher for unreasonable behaviour and the teacher shouts back at the child. It seems in this version that the teacher only shouts when provoked by the child or parent.

If the same number of tally marks were distributed in a different order, a very different story might emerge, for example:

	1	2	3	4	5	6	7
teacher shouts at the child	/	/	/	/		/	
child shouts at the teacher					/	/	/
parent shouts at the teacher					/	/	
teacher shouts at the parent			/	/			

In this scene the teacher is the instigator of the shouting, shouting at the child and then at the parent; the child and the parent only shout back when they have been provoked.

Instantaneous sampling

If it is important to know the chronology of events, then it is necessary to use instantaneous sampling, sometimes called time sampling. Here the researcher enters what she observes at standard intervals of time, for example, every twenty seconds, every minute. She notes what is happening at that precise interval moment and enters it into the appropriate category on the schedule. For example, imagine that the sampling will take place every thirty seconds; numbers 1–7 represent each 30-second interval thus:

	1	2	3	4	5	6	7
teacher smiles at the child	/	/	/	/			
child smiles at the teacher			/	/	/	/	
teacher smiles at the parent	/	/	/	/			
parent smiles at the teacher			/	/	/	/	

In this scene the researcher notes down what is happening on the 30-second point and notices from these precise moments that the teacher initiates the smiling but that all parties seem to be doing quite a lot of smiling, with the parent and the child doing the same amount of smiling each. Instantaneous sampling involves recording what is happening on the instant and entering it in the appropriate category. The chronology of events is preserved.

Interval recording

This method charts the chronology of events to some extent and, like instantaneous sampling, requires the data to be entered in the appropriate category at fixed intervals. However, instead of charting what *is happening* on the instant, it charts what *has happened* during the preceding interval. So, for example, if recording were to take place every thirty seconds, then the researcher would note down in the appropriate category what had happened during the preceding thirty seconds. Whilst this enables frequencies to be calculated, simple patterns to be observed and an approximate sequence of events to be noted, because it charts what has taken place in the preceding interval of time, some elements of the chronology might be lost. For example, if three events took place in the preceding thirty seconds of the example, then the order of the three events would be lost; we would know simply that they had occurred.

Wilkinson (2000, p. 236) distinguishes between *whole* interval recording and *partial* interval recording. In the former, behaviour is recorded only if it lasts for the whole of the interval; in the latter, behaviour is recorded if it occupies only a part of the interval in question. In the case of the partial interval recording, the researcher will need to specify how to record this.

Rating scales

Here the researcher makes some judgement about the events being observed, and enters responses into a rating scale. For example, Wragg (1994) suggests that observed teaching behaviour might be entered onto rating scales by placing the observed behaviour onto a continuum:

	1	2	3	4	5	
Warm	___	___	___	___	___	Aloof
Stimulating	___	___	___	___	___	Dull
Businesslike	___	___	___	___	___	Slipshod

An observer might wish to enter a rating according to a five-point scale of observed behaviour, for example:

1 = not at all 2 = very little 3 = a little
4 = a lot 5 = a very great deal

	1	*2*	*3*	*4*	*5*
Child seeks teacher's attention					
Teacher praises the child					
Teacher intervenes to stop misbehaviour					

Here the researcher has to move from low inference (simply reporting observations) to a higher degree of inference (making judgements about events observed). This might introduce a degree of unreliability into the observation (e.g. through: (a) the halo effect; (b) the central tendency, wherein observers will avoid extreme categories; (c) recency, where observers are influenced by more recent events than less recent events). However, this might be a helpful summary way of gathering observational data.

Simpson and Tuson (2003, pp. 42–4) suggest that researchers should ensure that:

- the categories included in ratings adequately cover the 'range of behaviours or features' (p. 42) of interest in the target group for observation;
- the anchor statements (descriptors) on each scale point adequately describe the 'range of possibilities' (p. 43) in the item for observation;
- sufficient specification of what and how to observe is given to researchers for completing the observational schedule, such that two independent observers complete the schedule of the 'same observed activities in the same way' (p. 44).

The duration of behaviour

So far we have concerned ourselves with single events and their recording. This is very suitable for single and usually short-lived behaviours. However, sometimes certain behaviours last a long time and 'over-run' the interval categories or event categories described above, i.e. it is continuous behaviour rather than a single event. For example, a child may remove her shoes only once, but she may continue to be without her shoes for a twenty-minute period; a child may delay starting writing for ten minutes, again a single behaviour but which continues for longer than each of the intervals in interval or instantaneous recording; a child may have a single tantrum which continues for twenty minutes, and so on. What we need is an indication of the *duration* of a particular behaviour. The observation is driven by the event, not the frequency of the observation. This means that the observer needs to structure the recording schedule to indicate the total duration of a single continuous behaviour.

For all the kinds of schedules discussed above, a decision will have to have been agreed in advance on how to enter data. Consistency of entering by a single observer and multiple observers will need to be founded on what counts as evidence, when, where and how to observe, and how many people on whom to focus. Indeed Barrett and Mills (2009) note that having more than one observer is useful for triangulation and reliability. Hill *et al*. (2012) note the importance of reliability checks, as wide variation may be found in data entry on the same observation sheets of the same observed phenomenon by different observers. In turn, this argues for the careful selection and preparation of observers (e.g. Hill *et al*. (2012) note the risk to neutrality in having school principals observing their own teachers).

Further, researchers will need to decide how the observation schedule will distinguish between one person being observed demonstrating the same behaviour twelve times (1 person × 12) or many people demonstrating the same behaviour fewer times (e.g. 2 people × 6 times each, or 4 people × 3 times each), i.e. whether the focus is to be on *people* or on *behaviour*.

Whilst structured observation can provide useful numerical data (e.g. the celebrated ORACLE study) (Galton and Simon, 1980), there are several concerns which must be addressed in this form of observation (Webster, 2015), for example:

- it excludes any mention of the intentions or motivations of the people being observed;
- the individual's subjectivity is lost to an aggregated score;
- it cannot catch certain important features of classrooms and people (e.g. creativity) or important background and contextual factors;
- there is an assumption that the observed behaviour provides evidence of underlying feelings, i.e. that concepts or constructs can be measured in observed occurrences.

This latter point is important, for it goes to the very heart of the notion of validity, since it requires researchers to satisfy themselves that it is valid to infer that a particular behaviour indicates a particular state of mind or particular intention or motivation. As Robson (2014) remarks: observation alone cannot tell us what is in a child's mind (p. 125), and inference can be dangerous. Further, the desire to operationalize concepts and constructs can easily lead researchers to provide overly simple indicators of complex concepts.

Structured observation can also neglect the significance of contexts – temporal and spatial – thereby overlooking the fact that behaviours may be context-specific (Webster, 2015). In their concern for the overt and the observable, researchers may overlook unintended outcomes which may have significance; they may be unable to show how significant are the behaviours of the participants being observed in their own terms, and they may over-simplify and thereby distort behaviour and phenomena (Denscombe, 2014, p. 212). Further, if we accept that behaviour is developmental, that interactions evolve over time and are therefore, by definition, fluid, then the methods of structured observation outlined above appear to take a series of 'freeze-frame' snapshots of behaviour, thereby violating the principle of fluidity of action. Captured for an instant in time, it is difficult to infer a particular meaning to one or more events, just as it is impossible to say with any certainty what is taking place when we study a single photograph or a set of photographs of a particular event. Put simply, the researcher may need to gather additional data from other sources to inform the interpretation of structured observational data. Structured observation runs in tandem with other data-collection methods.

This latter point is a matter not only for structured observation but, equally, for semi-structured and unstructured observation, for what is being suggested here is the point that *triangulation* (of methods, of observers, of time and space) can assist the researcher to generate reliable evidence (Jewitt, 2012; Lee *et al*., 2015). There is a risk that observations may be selective, and the effects of this can be attenuated by triangulation. One way of gathering more reliable data (e.g. about a particular student or group of students) is by *tracking* them through the course of a day or a week, following them from place to place, event to event. Students often behave very differently with one teacher than with another, and a full picture of students' behaviour might require the observer to see the same students in different contexts.

Taking account of criticisms of structured observations, Webster (2015) argues for fitness for purpose: systematic observations are useful in looking at activities that are 'straightforward to identify', 'limited to binary categories' and 'a meaningful expression of behaviour' (p. 995).

26.3 The need to practise structured observation

It may seem to be a naive truism to say that researchers need to practise observation, but they do! For example, they may need to practise entering data in the appropriate categories in the structured observation schedule, and at speed (Simpson and Tuson, 2003, p. 10). They may need to practise where to locate themselves when observing, what to focus on, where to look, what to record (e.g. the level of detail), where to move around the setting, whether to stand or sit, how to code *in situ*, and how to observe without those observed being too conscious of the observation taking place or the observation being too intrusive, what role to take in the classroom or setting, how to avoid eye contact (as this can be threatening or disturbing to the setting or the person being observed), how to observe discreetly or indirectly (e.g. without directly looking intently at a person or group, or without being seen to be looking directly or to be watching or tracking specific persons). Further, observers need to practise and pilot their structured observational instruments in order to find the optimum time intervals for observation schedules for instantaneous sampling, interval recording and duration recording (e.g. five seconds, one minute, two minutes, ten minutes etc.).

26.4 Analysing data from structured observations

For structured observations, researchers can count *frequencies*, for example, with reference to individuals, groups, classes, events, activities, behaviours and so on. One can observe *patterns*, for example in *sequences* of behaviours, conversations or interactions (for instance, by discourse analysis or question-and-answer sequences in classroom talk); or *frequently occurring* combinations of events, behaviours, people, kinds of interaction; or *aggregated data*, for example, from individuals to groups to classes, from individuals to males/females, from individual lessons to courses or subjects, from individual behaviours to categories of behaviour, from individual units of talk to kinds of talk such as closed questions/open questions, extended responses/one-word responses, teacher-initiated talk/student-initiated talk, and on-task/off-task behaviour. Where the data are converted into numbers, the panoply of suitable statistical analyses is available (see Part 5).

In addition to data from structured observations being 'quantitized', they can be turned into narrative accounts, descriptions and themes, i.e. 'qualitized', and we refer readers to Part 5 here.

26.5 Critical incidents

There will be times when reliability-as-consistency in observations is not necessary. For example, a student might only demonstrate a particular behaviour once, but it is so important that it should not be ruled out simply because it occurred once. One only has to commit a single murder to be branded a murderer! Sometimes one event can occur which reveals a very important insight into a person or situation. Critical incidents (Flanagan, 1949; Tripp, 1993) and critical events (Wragg, 1994) are particular events or occurrences that typify or illuminate very starkly a particular feature, for example, a teacher's behaviour or teaching style. Wragg (1994, p. 64) writes that these are events which appear to the observer to have more interest than other ones, and therefore warrant greater detail and recording than other events; they have an important insight to offer. For example, a child might unexpectedly behave very aggressively when asked to work with another child, and this might provide an insight into the child's social tolerance; a teacher might suddenly overreact when a student produces a substandard piece of work – the straw that breaks the camel's back – and this might indicate a level of stress, frustration, tolerance or intolerance, and the effects of that threshold of tolerance being reached. These events are critical in that they may be non-routine but very revealing; they offer the researcher an insight that would not be available by routine observation. They are frequently unusual events or events that have a major impact on what follows them.

26.6 Naturalistic and participant observation

Some observations take place in a context in which the researcher knows clearly and in advance what to look for, with categories and coding worked out before the observation takes place. This is not always the case. It is here that ethnographic and naturalistic observations are pre-eminent (see Chapter 15). Here the intention is to observe participants in their natural settings, their everyday social settings and their everyday behaviour in them. Observation here has a wide embrace, and includes visual observation, document analysis, interviewing, direct observation and introspection (Flick, 2009, p. 226). It is a process, moving from *descriptive observation* (orientation to a field) to *focused observation* (narrowing one's field of observation to focus on those problems and processes that are most germane to the research purpose and questions), and on to *selective observation* (to find further evidence for those items identified in the previous step) (Flick, 2009, p. 227).

Participant observation, as Simpson and Tuson (2003, p. 14) argue, is 'the most subtly intrusive' form of observation since it requires the researcher to be an empathic, sympathetic member of a group, in order to gain access to insiders' behaviours and activities, whilst still acting as a researcher with a degree of detachment. Indeed Watts (2011) suggests that participant observation strives to be non-intrusive, and, since the researcher stays in the situation for a long time, he/she becomes as familiar and unnoticed as everyday objects, part of the furniture, as it were (p. 303). All the participant observer has to do is to be around the place, to listen and watch (p. 303), to be immersed in the locale, to 'hang round' and make field notes (Marshall and Rossman, 2016, p. 143), to take on some participant role in the group – overtly or covertly – and record what was seen, heard, said etc.

Merriam (1998, p. 103) suggests that the participant observer is somewhat 'schizophrenic', as he/she has to balance participation in order to absorb the situation, with sufficient detachment to be able to analyse and observe it in a detached way. It is usually time-consuming, as not only does the researcher have to join in many activities and spend a long time with the group, but he/she has to write up field notes away from the activity itself (e.g. in the evening).

Participant observation is useful for enabling researchers to check their definitions of key terms that are used by participants, to observe events or behaviours that might not be mentioned in interviews, and to gather data on sensitive, unspoken topics (Kawulich, 2005). Participant observation can help in guiding relationships with participants and informants, enable the researcher to 'get a feel' of a situation and how matters are organized in a group or subculture, find out about interactions and relationships, raise questions for further investigation (Schensul *et al*., 1999), sensitize and familiarize a researcher to a context, and reduce reactivity in a short observation (Bernard, 1994). It enables rich descriptions of 'backstage culture' to be gathered (DeMunck and Sobo, 1998, p. 43) and can reveal the dynamics of behaviour, relationships and interactions (Watts, 2011, p. 302; Marshall and Rossman, 2016, p. 143).

As mentioned earlier, there are degrees of participation in observation (LeCompte and Preissle, 1993, pp. 93–4). The 'complete participant' is a researcher

who takes on an insider role in the group being studied, and maybe who does not even declare that she is a researcher (discussed later in comments about the ethics of covert research). The 'participant-as-observer', as its name suggests, is part of the social life of participants, documenting and recording what is happening for research purposes. The 'observer-as-participant', like the participant-as-observer, is known as a researcher to the group, and maybe has less extensive contact with the group. With the 'complete observer', participants may not realize that they are being observed (e.g. using a two-way mirror), hence this is a form of covert research. Hammersley and Atkinson (1983, pp. 93–5) suggest that comparative involvement may come in the forms of the complete participant and the participant-as-observer, with a degree of subjectivity and sympathy, whilst comparative detachment may come in the forms of the observer-as-participant and the complete observer, where objectivity and distance are key characteristics. Both complete participation and complete detachment are as limiting as each other.

As a complete participant, the researcher dare not go outside the confines of the group for fear of revealing her identity (in covert research), whilst as a complete observer there is no contact with the observed, and inference is dangerous. That said, both complete participation and complete detachment minimize reactivity, though in the former there is the risk of 'going native', where the researcher adopts the values, norms and behaviours of the group as her own, i.e. ceases to be a researcher or ceases to be objective (Kawulich, 2005, p. 4), becomes a member of the group and over-identifies with the group (Denscombe, 2014, p. 221).

Participant observation may be particularly useful in studying small groups, or for events and processes that only last a short time or are frequent, for activities that lend themselves to being observed, for researchers who wish to reach inside a situation and have a long time available to them to 'get under the skin' of behaviour or organizations (as in an ethnography), and when the prime interest is in gathering detailed information, both descriptive and explanatory, about what is happening. Participation may be required in order to understand a situation.

In participant observational studies, the researcher stays with the participants for a substantial period of time to reduce reactivity effects (the effects of the researcher on the researched, changing the behaviour of the latter, though Watts (2011) comments that reactivity diminishes quite quickly), and to develop empathy with the culture, values and behaviour of the group under study (Watts, 2011, p. 302). Observers record what is happening, whilst taking a role in that situation. In schools, this might be taking on some particular activities, sharing supervisions, participating in school life, recording impressions, conversations, observations, comments, behaviour, events and activities and the views of all participants in a situation. It is important for the researcher to balance 'participation' with 'observation'; too much of the former compromises the latter, and vice versa (Watts, 2011, p. 303).

Participant observation requires careful attention to gaining access, building trust, identifying a suitable role and being careful about with whom to be seen or with whom to 'hang out' (e.g. the school principal, a marginalized or fringe member of the group) (Kawulich, 2005, pp. 12–13). This latter point extends to the need for care in working with informants, so as not to be at the mercy of informants and gatekeepers. Researchers must recognize that informants may provide selective access to people and to data, and, indeed, depending on the views of the informant by other members of the group, they may prevent access to key people (Flick, 2009, p. 229).

Participant observation is often combined with other forms of data collection that, together, elicit the participants' definitions of the situation and their organizing constructs in accounting for situations and behaviour. By staying in a situation over a long period the researcher can also see how events, behaviours, relationships etc. evolve over time, catching the dynamics of situations, the people, personalities, contexts, resources, roles etc. Morrison (1993, p. 88) argues that by 'being immersed in a particular context over time not only will the salient features of the situation emerge and present themselves but a more holistic view will be gathered of the interrelationships of factors'. Such immersion facilitates the generation of 'thick descriptions' (Geertz, 1973), particularly of social processes and interaction, which lend themselves to accurate explanation and interpretation of events rather than relying on the researcher's own inferences. The data derived from participant observation are 'strong on reality'.

Components of 'thick descriptions' involve recording, for example (Carspecken, 1996, p. 47): speech acts; non-verbal communication; descriptions, using low-inference vocabulary; careful and frequent recording of the time and timing of events; the observer's comments, placed into categories; and detailed contextual data.

Observations, recorded in field notes, can be written at several levels. At the level of *description* they might include, for example (Spradley, 1980; Bogdan and Biklen, 1992, pp. 120–1; LeCompte and Preissle, 1993, pp. 224; Denscombe, 2014; Marshall and Rossman, 2016):

- quick, fragmentary jottings of keywords/symbols;
- transcriptions and more detailed observations written out fully;
- descriptions which, when assembled and written out, form a comprehensive and comprehensible account of what has happened;
- pen portraits of participants;
- reconstructions of conversations;
- descriptions of the physical settings of events;
- descriptions of events, behaviour and activities;
- descriptions of the researcher's activities and behaviour.

Lincoln and Guba (1985, p. 273) suggest a variety of elements or types of observations, including:

- ongoing notes, either verbatim or categorized *in situ*;
- logs or diaries of field experiences (similar to field notes, though usually written some time after the observations have been made);
- notes that are made on specific, predetermined themes (e.g. which have arisen from grounded theory);
- 'chronologs', where each separate behavioural episode is noted, together with the time at which it occurred, or recording an observation at regular time intervals, for example, every two or three minutes;
- context maps – maps, sketches, diagrams or some graphic display of the context (usually physical) within which the observation takes place, such graphics enabling movements to be charted;
- entries on predetermined schedules (including rating scales, checklists and structured observation charts), using taxonomic or categoric systems, where the categories derive from previous observational or interview data;
- sociometric diagrams (indicating social relationships, e.g. isolates (whom nobody chooses), stars (whom everyone chooses) and dyads (who choose each other));
- debriefing questionnaires from respondents that are devised for, and by, the observer only, to be used for reminding the observer of the main types of information and events once she or he has left the scene;
- data from debriefing sessions with other researchers, as an aide-memoire.

LeCompte and Preissle (1993, pp. 199–200) provide useful guidelines for directing observations of specific activities, events or scenes, suggesting that they should include answers to the following questions:

- Who is in the group/scene/activity, who is taking part?
- How many people are there, their identities and their characteristics?
- How do participants come to be members of the group/event/activity?
- What is taking place?
- How routine, regular, patterned, irregular and repetitive are the behaviours observed?
- What resources are being used in the scene?
- How are activities being described, justified, explained, organized, labelled?
- How do different participants behave towards each other?
- What are the statuses and roles of the participants?
- Who is making decisions, and for whom?
- What is being said, and by whom?
- What is being discussed frequently/infrequently?
- What appears to be the significant issues that are being discussed?
- What non-verbal communication is taking place?
- Who is talking and who is listening?
- Where does the event take place?
- When does the event take place?
- How long does the event take?
- How is time used in the event?
- How are the individual elements of the event connected?
- How are change and stability managed?
- What rules govern the social organization of, and behaviour in, the event?
- Why is this event occurring, and occurring in the way that it is?
- What meanings are participants attributing to what is happening?
- What are the history, goals and values of the group in question?

That this list is long (and by no means exhaustive) reflects the complexity of even the most apparently mundane activity. It can sensitize observers.

Lofland (1971) suggests six main categories of information in participant observation:

- acts (specific actions);
- activities (which last a longer time, for instance, a week, a term, months, e.g. attendance at school, membership of a club);
- meanings (e.g. how participants explain the causes, meanings and purposes of particular events and actions);
- participation (what the participants do, e.g. membership of a family group, school groups, peer group, clubs and societies, extra-curricular groups);

- relationships (those which are observed in the several settings and contexts in which the observation is undertaken);
- settings (descriptions of the settings of the actions and behaviours observed).

Spradley (1980, p. 78) suggests a checklist of contents of field notes:

- space: the physical setting;
- actors: the people in the situation;
- activities: the sets of related acts that are taking place;
- objects: the artefacts and physical things that are there;
- acts: the specific actions that participants are doing;
- events: the sets of activities that are taking place;
- time: the sequence of acts, activities and events;
- goals: what people are trying to achieve;
- feelings: what people feel and how they express this.

The context of observation is important (Silverman, 1993, p. 146). Moyles (2002, p. 181) suggests that researchers should record the physical and contextual setting of the observation, the participants (e.g. number, who they are, who comes and goes, what they do and what are their roles), the time of day of the observation, the layout of the setting (e.g. seating arrangements, arrangement of desks), the chronology of the events observed, and any critical incidents that happened.

At the level of *reflection*, field notes can include (Bogdan and Biklen, 1992, p. 122):

- reflections on the descriptions and analyses that have been done;
- reflections on the methods used in the observations and data collection and analysis;
- ethical issues, tensions, problems and dilemmas;
- reactions of the observer to what has been observed and recorded – attitude, emotion, analysis etc.;
- points of clarification that have been and/or need to be made;
- possible lines of further inquiry.

Lincoln and Guba (1985, p. 327) indicate three main types of item that might be included in a journal:

- a daily schedule, including practical matters, for example, logistics;
- a personal diary, for reflection, speculation and catharsis;
- notes on, and a log of, methodology.

In deciding what to focus on, Wilkinson (2000, p. 228) suggests an important distinction between observing *molecular* and *molar* units of behaviour. Small units of behaviour are molecular, for example, gestures, non-verbal behaviour, short actions, short phrases of a conversation. Whilst these yield very specific data, they risk being taken out of context, such that their meanings, and thereby their validity, are reduced. By contrast, the molar approach deals in large units of behaviour, the size of which is determined by the theoretical interests of the researcher. The researcher must ensure that the units of focus are valid indicators of the issues of concern to the researcher.

From all this we suggest that observational data should be comprehensive enough to enable the reader to reproduce the analysis that was performed. It should focus on the observable and make explicit the inferential, and the construction of abstractions and generalizations might commence early but should not starve the researcher of novel channels of inquiry (Sacks, 1992).

Spradley (1979) and Kirk and Miller (1986) suggest that observers should keep four sets of observational data to include: notes made *in situ*; expanded notes that are made as soon as possible after the initial observations; journal notes to record issues, ideas, difficulties etc. that arise during the fieldwork; and a developing, tentative running record of ongoing analysis and interpretation.

The intention here is to introduce some systematization into observations in order to increase their reliability. In this respect, Silverman (1993) reminds us of the important distinction between *etic* and *emic* analysis. *Etic* analysis uses an objective conceptual framework, perhaps that of the researcher, whilst *emic* approaches use the subjective conceptual frameworks of those being researched. Structured observation uses *etic* approaches, with predefined frameworks that are adhered to unswervingly, whilst *emic* approaches sit comfortably within qualitative approaches, where the definitions of the situations are captured through the eyes of the observed.

Participant observation is not without its critics, being described as subjective, biased, impressionistic, idiosyncratic and lacking in the precise quantifiable measures that are the hallmark of survey research and experimentation. Whilst it is probably true that nothing can give better insight into the life of a gang of juvenile delinquents than going to live with them for an extended period of time, critics of participant observation studies will point to the dangers of 'going native' as a result of playing a role within such a group. How do we know that observers do not lose their perspective and become blind to the peculiarities that they are

supposed to be investigating? How do they 'fight familiarity'?

Further, Johnson and Sackett (1998) suggest that participant observation risks being selective, unrepresentative and more concerned with the agenda of the researcher rather than the real situation (they report that researchers were more concerned with commenting on political and religious behaviours than with eating and sleeping behaviours, yet political and religious behaviours accounted for only 3 per cent of the participants' time whilst eating and sleeping accounted for 60 per cent of their time).

Adler and Adler (1994, p. 380) suggest several stages in an observation. Commencing with the selection of a setting on which to focus, the observer then seeks a means of gaining entry to the situation (e.g. taking on a role in it). Having gained entry the observer can then commence the observation proper, be it structured or unstructured, focused or unfocused. If quantitative observation is being used then data gathered can be analysed *post hoc*; if more ethnographic techniques are being used then *progressive focusing* requires the observer to undertake analysis *during* the period of observation itself.

The question that researchers frequently ask is 'how much observation must I do?' or 'when do I stop observation?'. Of course, there is no hard and fast rule here, though it may be appropriate to stop when 'theoretical saturation' has been reached (Adler and Adler, 1994, p. 380), i.e. when the situations that are being observed appear to be repeating data or issues that have already been collected (see also Chapter 37). It may be important to carry on collecting data at this point, to indicate overall frequencies of observed behaviour, enabling the researcher to find the most to the least common behaviours observed over time. Further, the greater the number of observations, the greater the reliability of the data might be, enabling emergent categories to be verified. What is being addressed here is the reliability of the observations (see Chapter 14 on triangulation).

26.7 Data analysis for unstructured observations and videos

For less structured and unstructured observational data (e.g. from field notes, videos), the tools of qualitative analysis can be used, for example: summarizing; narrative accounts (of individuals, groups, behaviours, events); thematic analysis and patterning; coding and categorizing; nodes and connections; constant comparison; theoretical saturation (see Part 5). This includes use of computer-based software for analysing qualitative processing (e.g. NVivo, ATLAS.ti, MAXQDA) (see also: www.surrey.ac.uk/sociology/research/researchcentres/caqdas/support/choosing/index.htm). For video material, NVivo, Orion, Transana and VideoTrace are also available at the time of writing.

Simpson and Tuson (2003, pp. 83–5) and Miles and Huberman (1984) indicate several strategies for data analysis of field notes and qualitative data, including, largely with reference to coding:

- reviewing, analysing and coding early rather than accumulating too much data before analysis;
- coding densely at first (i.e. avoiding moving too quickly into summarizing);
- keeping track of the data analysis over time (e.g. key codes and what they embrace, key people observed, keeping to the research questions (if appropriate, i.e. depending on the nature of the research));
- verifying intuitions with data;
- identifying themes and patterns (sometimes by counting frequencies or consistencies);
- looking for clusters of events, activities, people, behaviours etc.;
- writing metaphors to catch the essence of features;
- being prepared to disaggregate as well as aggregate data in order to preserve fidelity to the events/people/situations;
- putting codes into hierarchies (some codes are subsumed by others);
- ensuring conceptual coherence to the analysis.

Merriam (1998) suggests that it is useful for researchers to identify keywords, not only in the observed events, but in their analysis, together with attention to the start and end of observed conversations, as these are often significant and most easily remembered. Kawulich (2005) reports the value of 'quantitizing' data, looking for frequencies, together with narrative descriptions of settings, participants, activities and behaviours. She commends the use of two types of field notes for analysis: (a) observed data, including verbatim conversations; and (b) reflections, questions to be asked, issues for further exploration and comments (i.e. observations on observations). Hence observational data can be both mixed methods in themselves and in conjunction with other methods of data collection and analysis.

26.8 Natural and artificial settings for observation

Most observations by educational researchers will be undertaken in natural settings: schools, classrooms, playgrounds, lessons and suchlike. In studies of a psychological nature it may be that a contrived, artificial,

perhaps laboratory setting is organized in order to give greater observational power to the observers.

Some observational behavioural research uses a two-way mirror, in which those being observed see a mirror on a wall through which unseen observers watch what is happening without disturbing the setting under observation (e.g. counsellor training, young children interacting with each other, parents with their children), thereby causing anxiety among the participants. Often rooms are specifically prepared for this, and they may also include video camera installations. It raises questions of the ethics of covert research, discussed below.

In Chapter 30 we describe two classic studies in the field of social psychology, both of which used contrived settings: the Milgram study of obedience to authority and the Stanford Prison Experiment. Similarly, psychological researchers may wish to construct a classroom with a two-way mirror in order to observe children's behaviour without the presence of the observer. Again, this raises the ethical issue of overt and covert research. The advantage of a contrived, artificial setting is the degree of control that the researcher can exert over the situation, often as much as in a laboratory experiment. To the charge that this is an unrealistic situation and that humans should neither be controlled nor manipulated, we refer the reader to the ethical issues addressed in Chapter 7.

Settings may be classified by the degree of structure that is imposed on the environment by the observer/researcher, and by the degree of structure inherent in the environment itself (Cooper and Schindler, 2001, p. 378). Table 26.2 places settings for observation along a continuum from structured to unstructured and from natural to artificial.

Clearly the researcher will need to be guided by 'fitness for purpose' in the type of setting and the amount of structure imposed. There is fuzziness between the boundaries here. As mentioned earlier, structured settings may be useful in testing hypotheses whilst unstructured settings may be useful for generating hypotheses.

26.9 Video observations

In addition to the observer writing down details in field notes, audio-visual recording is useful (Erickson, 1992, pp. 209–10). Video recording equipment is now relatively cheap and accessible, and it provides a 'fine-grained multimodal record of an event detailing gaze, expression, body posture, and gesture' (Jewitt, 2012, p. 6).

Video recording can overcome the partialness of the observer's view of a single event (a video can be shared by several researchers) and can overcome the tendency towards only recording the frequently occurring events. Video recording can offer a more 'unfiltered' observational record of 'natural' human behaviour in real time, and it maintains the sequence of the event (Simpson and Tuson, 2003, p. 51; Jewitt, 2012; Blikstad-Balas, 2016). The video record can be viewed several times; it is not a 'once-and-for-all' observation. Video data have the capacity for completeness of analysis and comprehensiveness of material, reducing the dependence on prior interpretations by the researcher and enabling the researcher to scrutinize data.

On the other hand, one has to be cautious here, for installing video cameras might create the problem of reactivity (e.g. Jewitt, 2012; Lee *et al*., 2015); even if it is not obvious to the observer and even if people are not looking at the camera, their behaviour might change if they are being videoed, for example, they may behave in a socially desirable or deliberately acceptable way. Further, if fixed cameras are used, they might be as selective as participant observers, including and excluding areas of focus, even if the cameras are moveable (Jewitt, 2012). Like other forms of observation,

TABLE 26.2 STRUCTURED, UNSTRUCTURED, NATURAL AND ARTIFICIAL SETTINGS FOR OBSERVATION

	Natural setting	*Artificial setting*
Structured	Structured field studies (e.g. Sears *et al.*'s (1965) study of *Identification and Child Rearing*)	Completely structured laboratory (e.g. the Stanford Prison experiment, the Milgram experiment on obedience, see Chapter 26). Experiments with one-way mirrors or video recordings
Unstructured	Completely unstructured field study (e.g. Whyte's (1993) celebrated study of *Street Corner Society*, and ethnographic studies)	Unstructured laboratory (e.g. Axline's (1964) celebrated study of *Dibs in Search of Self*. Observations with one-way mirrors or video recordings)

the video only records what is observable – the material world – and this is only part of a situation; it 'frames' an event (p. 8), and this may risk losing the context in which the event is located.

Whilst a human observer can turn his/her attention to an event that occurs, for example, in a different part of the classroom, a fixed video camera cannot, and indeed a movable camera that changes direction to focus on that event or group of students might be very intrusive. Further, students, unintentionally, might block the camera's eye or move across the classroom and 'get in the way' of the focus of the camera, such that the observation is lost, whereas a human can see much more easily. Whilst having a second or third camera in the classroom might overcome this, it may be costly in terms of equipment, time needed to review and analyse the recordings, and intrusiveness.

Video cameras can be set in close-up focus to catch certain details (e.g. facial expressions), but this rules out the benefits of a panoramic focus (e.g. to catch other class members or activities); on the other hand, a panoramic focus may not have the degree of focus required for close-up detail.

Also available to some researchers is surveillance video footage (e.g. CCTV) data, with access, suitable permission, clearance, ethical approval and secure technical playback facilities. For example, schools are increasingly installing CCTV facilities; this unobtrusive measure is cost-efficient, catches hitherto 'blind spots' in locations, does not require a camera operator to be present and, because it is often archived, can also enable longitudinal studies to be conducted (though many CCTV systems will only store video data for a fixed period of time before being deleted) (Lee *et al*., 2015). The quality of such video images may also be poor, and the absence of audio material renders the video record incomplete.

To overcome the limitations of fixed and moveable cameras, another option is to have wearable cameras – a point of view (POV) camera – for example, students can wear headgear which has a mini-camera, or they may have digital pens which hold a small camera (Maltese *et al*., 2016). This enables the gaze of the camera to follow the focus, attention and direction of the wearer's gaze (Lahlou, 2011; Maltese *et al*., 2016). However, this overt form of observation may affect the behaviour of the participants even more than a fixed camera: the reactivity issue (though Heath *et al*. (2010) suggest that reactivity is exaggerated and reduces quickly).

Jewitt (2012), Robson (2014) and Lee *et al*. (2015) suggest that researchers use video observation in conjunction with other data sources in order to gather a rounded and triangulated picture of a situation, particularly if the video has no soundtrack. Video recordings, whilst enabling thick descriptions to be obtained, take time to watch and analyse, are heavy on detail and high granularity (risking data overload), and typically the video recording itself might comprise short rather than long periods of time, i.e. videos are selective in time events; hence they may overemphasize small details and lose the 'big picture' which is only obtained by longer-term observation (Lemke, 2007), though some of this challenge can be overcome by time-lapse videoing (Jewitt, 2012, p. 5). This also raises the issue of when to start and stop the video recording (Flick, 2009, p. 251).

In interpreting video material, the researcher may need expertise and suitable experience to make sense of the material. For example, Schindler (2009) reports the case of researchers who missed and did not understand data, in this instance concerning small physical movements performed in martial arts, because they were insufficiently knowledgeable about martial arts. We address video analysis in Part 5.

Researchers using video observation will need to decide (cf. Derry *et al*., 2010; Jewitt, 2012; Lee *et al*., 2015; Blikstad-Balas, 2016):

- what kind of recording to use (visual only, audio-visual, overt or covert, CCTV etc.);
- the focus of the video (e.g. close-up, distant) and how to balance close-up and long-distance focus;
- how many cameras, and what kind (e.g. fixed, moveable, wearable, digital pens etc.);
- whether to have a fixed, roaming or wearable camera;
- who operates the video camera(s);
- where to position the camera(s);
- when to start and stop the recording;
- how many events to record and over what time period (i.e. how much data to collect and from whom);
- how to catch the context of the video recording and the 'bigger picture' over time;
- how to avoid data overload;
- how to minimize reactivity;
- how to combine video data with other data to obtain a complete picture;
- the unit of analysis for the video, for example, individuals groups, events, behaviours, time, themes, etc.;
- how to analyse, interpret and report the video data.

26.10 Timing and causality with observational data

Observation in experimental procedures is prone to problems of timing: too soon and the effect may not be noticed or may be too short-term; too late and the effect might have gone or been submerged by other matters. Experiments typically suffer from the problem of only having two time points for observational measurement: the pre-test and the post-test, and this offers researchers little opportunity for identifying causal *processes* and *mechanisms* at work. The choice of timing of observation for establishing causation is crucial and it varies with the purposes of the research. The frequency of the observational data collection varies with the phenomenon under investigation, the scope of the phenomenon, the overall timescale of the phenomenon, the speed at which the dependent variable is likely to change and the level of detailed causal explanation required.

Sometimes micro-time is important (e.g. intervals of just a few seconds, as in the data collection for the ORACLE studies) (Galton and Simon, 1980). In other research a longer time frame is more suitable. Rather than fixing a specific time, it may be the events themselves that dictate the timing of the data collection, so that, for example, changes are reported when they occur, which may vary in time.

The first rule of thumb here is that the more accurately we wish to know the causal sequences, the more frequently and closer together must be the observational data-collection points. As the number of time points for data collection increases, so does the likelihood of making correct causal inferences and establishing correct causal processes and causation (Morrison, 2009, p. 168).

The second rule of thumb is that the more complex the phenomenon under investigation is, i.e. the more possible causal lines there are in a network of causation (Morrison, 2012), the more time points for observational data collection might be necessary in order to understand the causation at work. Hage and Meeker (1988, p. 177) comment that most causal processes are either not observable or not easily observable, i.e. inference overrules description. The shorter and more frequent are the time intervals and times of data collection respectively, the more the causal inferences become a matter of informed inference rather than of faith.

If we wish to understand causation at work then rich data are necessary. Hence, concomitant with the first two rules of thumb is the third rule of thumb: the more we wish to understand causation and causal processes, then the more it is that qualitative observational data can be useful, as they often have much greater explanatory potential than numerical data. Qualitative observational data can be ongoing and in-depth, and they can indicate causation at work, action narratives and agency within broader conditions and constraints. Consider clinical case studies of individuals, which may have masses of rich qualitative, observational data and field notes that thereby enable researchers to understand the processes and mechanisms of causation at work. Participant observation, rather than being peripheral in the battery of data-collection methods, becomes important in understanding causation at work. This is potentiated when used in combination with other qualitative methods (e.g. Hage and Meeker 1988, p. 179), not least because observation on its own does not establish causation, as much causation is unobservable.

Ethnography may have the edge over experimentation in understanding causal processes in the real world of education rather than the laboratory. The case for qualitative observational data in understanding causation and causal processes is powerful, even pre-eminent.

26.11 Ethical considerations in observations

There are several ethical considerations surrounding observation, and, typically, ethics committees for research will need to give clearance for the observation(s) to happen (Pearson, 2009; Derry *et al*., 2010; Jewitt, 2012; Marshall and Rossman, 2016). To undertake observation, as with many other forms of data collection, requires the informed consent of participants, the right not to be observed, permission from the school and the parents, and perhaps clearance concerning the researcher's reliability and safety to work with young people in schools. All of these take on even greater significance if the researcher is to conduct participant observation or if the research involves close-up observation, for example, observation which might invade the personal space of participants or contain any sense of threat (Simpson and Tuson, 2003, p. 61). Informed consent also has to attend to the cultural dimension of observation, for example knowing whom to approach, how to address them, how to secure permission in a culturally appropriate manner, and so on. However, it may simply be impractical to gain informed consent (e.g. if there are large groups of people being observed, such as in a public place, or if surveillance video data are being used (Watts, 2011, p. 305) or if covert research is being undertaken).

There is much literature on the dilemma surrounding overt and covert observation. Whereas in overt research the subjects know that they are being observed,

in covert research they do not. On the one hand, covert research appears to violate the principle of informed consent, invades the privacy of subjects and private space, treats the participants instrumentally – as research objects – and places the researcher in a position of misrepresenting her/his role (Mitchell, 1993), or rather, of denying it. On the other hand, there are some forms of knowledge that are legitimately in the public domain but access to which is only available to the covert researcher, for example, the fascinating account of the lookout 'watch queen' in the homosexual community (Humphreys, 1975). Covert research might be necessary to gain access to marginalized and stigmatized groups, or groups who would not willingly accede to the requests of a researcher to become involved in research. This might include those groups in sensitive positions, for example drug users and suppliers, HIV sufferers, political activists, child abusers, police informants and human traffickers.

Mitchell (1993) makes a powerful case for covert observational research, arguing that not to undertake covert research is to deny access to groups who operate under the protection of silence, to neglect research on sensitive but important topics and to reduce research to mealy-mouthed avoidance of difficult but strongly held issues and beliefs, i.e. to capitulate when the going gets rough. In a series of examples of covert research, Mitchell makes the case that not to undertake this kind of research is to deny the public access to areas of legitimate concern, the agendas of the powerful (who can manipulate silence and denial of access to their advantage) and public knowledge of poorly understood groups or situations.

Covert observation can also be justified on the grounds that it overcomes problems of reactivity, particularly if the researcher believes that individuals would change their natural behaviour if they knew that they were being observed. In some cases covert observation can produce more reliable, less biased results than overt observation, and indeed may be justified where the safety of the researcher may be at risk (Pearson, 2009).

That covert research can be threatening is well documented. For example, Patrick's (1973) study of a Glasgow gang, where the researcher had to take great care not to 'blow his cover' when witness to a murder, or Mitchell's (1993) research on mountaineers, where membership of the group involved initiation into the rigours and pains of mountaineering (the researcher had to become a fully fledged mountaineer to gain acceptance by the group).

Ethical issues also have to address the problem that observations often disturb the natural setting. Bernard (1994) suggests that participation may involve some deception, pretence and impression management in order to achieve rapport, access, immersion, objectivity and an ability to blend into the community or context, even if the researcher is overt rather than covert. The observer may have to feign ignorance or willingness to be involved in order to gain access to sensitive or confidential data (thereby using persons as objects rather than as subjects).

The ethical dilemmas of covert research are numerous, charting the tension between invasion and protection of privacy and the public's legitimate 'right to know', between informed consent and breaking this in the interests of a wider public. At issue is the dilemma that arises between protecting the individual and protecting the wider public, posing the question 'whose beneficence?': whom does the research serve or protect; is the greater good the protection and interests of the individual or the protection and interests of the wider public; will the research harm already damaged or vulnerable people or will it improve their lot; will the research have to treat people instrumentally in the interests of gathering otherwise unobtainable yet valuable research data? Should the researcher disclose all the data (Kawulich, 2005) or keep some private? (Kawulich (2005, p. 14) reports being told that she should not request additional funding for research if the research was not publishable, and she decided not to publish some data in order to retain good relationships with the group she was studying; her loyalty was to the group rather than to the public.) The researcher has inescapable moral obligations to consider, and, whilst ethical codes abound, each case must be judged on its own merits. Issues of disclosure concern confidentiality, non-traceability, protection of identity and, principally, the ethic of *primum non nocere*: first do no harm.

The need for covert research, with due protections, is justified ethically in guidelines and codes of ethics. For example, the British Sociological Association (2002, para. 31) indicates that 'the use of covert methods may be justified in certain circumstances' and that 'covert methods violate the principles of informed consent and may invade the privacy of those being studied. Covert researchers might need to take into account the emerging legal frameworks surrounding the right to privacy' (para. 32). The British Educational Research Association (2011) writes that 'researchers must therefore avoid deception or subterfuge unless their research design specifically requires it to ensure that the appropriate data is collected or that the welfare of the researcher is not put in jeopardy' (para. 14). The American Educational Research Association's *Ethical*

Standards (2000) state: 'Deception is discouraged; it should be used only when clearly necessary for scientific studies, and should then be minimized. After the study, the researcher should explain to the participants and institutional representatives the reasons for the deception' (para. 3); here the requirement for full subsequent disclosure might prevent certain kinds of research from being done. Pearson (2009, p. 244) comments that, in considering covert research, 'proportionality' has to be addressed, whereby the potential harm done to individuals and organizations is minimal, and much less than the public benefit to be gained from the research.

The issue of non-intervention is also ethically problematic. Whilst the claim for observation as being non-interventionist was made at the start of this chapter, the issue is not as clean as this, for researchers inhabit the world that they are researching, and their influence may not be neutral (the Hawthorne and halo effects discussed in Chapter 14). This is clearly an issue in, for example, school inspections, where the presence of an inspector in the classroom exerts a powerful influence on what takes place; it is disingenuous to pretend otherwise. Observer effects can be considerable.

Moreover, the non-interventionist observer has to consider carefully her/his position. In the example of Patrick's witness to a murder mentioned above, should the researcher have 'blown his cover' and reported the murder? What if not acting on the witnessed murder might have yielded access to further sensitive data? Should a researcher investigating drug or child abuse report the first incident or 'hang back' in order to gain access to further, more sensitive data? Should a witness to abuse simply report it or take action about it? If I see an incident of bullying, do I maintain my non-interventionist position? Do I 'turn a blind eye' to breaches of discipline or school rules (e.g. an individual's or group's plans to bully a student, to physically assault someone, to steal and so on), or even criminal acts or plans for criminal acts (Pearson, 2009, p. 246)? Do I undertake criminal acts in order to be an insider to a group (Pearson, 2009)? Is the observer merely a journalist, providing data for others to judge? When does non-intervention become morally reprehensible? Just because observation may not be illegal (e.g. photographing a couple kissing intimately in a public place), does this make it acceptable? These are issues for which one cannot turn to codes of conduct for a clear adjudication.

26.12 Reliability and validity in observations

Many observation situations carry the risk of bias (e.g. Wilkinson, 2000, p. 228; Moyles, 2002, p. 179; Robson, 2002, pp. 324–5; Shaughnessy *et al*., 2003, pp. 116–17; Flick, 2009, chapter 17; Jewitt, 2012; Breznau, 2016), for example by:

- *selective attention* of the observer: what we see is a function of where we look, what we look at, how we look, when we look, what we think we see, whom we look at, what is in our minds at the time of observation; what are our own interests and experiences;
- *reactivity*: participants may change their behaviour if they know that they are being observed, for example, they may try harder in class, they may feel more anxious, they may behave much better or much worse than normal, they may behave the way they think the researcher wishes them to, or in ways for which the researcher tacitly signals approval (Shaughnessy *et al*., 2003, p. 113);
- *attention deficit*: what if the observer is distracted, or looks away and misses an event?
- *validity of constructs*: decisions must be taken on what counts as valid evidence for a judgement. For example, is a smile a relaxed smile, a nervous smile, a friendly smile, a hostile smile? Does looking at a person's non-verbal gestures count as a valid indicator of interaction? Are the labels and indicators used to describe the behaviour of interest valid indicators of that behaviour?
- *selective data entry*: what we record can be affected by our personal judgement rather than the phenomenon itself; we may interpret the situation and then record our interpretation rather than the phenomenon;
- *selective memory*: if we write up our observations after the event, our memory neglects and selects data, sometimes overlooking the need to record the contextual details of the observation; notes should be written either during or immediately after the observation;
- *interpersonal matters and counter-transference*: our interpretations are affected by our judgements and preferences – what we like and what we don't like about people and their behaviour – together with the relationships that we may have developed with those being observed and the context of the situation; researchers may have to deliberately distance themselves from the situation and address reflexivity;
- *expectancy effects*: the observer knows the hypotheses to be tested, or the findings of similar studies, or has expectations of finding certain behaviours, and

these may influence her/his observations. Expectancy effects can be overcome by ensuring that the observers do not know the purpose of the research, the 'double-blind' approach;

- *decisions on how to record*: the same person in a group under observation may be demonstrating the behaviour repeatedly, but nobody else in the group may be demonstrating that behaviour; there is a need to record how many different people show the behaviour;
- *number of observers*: different observers of the same situation may be looking in different directions, so there may be inconsistency in the results. Therefore there is a need for training, for consistency, for clear definition of what constitutes the behaviour, of entry/judgement and for kinds of recording;
- *the problem of inference*: observations can only record what happens and what can be seen, and it may be dangerous, without any other evidence, for example, triangulation, to infer reasons, intentions, causes and purposes that lie behind actors' behaviours. One cannot always judge intention from observation, for example, a child may intend to be friendly, but it may be construed by an inexperienced observer as selfishness; a teacher may wish to be helpful but the researcher may interpret it as threatening. It is dangerous to infer a stimulus from a response, an intention from an observation. Similarly, one may not see certain phenomena emerging over time (e.g. biographical processes);
- *difference of interpretation of, and data aggregation and conclusions from, the same data*: Breznau (2016, p. 302) terms these 'secondary observer effects'.

The issues here concern validity and reliability. With regard to the validity of the observation, researchers have to ensure that the indicators of the construct under investigation are fair and operationalized, for example, there is agreement on what counts as constituting qualities such as 'friendly', 'happy', 'aggressive', 'sociable' and 'unapproachable'. The matter of what to observe is problematic. For example, do you only focus on certain people rather than the whole group, on certain events and at certain times rather than others, on molar or molecular units? Do you provide a close-grained, close-up observation or a holistic, wider-focused and wider-ranging observation, i.e. do you use a zoom lens and obtain high definition of a limited scope, or a wide-angle lens and obtain a full field but lacking in detail, or somewhere between the two? How do you decide on what to focus?

With regard to reliability, the indicators have to be applied fully, consistently and securely, with no variation in interpretation. Reliability resides not only in the instrument but their use by different raters (Hill *et al*., 2012). This is a matter not only for one observer – consistency in his or her observation and recording – but also if there are several observers. A formula for calculating the degree of agreement (as a percentage) between observers can be used, thus:

$$\frac{\text{Number of times two observers agree}}{\text{Number of possible opportunities to agree}} \times 100$$

In measuring inter-rater reliability one should strive for a high percentage (over 90 per cent minimum). Other measures of inter-rater reliability use correlations, and here coefficients of >0.90 (i.e. over 90 per cent) should be sought (Shaughnessy *et al*., 2003, p. 111). Hill *et al*. (2012) remind researchers that rater agreement measurement does not necessarily provide a complete picture of inter-rater reliability as there are other variables included (e.g. frequency of observations, frequency of behaviours observed, cognitive load on raters, number of items, random variation etc.).

To ensure reliability, it is likely that training is required, so that researchers:

- use the same operational definitions;
- record the same observations in the same way;
- look for the same things;
- have good concentration;
- can focus on detail;
- can be unobtrusive but attentive;
- have the necessary experience to make informed judgements from the observational data.

These qualities are essential in order to avoid fatigue, 'observer drift' (Cooper and Schindler, 2001, p. 380) and halo effects, all of which can reduce reliability.

With regard to reactivity, one suggestion is to adopt covert observation, though this raises ethical issues (see Chapter 7 and above). Another suggestion is to adopt habituation, i.e. the researcher remains in the situation for such a long time that participants become used to his/her presence and revert to their natural behaviour.

To aid reliability in the research, it is also important for the observer to write up notes as soon after the event as possible (writing may stimulate more thought), to write quickly yet to expect to take a long time to write notes, to use computer software (for subsequent data processing) and to make two copies: one of the original data and another for manipulation and analysis (e.g. cutting and pasting data).

26.13 Conclusion

Observation is a powerful tool for gaining insight into situations. As with other data-collection techniques, observation engages issues of validity and reliability. Even low inference observation, perhaps the safest form of observation, is itself selective, just as perception is selective. Higher forms of inference, whilst moving towards establishing causality, rely on greater levels of interpretation by the observer, with the observer making judgements about intentionality and motivation. In this respect, additional methods of gathering data can be employed, to provide corroboration and triangulation, in short, to ensure that reliable inferences are derived from reliable data.

In planning observations one has to consider:

- when, where, how and what to observe;
- how much degree of structure is necessary in the observation;
- the duration of the observation period, which must be suitable for the behaviour to occur and be observed;
- the timing of the observation period (e.g. morning, afternoon, evening);
- the context of the observation (a meeting, a lesson, a development workshop, a senior management briefing etc.);
- the nature of the observation (structured, semi-structured, open, molar, molecular etc.);
- the need for there to be an opportunity to observe, for example, to ensure that there is the presence of the people/behaviour to be observed;
- the merging of subjective and objective observation, even in a structured observation: an observation schedule can become highly subjective when it is being completed, as interpretation, selection and counter-transference may enter the observation, and operational definitions may not always be sufficiently clear;
- the value of covert participant observation in order to gain access and to reduce reactivity;
- threats to reliability and validity;
- the need to operationalize the observation so that what counts as evidence is consistent, unambiguous and valid, for example, what constitutes a particular quality (e.g. anti-social behaviour: what counts as anti-social behaviour – one person's 'sociable' is another's 'unsociable' and vice versa);
- the need to choose the appropriate kind of structured observation and recording (e.g. event sampling, instantaneous sampling, whole interval/partial interval recording, duration recording, dichotomous/rating scale recording);
- how to go under cover, or whether informed consent is necessary;
- ethically defensible observation;
- whether deception is justified;
- which role(s) to adopt on the continuum of complete participant, to participant-as-observer, to observer-as-participant, to complete observer.

Observation can be a very useful research tool. On the other hand, it exacts its price, for example: it may take a long time to catch the required behaviour or phenomenon, it can be costly in time and effort and prone to difficulties of interpreting or inferring what the data mean. This chapter has outlined several different types of observation and the premises that underlie them, the selection of the method to be used depending on 'fitness for purpose'. Overriding the issues of which specific method of observation to use, this chapter has suggested that observation places the observer into the moral domain, that it is insufficient simply to describe observation as a non-intrusive, non-interventionist technique and thereby to abrogate responsibility for the participants involved. Like other forms of data collection in the human sciences, observation is not a morally neutral enterprise. Observers, like other researchers, have obligations to participants as well as to the research community.

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Tests

CHAPTER 27

The field of testing is so extensive that the comments that follow must needs be of an introductory nature; the reader seeking a deeper understanding will need to refer to specialist texts and sources on the subject. Limitations of space permit no more than a brief outline of some key issues concerning tests and testing, including:

- what are we testing?
- parametric and non-parametric tests
- diagnostic tests
- norm-referenced, criterion-referenced and domain-referenced tests
- commercially produced tests and researcher-produced tests
- constructing and validating a test
- software for preparation of a test
- devising a pre-test and post-test
- ethical issues in testing
- computerized adaptive testing

27.1 Introduction

Since the spelling test of Rice (1897), the fatigue test of Ebbinghaus (1897) and the intelligence scale of Binet (1905), the growth of tests has proceeded at an extraordinary pace in terms of volume, variety, scope and sophistication. In tests, researchers have at their disposal a powerful method of data collection (and indeed secondary data) and an impressive array of tests for gathering data of a numerical rather than verbal kind. In considering testing for gathering research data, several issues need to be borne in mind, not least of which is why tests are being used at all:

- What are we testing (e.g. achievement, aptitude, attitude, personality, performance, intelligence, social adjustment etc.)?
- Are we dealing with parametric or non-parametric tests?
- Are they norm-referenced or criterion-referenced?
- Are they available commercially for researchers to use or will researchers have to develop home-produced tests?
- Do the test scores derive from a pre-test and post-test in the experimental method?
- Are they group or individual tests?
- Do they involve self-reporting or are they administered tests?
- How to construct and validate a test?

We unpack some of these issues in this chapter.

Larger-scale testing (e.g. national-level and international tests) has come into prominence with worldwide testing such as TIMMS (Trends in International Mathematics and Science Study), PIRLS (Progress in International Reading Literacy) and PISA (Programme for International Student Assessment). The websites of these organizations carry a wealth of materials, information and access to test data (which many researchers use in their own work).

27.2 What are we testing?

Tests can concern achievement (what a person can do or knows), diagnosis (where the strengths and weaknesses of a student are; where the student is going wrong or having problems), aptitude (what the student is good at doing), proficiency, performance, speed, and so on. Tests can be used to compare students; to see if a student has achieved a particular fixed criterion (e.g. mastery tests, i.e. regardless of comparing with other students) (see below: norm-referencing and criterion-referencing); to see how quickly students can work (speed tests); to see what skills a student has mastered (e.g. a power test); to diagnose (e.g. difficulties and problems) etc.

Hambleton (2012, p. 242) identifies eight kinds of test:

- norm-referenced achievement and aptitude tests (commercially produced);
- criterion-referenced achievement tests (often commercially produced);
- classroom tests (produced by researchers, and intended for one-off use);
- performance tests;

- personality tests;
- attitude scales;
- interest inventories (often commercially produced);
- questionnaires.

However, this is just a starting point. There are myriad tests, to cover all aspects of a student's life and for all ages (young children to old adults), for example:

Ability	Learning disabilities
Achievement	Locus of control
Admission	Motivation and interest
Anxiety	Neuropsychological assessment
Aptitude	Performance
Attainment	Performance in school subjects
Attitudes and values	Personality
Behavioural disorders	Personality disorders
Competence-based assessment	Placement
Computer-based assessment	Potential
Creativity	Projective tests
Critical thinking	Psychomotor development
Cross-cultural adjustment	Reading readiness
Depression	Self-esteem
Diagnostic assessment	Sensory and perceptual tests
Diagnosis of difficulties	Social adjustment
Higher order thinking	Spatial awareness
Intelligence	Special abilities and disabilities
Interest inventories	Stress and burnout
Introversion and extraversion	University entrance
Language proficiency tests	Verbal and non-verbal reasoning

The *Handbook of Psychoeducational Assessment* (Saklofske *et al*., 2001) includes sections on ability assessment, achievement assessment, behaviour assessment, cross-cultural cognitive assessment and neuropsychological assessment. The *Handbook of Psychological and Educational Assessment of Children: Intelligence, Aptitude and Achievement* (Reynolds and Kamphaus, 2003) provides a clear overview of, inter alia:

- the history of psychological and educational assessment;
- a practical model of test development;
- legal and ethical issues in the assessment of children;
- measurement and design issues in the assessment of children;
- intelligence testing, both verbal and non-verbal;
- memory testing;
- neuropsychological and biological perspectives on the assessment of children;
- assessment of academic skills;
- criterion-referenced testing;
- diagnostic assessment;
- writing abilities and instructional needs;
- assessment of learning disabilities;
- bias in aptitude assessment;
- assessment of culturally and linguistically diverse children;
- assessment of creativity;
- assessment of language impairment;
- assessment of psychological and educational needs of children with severe mental retardation and brain injury;
- computer-based assessment.

As can be seen, there is a copious amount of assessment and testing material available and it covers a very wide spectrum of topics. *The Nineteenth Mental Measurements Yearbook* (Carlson and Geisinger, 2014) and *Tests in Print IX* (Anderson *et al.*, 2016) are useful sources of published tests, as are specific publishers and the website of BUROS (e.g. http://buros.org/test-reviews-information). In designing tests, Izard (2005) and Kline (2016) are useful sources.

There are several organizations that publish lists of tests and suppliers:

- The American Psychological Association: Finding Information about Psychological Tests (www.apa.org/science/programs/testing/find-tests.aspx)
- The British Psychological Society:
  - Psychological Testing (http://ptc.bps.org.uk/psychological-testing)
  - Psychological Testing Centre (http://ptc.bps.org.uk)
  - Psychological Test Collection (www.bps.org.uk/what-we-do/bps/history-psychology-centre/collections-and-archives/psychological-test-collection/psychological-test-collection)
  - Finding a Suitable Test (http://ptc.bps.org.uk/psychological-testing/psychological-testing/i-want-find-suitable-test-use)
- The Buros Center for Testing (www.unl.edu/buros)
- Healthy Place (US) (www.healthyplace.com/psychological-tests)
- Assessment Psychology online (www.assessmentpsychology.com/psychsites.htm).

Additionally there are countless websites that list psychological tests and we identify some of these on the companion website. Standard texts that detail copious tests, suppliers and websites include: Gronlund and

Linn (1990); Kline (2000, 2016); Loewenthal (2001); Saklofske *et al*. (2001); Reynolds and Kamphaus (2003); Gronlund and Brookhart (2008); Aiken (2003); Miller *et al*. (2012).

27.3 Parametric and non-parametric tests

Parametric tests are designed to represent the wide population, for example, of a country or age group. They make assumptions about the wider population and its characteristics, i.e. the parameters are known. They assume that:

- there is a normal curve of distribution of scores in the population (the bell-shaped symmetry of the Gaussian curve of distribution seen, for example, in standardized scores of IQ or the measurement of people's height or the distribution of achievement on reading tests in the population as a whole);
- the characteristics of the wider population are known, so that the parameters of each element of a test can be fairly sampled and controlled;
- there are continuous and equal intervals between the test scores, and, with tests that have a true zero (see Chapter 38), the opportunity for a score of, say, 80 per cent to be double that of 40 per cent; this differs from the ordinal scaling of rating scales discussed in connection with questionnaire design where equal intervals between each score cannot be assumed.

Parametric tests are usually published tests which are commercially available and which have been piloted, validated and standardized on a large and representative sample of the whole population. They usually arrive complete with backup data on sampling, reliability and validity statistics which have been computed in devising the tests. Working with these tests enables the researcher to use statistics applicable to interval and ratio levels of data.

On the other hand, non-parametric tests make few or no assumptions about the distribution of the population (the parameters of the scores) or the characteristics of that population. The tests do not assume a regular bell-shaped curve of distribution in the wider population; indeed the wider population is perhaps irrelevant as these tests are designed for a given specific population: a class in school, a chemistry group, a primary school year group. Because they make no assumptions about the wider population, the researcher must work with appropriate non-parametric statistics (see Chapter 38).

The attraction of non-parametric statistics is their utility for small samples because they do not make any assumptions about how normal, even and regular the distributions of scores will be. Non-parametric tests have the advantage of being tailored to particular institutional, departmental and individual circumstances. They offer teachers a valuable opportunity for quick, relevant and focused feedback on student performance.

Commercially produced parametric tests are more powerful than non-parametric tests because they not only derive from standardized scores but enable the researcher to compare sub-populations with a whole population (e.g. to compare the results of one school or district authority with the whole country, for instance in comparing students' performance in norm-referenced or criterion-referenced tests against a national average score in that same test). They enable the researcher to use high-level statistics in data processing (see Chapters 38–44) and to make *inferences* from the results. Because non-parametric tests make no assumptions about the wider population a different set of statistics is available to the researcher (see Part 5). These can be used in very specific situations – one class of students, one year group, one style of teaching, one curriculum area – and hence are valuable to teachers.

27.4 Diagnostic tests

Diagnostic tests are designed to identify particular strengths, weaknesses and problems in the aspect with which they are concerned (akin to going to a doctor with a medical complaint). Diagnostic tests identify needs, difficulties, successes and where problems arise. Whilst teachers are constantly diagnosing students' needs, difficulties, strengths, weaknesses and problems, there is a wide array of formal, standardized diagnostic tests available in the public domain, often with restricted access (e.g. to registered educational psychologists).

Diagnostic tests are often used as the foundation for formative planning, informing what action needs to be taken next (just as a doctor diagnoses an illness and then prescribes treatment). The two are different: diagnosis does not prescribe treatment, the educationist then has to decide what 'treatment' to administer.

27.5 Norm-referenced, criterion-referenced and domain-referenced tests

Norm-referenced tests

A norm-referenced test compares students' achievements relative to other students' achievements (e.g. a national test of mathematical performance or a test of intelligence which has been standardized ('normed') on a large and representative sample of students between

the ages of six and sixteen). For example, a commercially produced intelligence test has been standardized so that, for instance, a score of 100 is that of a notional 'average' student and a score of 120 describes a student who is notionally above average. The concept of 'average' only makes sense when it is derived from or used for a comparison of students.

Norm-referencing is based on a curve of distribution, which may be the bell-shaped, symmetrical Gaussian curve or a skewed curve (e.g. skewed in order to give more students higher grades, though this is highly contentious). Norm-referencing is designed to fit quotas for what proportion of students will be awarded grades/percentages (e.g. 5 per cent might be awarded a grade A; 20 per cent a grade B; 40 per cent a grade C; 20 per cent a grade D; 10 per cent a grade E; and 5 per cent a Fail). They enable students to be ranked: 'an order of merit' (Izard, 2005, p. 20).

In educational institutions, a norm-referenced assessment enables institutions to guarantee a proportion of high achievers (though it also guarantees a proportion of low achievers). It means that standards vary across classes/groups/years, as the comparators vary. For example, a grade A student in one year might be a grade B in another year, if that second year comprises high-scoring students, or a grade D student in one year might be a failing student in another year if that second year comprises higher-scoring students. It means that students might obtain a first-class degree one year when, in another, the same work would only be awarded a second-class degree. An 'A' in one year is no guide as to the meaning or standard of 'A' in another year; an 'F' in one year is no guide as to an 'F' in another. As Izard (2005) argues, the fair use of norm-referenced tests relies on the curriculum being static over time (p. 19).

However, the argument is also raised that students have a right to expect that the standard of their grading and awards will not be affected by the numbers of students in a course or programme or by quotas but by their performance on given, transparent criteria, and only against these criteria. Similarly, it is argued that students have a right to know at the start of their courses, i.e. in advance of the course, what constitutes an 'A' grade, what constitutes a 'B' grade and so on – this concerns equity and transparency, rather than being told that their grades will only be awarded once the number of students on the course and their marks have been calculated, or that there is a limit to the number/proportion of people at each grade.

Just as a norm-referenced system guarantees a certain proportion of high grades, for example, A and B, so, by definition, it also guarantees a proportion of low grades and failures, regardless of actual performance, in order to conform to the curve of distribution.

The educational defensibility or desirability of norm-referencing may be questionable: a 'good' student may end up failing or scoring poorly if the class or group of students with whom she/he is being compared is even better. Norm-referencing may be useful for selection (e.g. for a fixed, limited number of places in an elite university), but it may not be equitable.

Further, norm-referenced tests (e.g. standardized tests) used in worldwide testing assume that the curriculum of each country is the same, and this may not be the case, for example, algebra and geometry are introduced much later in an American student's school curriculum than in an Australian curriculum (Izard, 2005).

Criterion-referenced tests

A criterion-referenced test does not compare student with student but, rather, requires the student to fulfil a given set of criteria, a predefined and absolute standard or outcome (Cunningham, 1998), for example, in terms of knowledge or skills. It tests what a student can and cannot do, and what he/she knows and does not know, regardless of what any other students can and cannot do. For example, a driving test is usually criterion-referenced since to pass it requires the ability to meet certain test items – reversing round a corner, undertaking an emergency stop etc. – *regardless* of how many other people have or have not passed the driving test. Similarly, many tests of playing a musical instrument require specified performances, for example, the ability to play a particular scale or arpeggio, the ability to play a Bach fugue without hesitation or technical error. If the student meets the criteria, then he or she passes the examination.

In criterion-referenced assessment the specific criteria for success are set out in advance and students are assessed on the extent to which they have achieved them, without any reference being made to the achievements of other students (which is norm-referencing). If they meet the criteria then they achieve the grade, regardless of how many other students do or do not achieve the grade (i.e. unlike norm-referencing).

There are minimum competency cut-off levels, below which students are deemed not to have achieved the criteria, and above which different grades or levels can be awarded for the achievement of criteria – for example, a grade A, B, C etc.

In a criterion-referenced assessment, unlike in a norm-referenced assessment, there are no ceilings on the numbers of students who might be awarded a particular grade. In a norm-referenced system there might be only a small percentage who are able to achieve a

grade A because of the imposed proportion/quota (the 'norming' of the test), whereas in a criterion-referenced assessment, if everyone meets the criterion for a grade A then everyone is awarded a grade A, and if everyone should fail then everyone fails.

A criterion-referenced test provides the researcher with information about exactly what a student has learned, what she can do, whereas a norm-referenced test can only provide the researcher with information on how well one student has achieved in comparison to another, enabling rank orderings of performance and achievement to be constructed. Hence a major feature of the norm-referenced test is its ability to discriminate between students and their achievements – a well-constructed norm-referenced test enables differences in achievement to be measured acutely, i.e. to provide variability or a great range of scores. For a criterion-referenced test this is less of a problem; the intention here is to indicate whether students have achieved a set of given criteria, regardless of how many others might or might not have achieved them, hence variability or range is less important here. Criterion-referencing is often used in outcomes-based education.

Domain-referenced tests

An outgrowth of criterion-referenced testing is domain-referenced tests. Here importance is accorded to the careful and detailed specification of the content or the domain to be assessed. The domain is the particular field or area of the subject that is being tested, for example, light in science, two-part counterpoint in music, parts of speech in English. The domain is set out very clearly and very fully, such that the full depth and breadth of the content are established. Test items are then selected from this full field, with careful attention to sampling procedures so that representativeness of the wider field of items is ensured in the test items. The student's achievements on that test are computed to yield a proportion of the maximum score possible, and this, in turn, is used as an index of the proportion of the overall domain that she has grasped. So, for example, if a domain has 1,000 items and the test has 50 items from this 1,000, and the student scores 30 marks from the possible 50 then it is inferred that she has grasped 60 per cent ($\{30 \div 50\} \times 100$) of the domain of 1,000 items. Here inferences are made from a limited number of items to the student's achievements in the whole domain; this requires careful and representative sampling procedures for test items.

27.6 Commercially produced tests and researcher-produced tests

There is a battery of tests in the public domain which cover a vast range of topics and which can be used for evaluative purposes (some are indicated at the start of this chapter).

Most schools will have used published tests at one time or another. There are several attractions to using published tests:

- they are objective;
- they have been piloted and refined;
- they have been standardized across a named population (e.g. a region of the country, the whole country, a particular age group or various age groups) so that they represent a wide population;
- they declare how reliable and valid they are (mentioned in the statistical details which are usually contained in the manual of instructions for administering the test);
- they tend to be parametric tests, hence enabling sophisticated statistics to be calculated;
- they come complete with instructions for administration;
- they are often straightforward and quick to administer and mark;
- guides to the interpretation of the data are usually included in the manual;
- researchers are spared the task of having to devise, pilot and refine their own test.

On the other hand, commercially produced tests are expensive to purchase and administer; some are often targeted to special rather than to general populations (e.g. in psychological testing), and some may not be exactly suited to the purpose required (Howitt and Cramer, 2014). Further, several commercially produced tests have restricted release or availability, and the researcher might have to register with a particular association or be given clearance to use the test or to have copies of it. There are different levels of clearance, and certain parties or researchers may not be eligible to have a test released to them because they do not fulfil particular criteria for eligibility.

Published tests, by definition, are not tailored to institutional or local contexts or needs; indeed their claim to objectivity is made on the grounds that they are deliberately supra-institutional. The researcher wishing to use published tests must be certain that the purposes, objectives and content of the published tests match those of the research. For example, a published diagnostic test might not fit the needs of the research to

have an achievement test; a test of achievement might not have the predictive quality which the researcher seeks in an aptitude test; a published reading test might not address the areas of reading that the researcher is wishing to cover; a verbal reading test written in English might contain language which is difficult for a student whose first language is not English. These are important considerations. A text on evaluating the utility for researchers of commercially available tests is produced by the American Psychological Association (2014) in the *Standards for Educational and Psychological Testing* (www.apa.org/science/programs/testing/standards.aspx).

The golden rule for deciding whether to use a published test is that it must demonstrate *fitness for purpose*. If it fails to demonstrate this, then tests will have to be devised by the researcher. The attraction of this latter type is that a 'home-grown' test will be closely tailored to the local and institutional context, i.e. the purposes, objectives and content of the test will be deliberately fitted to the *specific* needs of the researcher in a specific, given context. Cronbach (1949), Gronlund and Linn (1990) and Miller *et al*. (2012) set out a range of criteria against which a commercially produced test can be evaluated for its fitness for purpose.

Researchers should be cautious in considering whether to employ commercially produced tests, particularly if using them with individuals and groups which are different from those in which the test was devised, as many tests show cultural bias (personality tests are prone to this, some being based on the 'Big-5' personality attributes which may exist but be less prominent in cultures other than those in which the test was produced).

Further, there is the issue of the language medium of the test; for example, using the Wechsler tests of intelligence (in English medium) with students who are not native speakers of English or who do not know about certain aspects of English culture renders the test less a test of intelligence and more a test of English-language ability and English cultural knowledge.

Many commercially produced tests are available in languages other than the original, but the translations should be checked to see if they are correct and for the cultural significance of the test items themselves, to see that they hold the same meaning, connotations and significance in the target language as they do in the original language. It is often dangerous to import tests developed in one language and one culture into another language and another culture, as there are problems of validity, bias, meaningfulness and reliability.

However, there are also several important considerations in devising a 'home-grown' test. Not only might it be time-consuming to devise, pilot, refine and then administer the test, but, because much of it will probably be non-parametric, there will be a more limited range of statistics which may be applied to the data than in the case of parametric tests.

The scope of tests and testing is far-reaching; no areas of educational activity are untouched by them. Achievement tests, largely summative in nature, measure achieved performance in a given content area. Aptitude tests are intended to predict capability, achievement potential, learning potential and future achievements. However, the assumption that these two constructs – achievement and aptitude – are separate is questionable (Cunningham, 1998); indeed often aptitude in, say, geography, at a particular age or stage will be measured by using an achievement test at that age or stage. Cunningham (1998) has suggested that an achievement test might include more straightforward measures of basic skills whereas aptitude tests might put these in combination, for example, combining reasoning (often abstract) and particular knowledge, i.e. achievement and aptitude tests differ according to what they are testing.

Not only do the tests differ according to what they measure, but, since both can be used predictively, they differ according to what they might be able to predict. For example, because an achievement test is often tied to a specific content area, it will be useful as a predictor of future performance in that content area but will be largely unable to predict future performance outside that content area. An aptitude test tends to test more generalized abilities (e.g. aspects of 'intelligence', skills and abilities that are common to several areas of knowledge or curricula), hence it can be used as a more generalized predictor of achievement. Achievement tests, Gronlund (1985) and Gronlund and Brookhart (2008) suggest, are more linked to school experiences, whereas aptitude tests encompass out-of-school learning and wider experiences and abilities. However, Cunningham (1998), arguing that there is a considerable overlap between the two types, suggests that the difference is largely cosmetic. An achievement test tends to be much more specific and linked to instructional programmes and cognate areas than an aptitude test, which looks for more general aptitudes (Hanna, 1993), for example, intelligence or intelligences (Gardner, 1993).

27.7 Constructing and validating a test

Researchers considering constructing a test of their own must be aware of classical test theory (CTT) and Item Response Theory (IRT). Classical test theory assumes

that there is a 'true score', which is the score which an individual would obtain on that test if the measurement was made without error and the expected score that would be gained over an infinite number of independent test administrations. It is the score that would be found by calculating the mean score that the individual test-taker would obtain on that same test if that person took it on an infinite number of occasions.

However, CTT recognizes that, in fact, errors do arise in the real world, due to, for example, cultural and socio-economic backgrounds and bias in the test, administration and marking of the test, and attitudes to the test by the test-takers. Hence tests provide an 'observed score' rather than a 'true score'; the observed score (X) is the true score (T) plus the error (E) (X=T+E). A true score in CTT depends on the contents of the test rather than the characteristics of the test-taker, and the difficulty of the items might depend on the characteristics of the sample (a sampling issue) rather than on the item itself, i.e. it may be difficult to compare the results of different test-takers on different tests. Readers are advised to review classical test theory and reliability in connection with this formula and the calculation of the error (e.g. Kline, 2005b).

By contrast, Item Response Theory (IRT) is based on the principle that it is possible to measure single, specific latent traits, abilities and attributes that, themselves, are not observable, i.e. to determine observable quantities of unobservable qualities (e.g. Hambleton, 1993). The theory/model assumes a relationship between a person's possession or level of a particular attribute, trait or ability and his/her response to a test item. IRT is also based on the view that it is possible:

- to identify objective levels of difficulty of an item, for example, the Rasch model (Wainer and Mislevy, 1990);
- to devise items that can discriminate effectively between individuals;
- to describe an item independently of any particular sample of people who might be responding to it, i.e. is not group dependent (the item difficulty and item discriminability are independent of the sample);
- to describe a testee's proficiency in terms of his or her achievement of an item of a known difficulty level;
- to describe a person independently of any sample of items that has been administered to that person (i.e. a testee's ability does not depend on the particular sample of test items);
- to specify and predict the properties of a test before it has been administered;
- for traits to be unidimensional (single traits are specifiable, e.g. verbal ability, mathematical proficiency) and to account for test outcomes and performance in terms of that unidimensional trait, i.e. for an item to measure a single, unidimensional trait;
- for a set of items to measure a common trait or ability;
- for a testee's response to any one test item not to affect his or her response to another test item;
- that the probability of the correct response to an item does not depend on the number of testees who might be at the same level of ability;
- to identify objective levels of difficulty of an item;
- to calculate a statistic which indicates the precision of the measured ability for each testee, and that this statistic depends on the ability of the testee and the number and properties of the test items.

In devising a test the researcher will have to consider not only the foundations of the test (e.g. in CTT or IRT) but also:

- the *purposes* of the test (for answering evaluation questions and ensuring that it tests what it is supposed to be testing, e.g. the achievement of the objectives of a piece of the curriculum);
- the *type* of test (e.g. diagnostic, achievement, aptitude, criterion-referenced, norm-referenced);
- the *objectives* of the test (cast in very specific terms so that the content of the test items can be seen to relate to specific objectives of a programme or curriculum);
- the *content* of the test (what is being tested and what the test items are);
- the relative *weightings* of the *content items* (to fit the *objectives* of the test, e.g. knowledge, understanding, application, synthesis, evaluation (using Bloom's *Taxonomy of Educational Objectives* (1956)));
- the relative *weightings* of the *content areas* (e.g. topic 1: 60 per cent; topic 2: 30 per cent; topic 3: 10 per cent);
- the relative *weightings* of the different *kinds of question* (e.g. multiple choice: 30 per cent; essay: 50 per cent; short answer: 20 per cent);
- the relative *weightings* of the items to match the *difficulty* of the test items (e.g. easy items: 10 per cent; slightly difficult: 20 per cent; moderately difficult: 40 per cent; difficult: 20 per cent; very difficult: 10 per cent);
- the *construction* of the test, involving *item analysis* in order to clarify the *item discriminability* and *item difficulty* of the test (see below);

- the *task suitability* of the test, for example, suitability for age and experiences of the students, what is being measured, how a question is to be answered;
- the *format* of the test: its layout, instructions, method of working and of completion (e.g. oral instructions to clarify what students must write, or a written set of instructions to introduce a practical piece of work);
- the *piloting* of the test;
- the *validity and reliability* of the test;
- the *scoring* of the test (allocation for marks, and on what criteria);
- the provision of a *manual of instructions* for the administration, marking and data treatment of the test (this is particularly important if the test is not to be administered by the researcher or if the test is to be administered by several different people, so that reliability is ensured by having a standard procedure).

Izard (2005, p. 33) suggests a sequence of test construction which proceeds thus: decisions to gather evidence and allocate resources → content analysis → item writing → by item review → item scoring → producing trial test and testing it → second item review followed by amendment → consideration of whether more items are required → production of final version of the test. In planning a test the researcher can proceed as set out below.

Identify the purposes of the test

The purposes of a test are several, for example to *diagnose* a student's strengths, weaknesses and difficulties, to measure *achievement*, to measure *aptitude* and *potential*, to assess *personality* attributes or types, to identify *readiness* for a programme (Gronlund and Linn (1990) term this 'placement testing', normally designed to discover whether students have the essential prerequisites to begin a programme, e.g. knowledge, skills, understandings).

These types of test occur at different stages. For example, the placement test is conducted prior to the commencement of a programme, and identifies the initial or 'entry' abilities in a student. If the placement test is designed to assign students to tracks, sets or teaching groups (i.e. to place them into administrative or teaching groups), then the entry test might be criterion-referenced or norm-referenced; if it is designed to measure detailed starting points, knowledge, abilities and skills then it might be more criterion-referenced as it requires a high level of detail. It has its equivalent in 'baseline assessment' and is an important feature if one is to measure the 'value-added' component of teaching and learning: one can only assess how much a set of educational experiences has added value to the student if one knows that student's starting point, starting abilities and achievements.

Formative testing is undertaken during a programme, and is designed to monitor students' progress during that programme, to measure achievement of sections of the programme and to diagnose strengths and weaknesses so that action can be targeted. It is typically criterion-referenced.

Diagnostic testing is an in-depth test to discover particular strengths, weaknesses and difficulties that a student is experiencing, and is designed to expose causes and specific areas of weakness or strength. This often requires the test to include several items about the same feature, so that, for example, several types of difficulty in a student's understanding are exposed; the diagnostic test requires test items that focus on each of a range of very specific difficulties that students might be experiencing, in order to identify the exact problems that they are having from a range of possible problems. Clearly this type of test is criterion-referenced.

Summative testing is the test given at the end of the programme, and is designed to measure achievement, outcomes or 'mastery'. This might be criterion-referenced or norm-referenced, depending to some extent on the use to which the results will be put (e.g. to award certificates or grades, to identify achievement of specific objectives, to control entry to university).

Identify the test specifications

Test specifications include:

- the programme objectives and student learning outcomes to be addressed;
- the content areas to be addressed;
- the relative weightings, balance and coverage of items, with weightings addressing objectives, content areas, kinds of question and difficulty of the items;
- the total number of items in the test;
- the number of questions required to address a particular element of a programme or learning outcomes;
- the exact items in the test.

To ensure validity in a test it is essential that the objectives of the test are addressed fairly in the test items. Objectives, it is argued (Mager, 1962; Wiles and Bondi, 1984, 2014), should: (a) be specific and expressed with an appropriate degree of precision; (b) represent intended learning outcomes; (c) identify the actual and observable behaviour which demonstrates achievement; (d) include an active verb; (e) be unitary (focusing on one item per objective).

The test must measure what it purports to measure. It should demonstrate several forms of validity (e.g. construct, content, concurrent, predictive, criterion-related), discussed below (see also Chapter 14).

One way of ensuring that the objectives are fairly addressed in test items is through a matrix frame that indicates the *coverage* of content areas, *objectives* of the programme and the *relative weighting* of the items on the test. Such a matrix is set out in Table 27.1, taking the example from a secondary school history syllabus.

Table 27.1 indicates the main areas of the programme to be covered in the test (*content areas*); then it indicates which *objectives* and detailed *content areas* are covered (1a – 3c) – these numbers refer to the identified specifications in the syllabus; then it indicates the marks/percentages to be awarded for each area. This indicates several points:

- the least emphasis is given to the build-up to and end of the war (10 marks each in the 'total' column);
- the greatest emphasis is given to the invasion of France (35 marks in the 'total' column);
- there is fairly even coverage of the objectives specified (the figures in the 'total marks possible' row only vary from 9 to 13);
- greatest coverage is given to objectives 2a and 3a, and least coverage is given to objective 1c;
- some content areas are not covered in the test items (the blanks in the matrix).

We have here a test scheme that indicates relative weightings, coverage of objectives and content, and the relation between these two latter elements. Gronlund and Linn (1990) and Miller *et al*. (2012) suggest that relative weightings should be addressed by first assigning percentages at the foot of each column, then assigning percentages at the end of each row, and then completing each cell of the matrix within these specifications. This ensures that appropriate sampling and coverage of the items are achieved. The example of the matrix refers to specific objectives as column headings; of course these could be replaced by factual knowledge, conceptual knowledge and principles, and skills for each of the column headings. Alternatively, they could be replaced with specific aspects of an activity, for example (Cohen *et al.*, 2010, p. 411): designing a crane, making the crane, testing the crane, evaluating the results, improving the design. Indeed these latter could become content (row) headings, as shown in Table 27.2. Here practical skills carry fewer marks than recording skills (the column totals), and

TABLE 27.1 A MATRIX OF TEST ITEMS

Content areas	*Objective/area of programme content*			*Objective/area of programme content*			*Objective/area of programme content*			*Total*
Aspects of the 1939–45 war	1a	1b	1c	2a	2b	2c	3a	3b	3c	
The build-up to the 1939–45 world war	1	2		2	1	1	1	1	1	10
The invasion of Poland	2	1	1	3	2	2	3	3	3	20
The invasion of France	3	4	5	4	4	3	4	4	4	35
The allied invasion	3	2	3	3	4	3	3	2	2	25
The end of the conflict	2	1		1	1	1	2	2		10
Total	11	10	9	13	12	10	13	12	10	100

TABLE 27.2 COMPILING ELEMENTS OF TEST ITEMS

Content area	*Identifying key concepts and principles*	*Practical skills*	*Evaluative skills*	*Recording results*	*Total*
Designing a crane	2	1	1	3	7
Making the crane	2	5	2	3	12
Testing the crane	3	3	1	4	11
Evaluating the results	3		5	4	12
Improving the design	2	2	3	1	8
Total	12	11	12	15	50

making and evaluating carry equal marks (the row totals).

This exercise also indicates the number of items to be included in the test; for instance in the example of the history test (Table 27.1), the matrix is $9 \times 6 = 54$ possible items, and in the 'crane' activity (Table 27.2) the matrix is $5 \times 4 = 20$ possible items. Of course, there could be considerable variation in this, for example more test items could be inserted if it were deemed desirable to test one cell of the matrix with more than one item (possible for cross-checking), or indeed there could be fewer items if a single test item could serve more than one cell of the matrix. The difficulty in matrix construction is that it can easily become a runaway activity, generating very many test items and, hence, leading to an unworkably long test; typically the greater the degree of specificity required, the greater the number of test items there will be. One skill in test construction is to be able to have a single test item that provides valid and reliable data for more than a single factor/area.

Having undertaken the test specifications, the researcher should have achieved clarity on: (a) the exact test items that test specified aspects of achievement of objectives, programmes, contents etc.; (b) the coverage and balance of coverage of the test items; and (c) the relative weightings of the test items.

Address validity and reliability

Validity

Validity concerns the extent to which the test tests what it is supposed to test; it must measure what it purports to measure. A test should demonstrate several kinds of validity (see also Chapter 14):

- *face validity*: the test must appear to assess what it was intended to test;
- *construct validity*: the extent to which the test measures a particular construct, trait, behaviour, evidenced through convergent validity and discriminant, divergent validity, and by correlating the test with other published tests with the same purposes and similar contents. The test must provide a fair operationalization of the construct – often abstract – in question, for example, intelligence, creativity, spatial awareness, problem solving. This is often the most challenging kind of validity to address, not least because opinion is divided on what a fair construction of the construct actually is. For example, exactly what intelligence is, and what proxy indicators of intelligence might be, can founder if there is disagreement on whether it is a single ability, a multiple ability (e.g. Gardner's 'multiple intelligences'), a composite, fixed or capable of being developed (nature or nurture). One statistical means of addressing construct validity is to seek inter-correlations between several items which are intended to measure the same construct (or to undertake factor analysis, itself based on inter-correlations). The principle here is that inter-correlations between items in a test that are intended to measure the same construct should be higher than inter-correlations between items that are not intended to measure the same construct or which are intended to measure different constructs. Different types of question intended to measure the same construct should have stronger inter-correlations than inter-correlations using the same types of question to assess different constructs;
- *content validity*: adequate and representative coverage of the domain, field, tasks, behaviours, knowledge etc., without interference from extraneous variables. The test must cover the intended contents in sufficient depth and breadth so as to be fair and adequate, and not to exceed the boundaries of content (i.e. not to cover items or contents that were not included in the programme or curriculum);
- *concurrent validity*: the extent to which the test scores correlate with those of other tests in a similar field;
- *predictive validity*: that the test accurately predicts final scores/outcomes. This concerns how much the results of an assessment can be used to predict achievements in the future, for example, how much the scores at university entrance level might be fair indicators of future degree classifications. Low predictive validity (e.g. lower than 50 per cent) suggests that limited credence should be placed in such uses;
- *criterion-related validity*: the extent to which the performance on the test enables the researcher to infer the individual's performance on a particular criterion of interest. This is often calculated as a correlation between the score on a test and a score in another indication of the item that the test was intended to measure, for example, a test of performance on a job-specific matter and the individual's actual performance on that job-specific item in the real situation;
- *cultural validity*: fairness to the language and culture of the individual test-takers, and avoidance of cultural bias: a feature of all research instruments, not solely tests;
- *consequential validity*: the results of the test are used fairly and ethically (discussed later), and are

only used for the purpose of, and ways in which, the test was constructed and intended to be used. This requires the researcher to be clear on the intentions of the test and its uses.

Reliability

Reliability concerns the degree of confidence that can be placed in the results, which is often a matter of statistical calculation and subsequent test redesign. It concerns the stability and consistency of test scores (e.g. if a student takes a test twice, or similar versions of the same test, the scores should be similar). Reliability is addressed through the forms and techniques set out in Chapter 14: test–re-test, parallel forms, split-half and internal consistency (Cronbach's alpha).

Reliability is compromised when students of the same ability and achievements score different results on the same test, when the same student scores differently on different tests of the same matters/contents, or when the same student scores differently on the same (or very similar) test on a different occasion. Reliability means that the results are consistent and reproducible with different markers, occasions, test items, test types, marking conventions, grading procedures and contexts.

Reliability concerns consistency and dependability, for example, of marking practices/conventions and standards. An assessment has little reliability if it yields different results in the hands of another assessor or different results for similar students. Reliability requires comparability of practices to be addressed. This can be undertaken prior to assessments by agreement trials, so that a range of assessors can be clear on, and can agree on, the specific marks and grades to be awarded for particular samples of work, examination scripts, course work and marks scored in each element of an overall assessment, though in practice it often only becomes an issue in the post-assessment agreement of marks (moderation) and awards. Reliability concerns, and affects, the degree of confidence that one can put on assessment data and their interpretation.

Not only must reliability be addressed but it must be *seen* to be addressed; marking must be seen to be fair, i.e. transparency. Reliability can be improved by, among other things: joint planning between researchers/markers; using the intended learning outcomes to agree objectives for the test; and developing common activities focused on agreed objectives.

Sources of unreliability

There are many threats to reliability, and researchers (and teachers) need to do their best to reduce them.

With respect to *examiners* and *markers*:

- errors in marking (e.g. attributing, adding and transfer of marks);
- inter-rater reliability (different markers giving different marks for the same or similar pieces of work);
- inconsistency in the examiner/marker (e.g. being harsh in the early stages of the marking and lenient in the later stages of the marking of many scripts);
- variations in the award of grades for work that is close to grade boundaries (some markers placing the score in a higher or lower category than other markers);
- the halo effect (or its opposite, the horns effect), wherein a student who is judged to do well or badly in one test/assessment is given undeserved favourable or unfavourable test/assessment respectively in other areas.

With reference to the *students* and *teachers* themselves:

- motivation and interest in the task has a considerable effect on performance. Motivation to participate in tests is strongest when students have been helped to see its purpose, and where the examiner maintains a warm, purposeful attitude towards them during the testing session;
- the relationship (positive to negative) between the tester and the testee exerts an influence on the test. This takes on increasing significance where the students know the researcher/teacher personally and professionally – and vice versa – and where the assessment situation involves face-to-face contact between the researcher/teacher and the student;
- the conditions – physical, emotional, social – exert an influence on the test, particularly if they are unfamiliar. The advice generally given in connection with the location of a test is that the test-room should be well-lit, quiet and adequately ventilated. Wherever possible, students should take tests in familiar settings, preferably in their own classrooms under normal school conditions. Distractions in the form of extraneous noise, walking about the room by the invigilator and intrusions into the room can have an impact on the scores of the test-takers;
- the Hawthorne effect, wherein, in this context, simply informing a student that this is a test will be enough to disturb her performance – for better or worse (either case not being a fair reflection of her usual abilities);
- teacher's marking may be prone to bias in the halo effect and in the teacher's own confusion – perhaps with the best of motives – between effort and

achievement, rewarding high effort and industry even though the achievement may be poor (and blind marking may not be as 'blind' as is imagined, as teachers recognize their students' handwriting);
- distractions (including superfluous information);
- the time of the day, week, month can exert an influence on performance. Some students are fresher in the morning and more capable of concentration;
- students are not always clear on what they think is being asked in the question; they may know the right answer but not infer that this is what is required in the question;
- a student may perform better with a different set of questions which test the same matters;
- teachers teach to the test. This is perhaps unsurprising in high-stakes tests. Here a biased result is obtained: students do well in the test without much understanding; they are groomed in test-taking;
- teachers and students practise test-like materials;
- teachers conducting their own tests may resort unconsciously to simplistic testing rather than richer and more extended forms of assessment;
- a student may be able to perform a specific skill in a test but not be able to select or perform it in the wider context of learning;
- cultural, ethnic and gender background affect how meaningful a test task or activity is to students, and meaningfulness affects their performance;
- students' personalities may make a difference to their test performance;
- students' learning strategies and styles may make a difference to their test performance;
- marking practices are not always reliable; teachers may be too generous, marking by effort and ability rather than performance;
- the context in which the task is presented affects performance: some students can perform the task in everyday life but not under test conditions.

With regard to the *test items*:

- the task itself may be multi-dimensional, for example, testing 'reading' may require several components and constructs. Students can execute a mathematics operation in the mathematics class but they cannot perform the same operation in, for example, a physics class. This raises the issue of the number of contexts in which the behaviour must be demonstrated before a criterion is deemed to have been achieved. The *context* of the task affects the student's performance;
- the validity of the items may be in question;
- the language of the test and the tester exerts an influence on the testee, for example, if the test is conducted in the testee's second language;
- the readability level of the task can exert an influence on the test, for example, a difficulty in reading might distract from the purpose of a test which is to test the use of a mathematical algorithm;
- the number and type of operations and stages to a task: a student might know how to perform each element, but when they are presented in combination the size of the task can be overwhelming;
- the form and presentation of questions affects the results, giving variability in students' performances;
- a single error early on in a complex sequence may confound the later stages of the sequence (within a question or across a set of questions), even though the student might have been able to perform the later stages of the sequence, thereby preventing the student from gaining credit for all she or he can, in fact, do;
- essay questions may favour males if they concern impersonal topics and females if they concern personal and interpersonal topics;
- males may perform better than females on multiple-choice questions and females may perform better than males on essay-type questions, and females may perform better in written work than males;
- some students may be more anxious about tests than others, and consequently their performance may suffer;
- questions and tests may be culture-bound: what is comprehensible in one culture may be incomprehensible in another;
- the test may be so long, in order to ensure coverage, that boredom and loss of concentration may impair reliability.

Select the contents of the test

Item analysis

Gronlund and Linn (1990), Izard (2005) and Miller *et al*. (2012) suggest that an item analysis will need to consider:

- the suitability of the format of each item for the (learning) objective (appropriateness);
- the fairness of the item for the age, educational level and experiences of the student;
- the representativeness of the item (an individual item or group of items) for the matter(s) to be tested;
- the ability of each item to enable students to demonstrate their performance of the (learning) objective (relevance);

- the task requirements and contents;
- what the task is intended to cover (e.g. which elements of the curriculum);
- the clarity of the task and its requirements for each item;
- the nature and contents of the answer (e.g. a single correct answer, a 'best' answer for the item);
- the language and wording used (e.g. its difficulty and age-appropriateness);
- the straightforwardness of the task;
- the removal of unintended clues;
- the unambiguity of the outcome of each item, and agreement on what that outcome should be;
- the cultural, gender, racial etc. fairness of each item;
- the meaningfulness of the task (e.g. for age, ability, experiences, culture);
- the independence of each item (i.e. where the influence of other items of the test is minimal and where successful completion of one item is not dependent on successful completion of another);
- the adequacy of coverage of each (learning) objective by the items of the test;
- practical concerns, such as timing and duration; whether the students will be told the scoring of items; advice on how and where to answer, for example, on the examination question sheet, on separate paper/computer; layout of the paper.

In test construction the researcher will need to consider how each element to be tested will be *operationalized*: (a) what indicators and kinds of evidence of achievement of the objective will be required; (b) what indicators of high, moderate and low achievement there will be; (c) how the task will be introduced (e.g. written, oral, pictorial, computer, practical demonstration); (d) what the students will be doing when they are working on each element of the test; (e) what the outcome of the test will be (e.g. a written response, a tick in a box of multiple-choice items, an essay, a diagram, a computation).

The Task Group on Assessment and Testing in the UK (1988) suggest that attention will have to be given to the *presentation*, *operation* and *response* modes of a test: (a) how the task will be introduced (e.g. oral, written, pictorial, computer, practical demonstration); (b) what the students will be doing when they are working on the test (e.g. mental computation, practical work, oral work, written); and (c) what the outcome will be – how they will show achievement and present the outcomes (e.g. choosing one item from a multiple-choice question, writing a short response, open-ended writing, oral, practical outcome, computer output).

Operationalizing a test from objectives can proceed by stages:

- identify the objectives/outcomes/elements to be covered;
- break down the objectives/outcomes/elements into constituent components or elements;
- select the components that will feature in the test, such that, if possible, they will represent the larger field (i.e. domain-referencing, if required);
- recast the components in terms of specific, practical, observable behaviours, activities and practices that fairly represent and cover that component;
- specify the kinds of data required to provide information on the achievement of the criteria;
- specify the success criteria (performance indicators) in practical terms, working out marks and grades to be awarded and how to address weightings;
- write each item of the test;
- conduct a pilot to refine the language/readability and presentation of the items, to gauge item discriminability, item difficulty and distracters (discussed below), and to address validity and reliability.

Item analysis, Gronlund and Linn (1990, p. 255) aver, is designed to ensure that: (a) the items function as they are intended, for example, that criterion-referenced items fairly cover the fields and criteria and that norm-referenced items demonstrate *item discriminability* (discussed below); (b) the level of difficulty of the items is appropriate (see below: *item difficulty*); (c) the test is reliable (free of distractors – unnecessary information and irrelevant cues, see below: *distractors*) (see Millman and Greene, 1993). An item analysis will consider the accuracy levels available in the answer, the item difficulty, the importance of the knowledge or skill being tested, the match of the item to the programme and the number of items to be included. The foundation for item analysis lies in Item Response Theory, discussed earlier.

Item discriminability

In constructing a test the researcher will need to address the *item discriminability* of each item of the test. *Item discriminability* refers to the potential of the item in question to be answered correctly by those students who have a lot of the particular quality that the item is designed to measure and to be answered incorrectly by those students who have less of the particular quality that the same item is designed to measure. In other words, how effective is the test item in showing up differences among a group of students? Does the item enable us to discriminate between students' abilities in

a given field? An item with high discriminability will enable the researcher to see a potentially wide variety of scores on that item; an item with low discriminability will show scores on that item poorly differentiated. Clearly a high measure of discriminability is desirable, and items with low discriminability should be discarded.

Suppose the researcher wishes to construct a test of mathematics for eventual use with thirty students in a particular school (or with class A in a particular school). The researcher devises a test and *pilots* it in a different school or class B respectively, administering the test to thirty students of the same age (i.e. she matches the sample of the pilot school or class to the sample in the school which eventually will be used). The scores of the thirty pilot children are then split into three groups of ten students each (high, medium and low scores). It would be reasonable to assume that there will be more correct answers to a particular item among the high scorers than among the low scorers. For each item compute the following:

$$\frac{A-B}{\frac{1}{2}(N)}$$

where:
A = the number of *correct* scores from the high-scoring group;
B = the number of *correct* scores from the low-scoring group;
N = the *total* number of students in the two groups.

Suppose all ten students from the high-scoring group answered the item correctly and two students from the low-scoring group answered the item correctly. The formula would work out thus:

$$\frac{8}{\frac{1}{2}(10+10)} = 0.80 \text{ (index of discriminability)}$$

The maximum index of discriminability is 1.00. Any item whose index of discriminability is lower than 0.67 is too undiscriminating and should be reviewed to find out whether this is due to ambiguity in the wording or possible clues in the wording. If this is not the case, then whether the researcher uses an item with an index lower than 0.67 is a matter of judgement. The item in the example here would be appropriate to use in a test. For a further discussion of item discriminability, see Linn (1993) and Aiken (2003).

One can use the discriminability index to examine the effectiveness of *distractors*. This is based on the premise that an effective distractor should attract more students from a low-scoring group than from a high-scoring group. Consider the following example, where low- and high-scoring groups are identified:

	A	*B*	*C*
Top 10 students	10	0	2
Bottom 10 students	8	0	10

In example A, the item attracts only a few more correct responses (10) from the top ten students than the bottom ten (8) and hence is a poor distractor. Example B is an ineffective distractor because nobody was included from either group. Example C is an effective distractor because it includes far more students from the bottom ten students (10) than the higher group (2). However, in this case any ambiguities must be ruled out before the discriminating power can be improved.

Distractors

Distractors are the stuff of multiple-choice items, where incorrect alternatives are offered, and students have to select the correct alternatives. Here a simple frequency count of the number of times a particular alternative is selected will provide information on the effectiveness of the distractor: if it is selected many times then it is working effectively; if it is seldom or never selected then it is not working effectively and should be replaced.

Item difficulty

Researchers do not wish to have a test which is too easy (the ceiling effect) nor too difficult (the floor effect) (Ary *et al*., 2002, pp. 218–19). In constructing a test, the researcher will need to address the *item difficulty* of each item of the test. If we wish to calculate the *item difficulty* of a test, we can use the following formula:

$$\frac{A}{N} \times 100$$

where:
A = the number of students who answered the item correctly;
N = the *total* number of students who attempted the item.

Hence if twelve students out of a class of twenty answered the item correctly, then the formula would work out thus:

$$\frac{12}{20} \times 100 = 60\%$$

The maximum index of difficulty is 100 per cent. Items falling below 33 per cent and above 67 per cent are likely to be too difficult and too easy respectively. It would appear, then, that this item would be appropriate to use in a test. Here, again, whether the researcher uses an item with an index of difficulty below or above the cut-off points is a matter of judgement. In a norm-referenced test the item difficulty should be around 50 per cent (Frisbie, 1981). For further discussion of item difficulty, see Linn (1993) and Hanna (1993).

With regard to item difficulty, in a criterion-referenced test the level of difficulty is that which is appropriate to the task or objective. Hence if an objective is easily achieved then the test item should be easily achieved; if the objective is difficult then the test item should be correspondingly difficult. This means that, unlike a norm-referenced test where an item might be reworked in order to increase its discriminability index, this is less of an issue in criterion-referencing. Of course, this is not to deny the value of undertaking an item difficulty analysis; rather it is to question the centrality of such a concern. Gronlund and Linn (1990, p. 265) suggest that where instruction has been effective the item difficulty index of a criterion-referenced test will be high.

Given that the researcher can only know the degree of item discriminability and difficulty once a test has been undertaken, there is an unavoidable need to pilot home-grown tests. Items with limited discriminability and limited difficulty must be weeded out and replaced, those items with the greatest discriminability and the most appropriate degrees of difficulty can be retained; this can only be undertaken once data from a pilot have been analysed.

Item discriminability and item difficulty have different significance in norm-referenced and criterion-referenced tests. In a norm-referenced test we wish to compare students with each other, hence item discriminability is very important. In a criterion-referenced test, on the other hand, it is not important per se to be able to compare or discriminate between students' performance. For example, it may be the case that we wish to discover whether a group of students has learnt a particular body of knowledge, that is the objective, rather than, say, finding out how many have learned it better than others. Hence it may be that a criterion-referenced test has very low discriminability if all the students achieve very well or achieve very poorly, but the discriminability is less important than the fact that the students have or have not learnt the material. A norm-referenced test would regard such a poorly discriminating item as unsuitable for inclusion, whereas a criterion-referenced test might regard such an item as providing useful information (on success or failure).

In addressing item discriminability, item difficulty and distractor effects of particular test items, it is advisable to pilot these tests and to avoid placing too great a store on indices of difficulty and discriminability that are computed from small samples.

In constructing a test with item analysis, item discriminability, item difficulty and distractor effects in mind, it is important also to consider the actual requirements of the test (Nuttall, 1987; Cresswell and Houston, 1991), for example:

- Are all the items in the test equally difficult?
- Which items are easy, moderately hard, hard, very hard?
- What kinds of task is each item addressing, for example, is it: (a) repeating known knowledge; (b) applying known knowledge; (c) a synthesis item – bringing together and integrating diverse areas of knowledge?
- What makes some items more difficult than the rest?
- Are the items sufficiently within the experience of the students?
- How motivated will students be by the contents of each item (i.e. how relevant they perceive the item to be, how interesting it is)?

The contents of the test will also need to take account of the notion of *fitness for purpose*, for example in the types of test items. Here the researcher will need to consider whether ability, understanding and achievement will be best demonstrated in, for example (Lewis, 1974; Cohen *et al*., 2010, chapter 15):

- an open essay;
- a factual and heavily directed essay;
- short answer questions;
- divergent thinking items;
- completion items;
- multiple-choice items (with one correct answer or more than one correct answer);
- matching pairs of items or statements;
- inserting missing words/numbers;
- incomplete sentences or incomplete, unlabelled diagrams;
- true/false statements;
- short essay questions;
- long essay questions;
- open-ended questions where students are given guidance on how much to write (e.g. 300 words, a sentence, a paragraph);
- closed questions.

These items can test recall, knowledge, comprehension, application, analysis, synthesis and evaluation, i.e. different orders of thinking, and the weighting of marks will reflect the emphasis given to different levels (orders) of thinking: low-order to high-order thinking. These take their rationale from Bloom (1956) on hierarchies of thinking – from low-order (comprehension, application), through middle-order (analysis, synthesis) to higher-order thinking (evaluation, judgement, criticism, creation). The selection of the form of the test item will be based on the principle of gaining the maximum amount of information in the most economical way (and machine-scorable multiple-choice completion tests, for example, enable optical mark readers and scanners to enter and process large-scale data rapidly).

In considering the contents of a test, the test writer must also consider the *scale* for some kinds of test. Many psychological tests used in educational research are *unidimensional*, that is, the items all measure a single element or dimension. Other tests may be *multi-dimensional*, i.e. where two or more factors or dimensions are being measured in the same test. Test constructors must be clear whether they are using a unidimensional or a multi-dimensional scale. Many texts, whilst advocating the purity of using a unidimensional test that measures a single construct or concept, also recognize the efficacy, practicality and efficiency in using multi-dimensional tests. For example, though one might regard intelligence as a unidimensional factor, in fact a stronger measure of intelligence would be obtained by regarding it as a multi-dimensional construct, thereby requiring multi-dimensional scaling. Some items on a test are automatically unidimensional, for example, age, hours spent on homework.

Further, the selection of the items needs to be considered in order to have the highest reliability. Let us say that we have ten items that measure students' negative examination stress. Each item is intended to measure stress, for example:

Item 1 Loss of sleep at examination time;
Item 2 Anxiety at examination time;
Item 3 Irritability at examination time;
Item 4 Depression at examination time;
Item 5 Tearfulness at examination time;
Item 6 Unwillingness to do household chores at examination time;
Item 7 Mood swings at examination time;
Item 8 Increased consumption of coffee at examination time;
Item 9 Positive attitude and cheerfulness at examination time;
Item 10 Eager anticipation of the examination.

You run a reliability test (see Chapter 40) of internal consistency and find strong inter-correlations between items 1–5 (e.g. around 0.85), negative correlations between items 9 and 10 and all the other items (e.g. –0.79), and a very low inter-correlation between items 6 and 8 and all the others (e.g. 0.26). Item-to-total correlations (one kind of item analysis in which the item in question is correlated with the sum of the other items) vary here. What do you do? You can retain items 1–5. For items 9 and 10 you can reverse the scoring (as these items looked at positive rather than negative aspects), and for items 6 and 8 you can consider excluding them from the test, as they appear to be measuring something else. Such item analysis is designed to include items that measure the same construct and to exclude items that do not. We refer readers to Howitt and Cramer (2005, chapter 12) for further discussion of this.

An alternative approach to deciding which items to retain or exclude from the list of ten items above is to use factor analysis (see Chapter 43). Factor analysis groups together a cluster of similar items and keeps that cluster separate from clusters of other items. So, for our example above, the factor analysis could have found, by way of illustration, three factors:

- positive feelings (items 9 and 10);
- negative psychological states (items 2, 3, 4, 5, 7);
- physical, behavioural changes (items 1, 6, 8).

By looking at the factor loadings (see Chapter 43) the researcher would have to decide which were the most appropriate factors to retain, and thereby which items to include and exclude. As a general rule, items with low factor loadings (e.g. <0.3) should be considered for exclusion, as they do not contribute sufficiently to the factor. Factor analysis will indicate, also, whether the construct is unidimensional or multi-dimensional (if there is only one factor it is probably unidimensional).

Consider the form of the test

Much of the discussion in this chapter assumes that the test is of the pen-and-paper variety. Clearly this need not be the case: for example, tests can be written, oral, practical, interactive, computer-based, dramatic, diagrammatic, pictorial, photographic, involve the use of audio and video material, presentations, role-play and simulations. Oral tests, for example, can be conducted if the researcher feels that reading and writing will obstruct the true purpose of the test (i.e. it becomes a reading and writing test rather than, say, a test of mathematics). The form of the test will still need to consider, for example, reliability and validity, difficulty, discriminability, marking and grading, item analysis,

timing. Indeed several of these factors take on an added significance in non-written forms of testing; for example: (a) reliability is a major issue in judging live musical performance or the performance of a gymnastics routine – where a live, 'one-off' event takes place; (b) reliability and validity are significant issues in group performance or group exercises – where group dynamics may prevent a testee's true abilities from being demonstrated. Clearly the researcher will need to consider whether the test will be undertaken individually, or in a group, and what form it will take.

Write the test item

Here the test item is written which will test the knowledge, skills, aptitudes, performance etc. of the student. Care must be taken to ensure that only the area in question is included, not other areas, and that the item is unambiguous, indicating clearly what is required and what will provide evidence of the matter being tested. Care must be taken to ensure that what is required to be measured is included rather than, for example, only what is easily measured (Izard, 2005, p. 35), i.e. avoid superficiality.

The test will need to address the intended and unintended clues that might be provided in it, for example (Morris *et al*., 1987):

- the number of blanks might indicate the number of words required;
- the number of dots might indicate the number of letters required;
- the length of blanks might indicate the length of response required;
- the space left for completion will give cues about how much to write;
- blanks in different parts of a sentence will be assisted by the reader having read the other parts of the sentence (anaphoric and cataphoric reading cues).

Hanna (1993, pp. 139–41) and Cunningham (1998) provide several guidelines for constructing short-answer items to overcome some of these problems:

- make the blanks close to the end of the sentence;
- keep the blanks the same length;
- ensure that there can be only a single correct answer;
- avoid putting several blanks close to each other (in a sentence or paragraph) such that the overall meaning is obscured;
- only make blanks of key words or concepts, rather than of trivial words;
- avoid addressing only trivial matters;
- ensure that students know exactly the kind and specificity of the answer required;
- specify the units in which a numerical answer is to be given;
- use short answers for testing knowledge recall.

With regard to multiple-choice items there are several potential problems:

- the number of choices in a single multiple-choice item, and whether there is one or more right answer(s);
- the number and realism of the distractors in a multiple-choice item, for example, there might be many distractors but many of them are too obvious to be chosen – there may be several redundant items;
- the sequence of items and their effects on each other;
- the location of the correct response(s) in a multiple-choice item.

Gronlund and Linn (1990), Hanna (1993, pp. 161–75), Cunningham (1998) and Aiken (2003) set out several suggestions for constructing effective multiple-choice test items:

- ensure that they catch significant knowledge and learning rather than low-level recall of facts;
- frame the nature of the issue in the stem of the item, ensuring that the stem is meaningful in itself (e.g. replace the general stem 'sheep: (a) are graminivorous, (b) are cloven-footed, (c) usually give birth to one or two lambs at a time', with 'how many lambs are normally born to a sheep at one time?');
- ensure that the stem includes as much of the item as possible, with no irrelevancies;
- avoid negative stems to the item;
- keep the readability levels low;
- ensure clarity and unambiguity;
- ensure that all the options are plausible so that guessing of the only possible option is avoided;
- avoid the possibility of students making the correct choice through incorrect reasoning;
- include some novelty to the item if it is being used to measure understanding;
- ensure that there can only be a single correct option (if a single answer is required) and that it is unambiguously the right response;
- avoid syntactical and grammatical clues by making all options syntactically and grammatically parallel and by avoiding matching the phrasing of a stem with similar phrasing in the response;

- avoid including in the stem clues as to which may be the correct response;
- ensure that the length of each response item is the same (e.g. to avoid one long correct answer from standing out);
- keep each option separate, avoiding options which are included in each other;
- ensure that the correct option is positioned differently for each item (e.g. so that it is not always option 2);
- avoid using options such as 'all of the above' or 'none of the above' unless essential;
- avoid answers from one item being used to cue answers to another item – keep items separate.

The response categories of tests need to be considered, and we refer readers to our discussion of this topic in Chapter 24 on questionnaires (e.g. Likert scales, Guttman scales, semantic differential scales, Thurstone scales).

Morris *et al.* (1987, p. 161), Gronlund and Linn (1990), Hanna (1993, p. 147), Cunningham (1998) and Aiken (2003) also indicate particular problems in true/false questions:

- ambiguity of meaning;
- some items might be partly true or partly false;
- items that polarize: too easy or too hard;
- most items might be true or false under certain conditions;
- it may not be clear to the student whether facts or opinions are being sought;
- as this is dichotomous, students have an even chance of guessing the correct answer;
- an imbalance of true to false statements;
- some items might contain 'absolutes' which give powerful clues, for example, 'always', 'never', 'all', 'none'.

To overcome these problems the authors suggest several points that can be addressed:

- avoid generalized statements (as they are usually false);
- avoid trivial questions;
- avoid negatives and double negatives in statements;
- avoid over-long and over-complex statements;
- ensure that items are rooted in facts;
- ensure that statements can only be either true or false;
- write statements in everyday language;
- decide where it is appropriate to use 'degrees' – 'generally', 'usually', 'often' – as these are capable of interpretation;
- avoid ambiguities;
- ensure that each statement only contains one idea;
- if an opinion is to be sought then ensure that it is attributable to a named source;
- ensure that true statements and false statements are equal in length and number.

Morris *et al.* (1987), Hanna (1993, pp. 150–2), Cunningham (1998) and Aiken (2003) also indicate particular potential difficulties in matching items:

- it might be very clear to a student which items in a list simply *cannot* be matched to items in the other list (e.g. by dint of content, grammar, concepts), thereby enabling the student to complete the matching by elimination rather than understanding;
- one item in one list might be able to be matched to several items in the other;
- the lists might contain unequal numbers of items, thereby introducing distractors – rendering the selection as much a multiple-choice item as a matching exercise.

The authors suggest that difficulties in matching items can be addressed thus:

- ensure that the items for matching are homogeneous – similar – over the whole test (to render guessing more difficult);
- avoid constructing matching items to answers that can be worked out by elimination, for example, by ensuring that: (a) there are different numbers of items in each column so that there are more options to be matched than there are items; (b) students can avoid being able to reduce the field of options as they increase the number of items that they have matched; (c) the same option may be used more than once;
- decide whether to mix the two columns of matched items, i.e. ensure, if desired, that each column includes both items and options;
- sequence the options for matching so that they are logical and easy to follow, for example, by number, by chronology;
- avoid over-long columns and keep the columns on a single page;
- make the statements in the options columns as brief as possible;
- avoid ambiguity by ensuring that there is a clearly suitable option that stands out from its rivals;
- make it clear what the nature of the relationship should be between the item and the option (on what terms they relate to each other);
- number the items and letter the options.

With regard to essay questions, there are several claimed advantages. For example, an essay, as an open form of testing, enables complex learning outcomes to be measured, it enables the student to integrate, apply and synthesize knowledge, to demonstrate the ability for expression and self-expression, and to demonstrate higher-order and divergent cognitive processes. Further, it is comparatively easy to construct an essay title. On the other hand, essays have been criticized for yielding unreliable data (Gronlund and Linn, 1990; Cunningham, 1998) and for being prone to unreliable scoring (inconsistent and variable), neglectful of intended learning outcomes and prone to marker bias and preference (being too intuitive, subjective, holistic and time-consuming to mark). To overcome these difficulties, the authors suggest that:

- the essay question must be restricted to those learning outcomes that are unable to be measured more objectively;
- the essay question must ensure that it is clearly linked to desired learning outcomes; that it is clear what behaviours the students must demonstrate;
- the essay question must indicate the field and tasks very clearly (e.g. 'compare', 'justify', 'critique', 'summarize', 'classify', 'analyse', 'clarify', 'examine', 'apply', 'evaluate', 'synthesize', 'contrast', 'explain', 'illustrate');
- time limits are set for each essay;
- options are avoided, or, if options are given, ensure that, if students have a list of titles from which to choose, each title is equally difficult and equally capable of enabling the student to demonstrate achievement, understanding etc.;
- marking criteria are prepared and are explicit, indicating what must be included in the answers and the points to be awarded for such inclusions or ratings to be scored for the extent to which certain criteria have been met;
- decisions are agreed on how to address and score irrelevancies, inaccuracies, poor grammar and spelling;
- the work is blind double marked (markers are undisclosed to each other), and, where appropriate, blind marked (without the marker knowing (the name of) the essay writer).

These are issues of reliability (see Chapter 14). For a general introduction to writing test items, see Cohen and Wollack (2010).

Consider the layout of the test

This will include (Gronlund and Linn, 1990; Hanna, 1993; Linn, 1993; Cunningham, 1998):

- the nature, length and clarity of the instructions, for example, what to do, how long to take, how much to do, how many items to attempt, what kind of response is required (a single word, a sentence, a paragraph, a formula, a number, a statement etc.), how and where to enter the response, where to show the 'working out' of a problem, where to start new answers (e.g. in a separate booklet), whether one answer only is required to a multiple-choice item, or whether more than one answer is required;
- spreading out the instructions through the test, avoiding overloading students with too much information at first, and providing instructions for each section as they come to it;
- indicating the marks able to be awarded for each part of the test;
- minimizing ambiguity and taking care over the readability of the items;
- progression from the easy to the more difficult items of the test (i.e. the location and sequence of items);
- the visual layout of the page, for example, avoiding overloading students with visual material or words;
- the grouping of items – keeping together items that have the same contents or the same format;
- the layout of answer sheets/locations so that they can be entered onto computers and read by optical mark readers and scanners (if appropriate).

Layout can exert a profound effect on the test. The layout of the text should be such that it supports the completion of the test and that this is done as efficiently and as effectively as possible for the student.

Consider the timing of the test

This refers to two areas: (a) when the test will take place (the day of the week, month, time of day), and (b) the time allowances to be given to the test and its component items. With regard to the former, in part this is a matter of reliability, for the time of day, day of the week etc. might influence how alert, motivated or capable a student might be. With regard to the latter, the researcher will need to decide what time restrictions are being imposed and why, for example, is the pressure of a time constraint desirable – to show what a student can do under time pressure (a speed test) – or an unnecessary impediment, putting a time boundary around something that need not be bounded – was Van Gogh put under a time pressure to produce the painting of sunflowers?

Though it is vital that the student knows what the overall time allowance is for the test, clearly it might be helpful to the student to indicate notional time allowances for different elements of the test; if these are aligned to the relative weightings of the test (see the discussions of weighting and scoring) they enable a student to decide where to place emphasis in the test – she may want to concentrate her time on the high-scoring elements of the test. Further, if the items of the test have exact time allowances, this enables a degree of standardization to be built into the test, and this may be useful if the results are going to be used to compare individuals or groups.

Plan the scoring of the test

The awarding of scores for different items of the test is a clear indication of the relative significance of each item – the weightings of each item are addressed in their scoring. It is important to ensure that easier parts of the test attract fewer marks than the more difficult parts, otherwise a student's results might be artificially inflated by answering many easy questions and fewer more difficult questions (Gronlund and Linn, 1990). Additionally, there are several attractions to making the scoring of tests as detailed and specific as possible (Cresswell and Houston, 1991; Gipps, 1994; Aiken, 2003; Izard, 2005), awarding specific points for each item and sub-item, for example:

- it enables partial completion of the task to be recognized – students gain marks in proportion to how much of the task they have completed successfully (an important feature of domain-referencing);
- it enables a student to compensate for doing badly in some parts of a test by doing well in other parts of the test;
- it enables weightings to be made explicit to the students;
- it enables the rewards for successful completion of parts of a test to reflect considerations such as the length of the item, the time required to complete it, its level of difficulty, its level of importance;
- it facilitates moderation because it is clear and specific;
- it enables comparisons to be made across groups by item;
- it enables reliability indices to be calculated (see discussions of reliability);
- scores can be aggregated and converted into grades straightforwardly.

Ebel (1979) argues that the more marks that are available to indicate different levels of achievement (e.g. for the awarding of grades), the greater the reliability of the grades will be, though clearly this could make the test longer. Scoring will also need to be prepared to handle issues of poor spelling, grammar and punctuation; is it to be penalized, and how will consistency be assured here? Further, how will issues of omission be treated, for example, if a student omits the units of measurement (miles per hour, dollars or pounds, metres or centimetres)?

Related to the scoring of the test is the issue of reporting the results. Results may be reported item by item, section by section, or by the whole test. This degree of flexibility might be useful for the researcher, as it will enable particular strengths and weaknesses in groups of students to be exposed.

The desirability of some of the above points is open to question. For example, it could be argued that the strength of criterion-referencing is precisely its specificity, and that to aggregate data (e.g. to assign grades) is to lose the very purpose of the criterion-referencing (Gipps, 1994, p. 85). For example, if I am awarded a grade E for spelling in English, and a grade A for imaginative writing, this could be aggregated into a C grade as an overall grade of my English-language competence, but what does this C grade mean? It is meaningless, it has no frame of reference or clear criteria, it loses the useful specificity of the A and E grades, it is a compromise that actually tells us nothing. Further, aggregating such grades assumes equal levels of difficulty of all items.

If a test is designed to assess 'mastery' of a subject, then the researcher is faced with the issue of deciding what constitutes 'mastery' – is it an absolute (i.e. very high score) or are there gradations, and if the latter, then where do these gradations fall (or is it a pass/fail: either a driver can reverse safely round a corner or he can't)? For published tests, the scoring is standardized and already made clear, as are the conversions of scores into, for example, percentiles and grades.

Underpinning the discussion of scoring is the need to make it unequivocally clear exactly what the marking criteria are: what will and will not score points. This requires a clarification of whether there is a 'checklist' of features that must be present in a student's answer.

Criterion-referenced tests will have to declare their lowest boundary: a cut-off point below which the student has been deemed to fail to meet the criteria. A compromise can be seen in those criterion-referenced tests which award different grades for different levels of performance of the same task, necessitating the clarification of different cut-off points in the examination, where compensation is possible (a fail in one area can be compensated by a high pass in another, for example, pianoforte examinations).

Ebel (1979) argues that one principle in assignation of grades is that they should represent equal intervals on the score scales. Reference is made to median scores and standard deviations, median scores because it is meaningless to assume an absolute zero on scoring, and standard deviations as the unit of convenient size for inclusion of scores for each grade (see also Cohen and Holliday, 1996). One procedure is thus:

Step 1 Calculate the median and standard deviation of the scores.
Step 2 Determine the lower score limits of the mark intervals using the median and the standard deviation as the unit of size for each grade.

However, the issue of cut-off scores is complicated by the fact that they may vary according to the different purposes and uses of scores (e.g. for diagnosis, for certification, for selection, for programme evaluation), as these purposes will affect the number of cut-off points and grades and the precision of detail required. For a full analysis of determining cut-off grades, see Linn (1993).

The issue of scoring covers a range of factors, such as grade norms, age norms, percentile norms and standard score norms, for example, z-scores and T-scores (see Chapter 42), stanine scores, percentiles (see Chapter 40). Readers are referred to Cronbach (1970), Gronlund and Linn (1990), Cohen and Holliday (1996) and Hopkins *et al*. (1996) for further discussion of these.

Pilot the test

Piloting can be done in several ways:

- a small group of experts can examine the items in the test for their suitability, validity, relevance, possible cultural biases and sources of invalidity and unreliability, remoteness from the test-takers' experiences;
- a small group of test-takers, asking them to give feedback on:
  - the clarity of the items, instructions and layout
  - ambiguities or difficulties in wording
  - readability levels and language problems for the target audience
  - the *type* of question and its format (e.g. rating scale, multiple choice, open, closed etc.)
  - response categories for closed questions and multiple-choice items, and for the appropriateness of specific questions or stems of questions
  - omissions, redundant and irrelevant items
  - the clarity of the layout of the test
  - the time taken to complete the test
  - the complexity of the test items;
- involve a larger group of test-takers, to gather sufficiently large-scale data to calculate reliability levels (alphas), item difficulty and item discriminability, to identify commonly misunderstood or non-completed items, to check which items are consistently omitted or not reached (i.e. if the time was too short so that test-takers run out of time) and to be able to test out the marking scheme.

27.8 Software for preparation of a test

There are very many websites that researchers can visit to download software either free or for inexpensive purchase for test preparation, construction, layout, marking and for collation and weighting of marks, and we list these on the accompanying website. Such software does not exonerate the researcher/test deviser from the thinking that goes into the test construction; rather, it follows from that thinking and preparation, and turns it into practical formats for administration either in hard copy or online. These kinds of software packages do not address validity and reliability, and the researcher will need to pilot and refine the test before final use.

The use of software and online testing can remove some of the burden of marking, data entry and analysis, as online tests can perform these calculations automatically (e.g. for closed/multiple-choice items), and optical mark scanners can also be used to read in marks from hard copy into a computer file.

27.9 Devising a pre-test and post-test

The construction and administration of tests is an essential part of the experimental model of research, where a pre-test and a post-test must be devised for the control and experimental groups. The pre-test and post-test must adhere to several guidelines:

- The pre-test may have questions which differ in form or wording from the post-test, though the two tests must test the same content, i.e. they will be alternate forms of a test for the same groups.
- The pre-test must be the same for the control and experimental groups.
- The post-test must be the same for both groups.
- Care must be taken in the construction of a post-test to avoid making the test easier to complete by one group than another.
- The level of difficulty must be the same in both tests.

Test data feature centrally in the experimental model of research; additionally, they may feature as part of a questionnaire, interview and documentary material.

27.10 Ethical issues in testing

A major source of unreliability of test data derives from the extent and ways in which students have been prepared for the test. These can be located on a continuum from direct and specific preparation, through indirect and general preparation, to no preparation at all. With the growing demand for test data (e.g. for selection, certification, grading, employment, tracking, entry to higher education, accountability, judging schools and teachers) there is a perhaps understandable pressure to prepare students for tests. This is the 'high-stakes' aspect of testing, where much hinges on the test results. At one level this can be seen in the backwash effect of examinations on curricula and syllabuses; at another level it can lead to the direct preparation of students for specific examinations (Zhao, 2014). Preparation can take many forms (Mehrens and Kaminski, 1989; Gipps, 1994; Zhao, 2014):

- ensuring coverage, among other programme contents and objectives, of the objectives and programme that will be tested;
- restricting the coverage of the programme content and objectives only to those that will be tested;
- preparing students with 'exam technique';
- practising with past/similar papers;
- directly matching the teaching to specific test items, where each piece of teaching and contents is the same as each test item;
- practising on an exactly parallel form of the test;
- telling students in advance what will appear on the test;
- practising on, and preparation of, the identical test itself (e.g. giving out test papers in advance) without teacher input;
- practising on, and preparation of, the identical test itself (e.g. giving out the test papers in advance), with the teacher working through the items, maybe providing sample answers.

How ethical it is to undertake the final four of these, or indeed any apart from the first on the list, is questionable. Are the items cheating or legitimate test preparation? Should one teach to a test; is not to do so a dereliction of duty (e.g. in criterion- and domain-referenced tests) or giving students an unfair advantage and thus reducing the reliability of the test as a true and fair measure of ability or achievement? In high-stakes testing (e.g. for public accountability, to compare schools and teachers, for entrance to higher education and employment) there is even the issue of not entering for tests students whose performance will be low (e.g. Haladyna *et al*., 1991). There is a risk of a correlation between the 'stakes' and the degree of unethical practice: the greater the stakes, the greater the incidence of unethical practice. Unethical practice occurs where scores are inflated but reliable inference on performance or achievement is not, and where different groups of students are prepared differentially for tests, i.e. giving some students an unfair advantage over others. To overcome such problems, it is ethical and legitimate for teachers to teach to a broader domain than the test, teachers should not teach directly to the test, and the situation should only be that better instruction rather than test preparation is acceptable (Cunningham, 1998).

One can add to this list of considerations (Cronbach, 1970; Hanna, 1993; Cunningham, 1998) the view that:

- tests must be valid and reliable (see Chapter 14);
- the administration, marking and use of the test should only be undertaken by suitably competent/qualified people (i.e. people and projects should be vetted);
- access to test materials should be controlled, for instance: test items should not be reproduced apart from selections in professional publications; the tests should only be released to suitably qualified professionals in connection with specific professionally acceptable projects;
- tests should benefit the testee (beneficence);
- clear marking and grading protocols should exist (the issue of transparency is discussed in Chapter 7);
- test results are only reported in a way that cannot be misinterpreted;
- the privacy and dignity of individuals should be respected (e.g. confidentiality, anonymity, non-traceability);
- individuals should not be harmed by the test or its results (non-maleficence);
- informed consent to participate in the test should be sought.

Whilst the use of tests in research is bound by the same ethical requirements as other forms of data collection (e.g. informed consent, non-maleficence, anonymity and confidentiality, rights to non-participation and withdrawal etc.), a further major ethical issue concerns the use made of the test data (consequential validity). Here the test data should only be used for the purpose for which the test was constructed; too often test data become used for purposes other than these, and this is ethically highly questionable.

27.11 Computerized adaptive testing

Computerized adaptive testing (Wainer and Dorans, 2000; Aiken, 2003; Wainer, 2015) focuses on which particular test items to give to participants, based on their responses to previous items. It is particularly useful for large-scale testing, where a wide range of ability can be expected. Here a test is devised that enables the tester to cover this wide range of ability, hence it must include some easy to some difficult items; too easy and it does not enable a range of high ability to be charted (testees simply getting all the answers right); too difficult and it does not enable a range of low ability to be charted (testees simply getting all the answers wrong). We find out very little about a testee if we ask a battery of questions which are too easy or too difficult. Further, it is more efficient and reliable if a test can avoid the problem for high-ability testees of having to work through a mass of easy items in order to reach the more difficult items and for low-ability testees of having to try to guess the answers to more difficult items. Hence it is useful to have a test that is flexible and that can be adapted to the testees. For example, if a testee found an item too hard the next item could adapt to this and be easier, and, conversely, if a testee was successful on an item the next item could be harder.

Wainer (2015) indicates that in an adaptive test the first item is pitched in the middle of the assumed ability range; if the testee answers it correctly then it is followed by a more difficult item, and if the testee answers it incorrectly then it is followed by an easier item. Computers provide an ideal opportunity to address the flexibility, discriminability and efficiency of testing. Aiken (2003, p. 51) suggests that computer adaptive testing can reduce the number of test items present to around 50 per cent of those used in conventional tests. Testees can work at their own pace, they need not be discouraged but can be challenged, the test is scored instantly to provide feedback to the testee, a greater range of items can be included in the test and a greater degree of precision and reliability of measurement can be achieved; indeed test security can be increased and the problem of understanding answer sheets is avoided.

Computer adaptive testing has several putative attractions. On the other hand, it requires different skills from those in traditional tests, which might compromise the reliability of the test, for example:

- the mental processes required to work with a computer screen and computer program differ from those required for a pen-and-paper test;
- motivation and anxiety levels increase or decrease when testees work with computers;
- the physical environment might exert a significant difference, for example, lighting, glare from the screen, loading and running the software;
- reliability shifts from an index of the variability of the test to an index of the standard error of the testee's performance. The usual formula for calculating standard error assumes that error variance is the same for all scores, whereas in Item Response Theory it is assumed that error variance depends on each testee's ability – the conventional statistic of error variance calculates a single average variance of summed scores, whereas in Item Response Theory this is at best very crude, and at worst misleading as variation is a function of ability rather than test variation and cannot fairly be summed (see Thissen (1990) for an analysis of how to address this issue);
- having so many test items increases the chance of including poor items.

Computer adaptive testing requires a large item pool for each area of content domain to be developed (Wainer, 2015), with sufficient numbers, variety and spread of difficulty. All items must measure a single aptitude or dimension, and the items must be independent of each other, i.e. a person's response to an item should not depend on that person's response to another item. The items have to be pre-tested and validated, their difficulty and discriminability calculated, the effect of distractors reduced, the capability of the test to address unidimensionality and/or multi-dimensionality to be clarified, and the rules for selecting items to be enacted.

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Using secondary data in educational research

CHAPTER 28

This chapter introduces researchers to the use of secondary data in educational research. It raises considerations such as:

- defining secondary data
- advantages of using secondary data
- challenges in using secondary data
- ethical issues in using secondary data
- examples of secondary data analysis
- working with secondary data

28.1 Introduction

Secondary data are a valuable source for researchers, yet, despite the massive amount of such data on the Internet, they are often under-used by educational researchers (Smith, 2011). They have considerable potential for yielding important insights and foci for research (Heaton, 2008). Secondary analysis can be used to test hypotheses, to generate new knowledge and to support, challenge and extend existing theories or findings (Heaton, 1998, 2008).

Defining secondary data is not straightforward, as there are many definitions. However, generally speaking, secondary data and its analysis work on data that were originally collected for a different purpose (Glaser, 1963, p. 11) or use pre-existing data, sometimes from the same researcher but usually collected by someone else, for answering new or additional research questions or 'to pursue a research interest that is distinct from that of the original research' (Heaton, 1998, p. 1), addressing new or additional purposes, or re-analysing existing data from a new angle or with new analytical tools (cf. Vartanian, 2011). In a sense they can be regarded as second-hand data, having already been used previously. Such data often come in the form of survey data, and comprise, for example:

- official statistics;
- national surveys (census and survey data from governments or organizations), for example, the General Household Survey;
- universities' and other institutions' records and administrative data;
- international surveys and assessments, for example, Trends in International Mathematics and Science Study (TIMMS), the Programme for International Student Assessment (PISA), the Progress in International Reading Literacy Study (PIRLS);
- ongoing databases (e.g. the National Pupil Database);
- longitudinal, regular and cohort studies (e.g. the British Household Panel Survey, the British Cohort Study, national birth cohort studies such as the Millennium Cohort Study, the National Child Development Study, the Longitudinal Study of Young People in England, the German National Educational Panel Study);
- data archives (e.g. the Consortium for European Social Science Data Archives; the European Social Survey);
- large-scale, specific surveys (e.g. the Youth Cohort Study, the Young People's Social Attitudes Survey);
- learning analytics;
- library records;
- accounts;
- administrative records (e.g. from governments and professions, such as the Department for Education).

Secondary data, both quantitative and qualitative, can also include meta-analyses, literature, reports, technical reports and summaries, scholarly journals and books, though some might argue that these are tertiary data, for example, summaries of previous secondary data.

Data for secondary analysis are held in national and international databases, for example:

- UNESCO
- OECD
- Programme for International Student Assessment (PISA)
- Trends in International Mathematics and Science Study (TIMMS)
- World Bank
- Higher Education Statistics Agency
- Higher Education Funding Council for England (HEFCE)
- government offices

- Office for National Statistics
- National Center for Educational Statistics
- data archives
- National Pupil Database
- What Works Clearinghouse
- Social Trends Database
- government department databases (e.g. the Department for Education)
- Skills Funding Agency
- Education Funding Agency
- UK Data Service
- British Social Attitudes Survey
- Universities Central Admissions Service (UCAS)
- organizations which provide information about and access to databases on educational topics
- other data providers: for example, the Inter-University Consortium for Political and Social Research.

The websites for these are provided in the companion website.

Vignoles (2007) notes that many governments are linking data from different studies by giving a unique identifier to each individual. She comments on potential benefits here but also potential ethical problems, for example, who has oversight and access and how confidentiality is to be addressed. Mostafa (2016) reports steps that have been taken to link education, health and economic records, and issues of privacy, confidentiality and consent that this raises.

Secondary data can be quantitative and/or qualitative. Quantitative data often feature in surveys, assessment data, census returns and government data sets, and can contribute to the 'political arithmetic' tradition (Smith, 2008). Heaton (2008) identifies five types of secondary analysis of qualitative data:

- supplementary analysis: in-depth analysis and additional subset/sub-sample analysis of an issue or aspect of the data that only emerged from, or which was only partially addressed in, the original research;
- supra analysis: where 'the aims and focus of the secondary study transcend those of the original research' (p. 35);
- re-analysis: to validate and confirm findings of the original study;
- amplified analysis: to conduct comparative or combined analysis of two or more qualitative data sets;
- assorted analysis: to use existing data with new primary data in the same study.

Heaton's classification alerts the researcher to the need to distinguish between microdata, metadata and results.

28.2 Advantages of using secondary data

Using secondary data has many attractions (e.g. Vignoles, 2007; Smith, 2008, 2011, 2012; Long-Sutehall *et al*., 2010; Mueller and Hart, 2010; Yorke, 2011; Gorard, 2013; Johnston, 2014; Morrow *et al*., 2014; Mostafa, 2016). For example, the scale, scope and amount of the data are usually much larger and more representative than a single researcher could gather, and the large scale and scope of data can be analysed at a level of complexity not available to smaller-scale research. Large-scale data may be more robust than small-scale data, with greater validity, and the quality of the data might be higher and more rigorous than those collected by individuals. Indeed the data have already been collected; they already exist, so the researcher does not need to worry too much about challenges of data collection, for example, financing the data collection, time taken to collect data (particularly from large samples), access to people, permissions from gatekeepers etc. Secondary data are low-cost, even free of charge, convenient and not beyond the scope of the individual researcher; they save time and money, and they are often cheaper than new research. Access to secondary data is often quick, even immediate, and this holds the advantage of timeliness and speed for decision making, in contrast to some data which require a longer time to collect; they are accessible to all and typically without much bureaucratic procedure.

Secondary data provide materials for useful descriptive analysis and the range of topics available is vast. Data come from different sources and can be combined to yield a robust analysis; they can be analysed using different approaches and perspectives which were not undertaken in the original research. Alternative relationships between variables can be explored, and new modelling techniques and statistics that were not available when the original data were produced can be tried and tested. Indeed the data may be used for research training and practice purposes, i.e. for capacity building.

As secondary data are already in existence, the research is unobtrusive and can respect ethical issues of privacy, confidentiality, anonymity, non-traceability and leaving people alone. Data may exist on sensitive topics and from 'hard to reach' people (Smith, 2008, p. 40) or an 'elusive population' (Fielding, 2004), which a researcher might otherwise have difficulty in gathering, from groups and topics to which access may be restricted or banned, for example, prisoners, victims of child abuse. Oversampling of some hard-to-reach

groups may give greater precision to the data, and data from sub-groups and minority and vulnerable groups may be sufficient for robust data analysis. Further, the data may be about a population from which a sample can be drawn.

With regard to populations and sampling, many of the data types (e.g. administrative data, government-funded research) are at the individual level, thereby enabling detailed analysis over time and contexts, and enabling systemic or ecological factors to be explored. The data may be about a population from which a sample can be drawn.

Making secondary data available serves scientific, utilitarian, pragmatic and moral arguments (for the public good and for greater benefit from public money spent on research). The data may be used for triangulation (e.g. of perspectives, sources, data, methods, time, location etc.), for longitudinal studies, replication studies, for re-analysis and re-interpretation of existing studies, and for trend analysis. They can be used to identify problems or areas for further research, to develop research questions, and for setting a context or background for further in-depth or mixed methods study, or, indeed, be a part of a mixed methods study.

28.3 Challenges in using secondary data

Secondary data are not without their challenges (e.g. Dale *et al*., 1998; Coyer and Gallo, 2005; Croxford, 2006; Vignoles, 2007; Smith, 2008; Yorke, 2011; Mostafa, 2016). For example, such data have been collected for purposes, interests, and to answer research questions and in contexts (however defined) that differ substantially from those of the present researcher, and this may bias the present research. The data may not be a sufficiently close fit to the conceptual framework, purposes, sampling or data types sought for the present research. The definitions used in the original data may be a poor fit to the present research and may change over time, and, indeed, there may be limited or no evidence on how the original data were collected, from whom and by whom, and with what response rates. Knowledge of the original research design, instruments and methods for the data collection may be unavailable and there may be limited accompanying information on the studies.

For example, in longitudinal studies, even for the same named survey (e.g. the Youth Cohort Surveys), at each time point: the designs may change; the impact of competitive tendering may affect the study (e.g. different people or institutions conduct the study); there may be inadequate, ambiguous, inconsistent or different questions and coding of responses; classifications and categories, and what is entered into them, may change over time (Uprichard, 2012); definitions and scope of issues may change; there may be a lack of continuity in content, questions, foci and analysis; there may be inadequate documentation of procedures used from the previous time; and there may be sample attrition (Croxford, 2006).

Further, there may be restrictions on how the data may be used and shared, including attention to ethical issues of informed consent and confidentiality in an era of freedom of information, and restrictions on when the data become available for public access and use. Some holders of primary research data may not permit access or may be reluctant to grant access.

Secondary data may not be neutral, but may emanate from governments, associations and institutions, i.e. those with power and with a particular agenda at the time (e.g. unemployment and welfare data and how they are measured, recognizing that how they are measured changes over time). Such data, particularly official statistics, may be social, ideological and political products (Smith, 2008, p. 79). They may be imperfect representations of the real situation, may not be very detailed or rich, or may be out of date and ill-suited to the present situation. Indeed Smith notes that the data are socially constructed, i.e. the concepts and categories they use are social constructions, and the scales for entering data are a social construction (e.g. what is meant by 'school exclusion'). The concepts may be too complex to fairly reduce to numbers, and may not be truly objective. She notes (pp. 27–9) that official statistics on items such as suicide and school exclusion may be unreliable (e.g. suicides may not be reported as such) and their measurement may be fallible. This does not necessarily mean that they are not valuable, but that researchers have to be cautious in using them (p. 29).

There are other practical issues in using secondary data, for example: the data may be ambiguous and contain errors (which might be impossible to know) and the data may have been saved selectively, i.e. some data may be excluded from the original study; some constructs or composite factors may be defined operationally by a limited range of variables. The data might not address the important issue of *why* something is as it is or was as it was; i.e. they offer descriptions rather than explanations (this may not be a problem, indeed Campbell *et al*. (1982) see this descriptive function as a powerful and important stage in research, or even as the main topic of research itself).

Secondary data may not sustain comparative analysis, being rooted in local, regional and national cultures, socio-cultural, spatial and temporal contexts,

for example, test items (Smith (2008, p. 35) gives the example of the TIMMS study), and they may have a historical bias because of events leading to the original research.

Researchers working with secondary data must ensure that their present purposes are sufficiently compatible with the original data sets on which they are working and that the data lend themselves fairly to the kinds of analysis being used and purposes for which they are being used. This means comparing the researcher's purposes with those for which the original data were collected, and being aware of possible biases in the data. The researcher must be sensitive to the commissioners of the original data: for example, if they are governments or interest and advocacy groups, the data might be biased. This applies not only to governments but to associations, institutions and academic departments, and such information can often be found in the manuals and reports that accompany the original research.

28.4 Ethical issues in using secondary data

Simply because data are already in existence does not absolve the researchers from addressing ethical issues. Morrow *et al*. (2014) remark that, regardless of whether the data are or are not public, the researcher has to address responsibilities to the original participants, including the original researchers, and must avoid misinterpretation of the original findings and their contexts (e.g. in cross-cultural research or if researchers from one culture are using data from another, original culture).

In providing qualitative data for secondary analysis, Morrow *et al*. also note that making data available for re-use through the sharing of archived data, rather than destroying data at the end of a project, has become much more widespread with open access, and this raises ethical issues concerning both benefits and risks (see also Mostafa, 2016). On the one hand, the benefits – scientific, utilitarian, moral and pragmatic – of secondary analysis outlined earlier in this chapter are plain. On the other hand, researchers have to consider the original informed consent, confidentiality, anonymity, data protection, the avoidance of harm (including stigmatization, prejudice, misrepresentation or marginalization), ownership of data (whether it is acceptable to have such shared, common ownership, not least if the intentions of the later usage contradict those of the original use) (cf. Mauthner, 2012; Mostafa, 2016), and the ethics of using data in ways for which they were not originally collected or intended.

Researchers and participants in the original study will not know how information which is archived will be used; as Morrow *et al*. (2014) remark, when researchers seek the consent of participants, in effect they are asking them to consent to something which is uncertain, as the future and the future use are uncertain, thereby rendering informed consent as not really being fully informed (p. 10). It may be possible, for example, to identify participants by the quality and rich detail that they provide, even with anonymization and anonymity; here secondary analysis faces a challenge of how much data to report, as rich, context-laden data – the stuff of qualitative research – may breach anonymity and non-traceability.

Addressing anonymity and non-traceability, avoiding misrepresentation and abuse of data, doing no harm, just as in other forms of research (see Chapter 7), should prevail. Secondary data researchers must consider their responsibilities to the original participants.

28.5 Examples of secondary data analysis

Examples of secondary data analysis are plentiful (cf. Heaton, 2008; Smith, 2008). For example, Smith (2012) looks at UK National Census data in relation to the Sure Start programme and at UCAS data on recruitment to higher education. Her earlier volume (2008) contains very many worked examples of different studies in a range of fields of education, using data from different education sources.

Rutkowski *et al*. (2010) comment on how to improve secondary analysis and reporting for international large-scale assessment data, and Hampden-Thompson *et al*. (2011) report an example of how large-scale secondary data analysis can be combined with in-depth qualitative approaches. Mueller and Hart (2010) report an example of secondary analysis of archived data on gifted education, and comment on two major sources of archived data sets (the National Longitudinal Study of Adolescent Health and the Educational Longitudinal Study). Homer *et al*. (2011) use the National Pupil Database to investigate performance across a range of science courses, using different valued-added approaches. Their study draws attention to problems for research deriving from students changing schools (7.7 per cent of students between Key Stages 3 and 4) and missing data (some 6.6 per cent of cases).

28.6 Working with secondary data

In working with secondary data the researcher must understand several matters concerning the original

research in relation to the present research (Smith, 2008; Newby, 2010; Johnston, 2014), including:

- the original purposes, conceptual and theoretical structure of the data (Smith, 2008, p. 62), and the inclusion and exclusion of variables and indicators in the original research that might be important for the present researcher, i.e. a comparative analysis of necessary and important variables and indicators (p. 65), and the relevance and suitability of the data for the researcher's present purposes;
- the definitions of terms being used in the original and present research. This is a particular problem with definitions emanating from those in power, for example, governments, who may have definitions which do not accord with the researcher's or which may change markedly over time, for example, definitions of 'employed' and 'unemployed';
- the type and quality of the original data, for example, were they 'hard' data, perception-based or opinion-based data, and how was verification undertaken of 'hard' data (and how they were collected);
- who collected the data (e.g. trained researchers and data collectors, data-collection agencies, market researchers, opinion pollsters) and the credentials and sources of the authors of the original data;
- who gave the original data (i.e. how trustworthy are the original data), how were the original data collected (e.g. online, face-to-face, by post, by telephone, from professional registers and records) and what incentives, if any, were used to encourage participation and response?
- what was the sampling strategy in the original research, and how does it fit the present researcher's purposes; what were the response rates and attrition rates, and which groups were over-represented, under-represented or absent, i.e. sampling bias and population characteristics (such data are usually present in the research manuals and reports for the original research)?
- what questions and kinds of questions were asked and how were they asked, what response categories and scales were used (e.g. Likert scales, rankings) in the original data and how compatible are they to the present researcher's purposes (i.e. are the original instruments for data collection available so that the researcher can check for compatibility and utility with the present research purposes and contents)?
- the date of publication of the original data (i.e. are the data now out of date?), their intended audience, the intended and actual coverage of the topic or issue, in what socio-temporal contexts, and how well these match the present researcher's contexts, situation and purposes (i.e. a question of relevance between the original and the contemporary context);
- how factually correct were the original data; what and how much missing data were there in the original data set?
- the format of the data archive (the researcher may need to rework the format, which can be time-consuming);
- how were the original data analysed and grouped (which could affect how they were presented in the original data set); what level of analysis was used (e.g. individual, organizational, local, regional, national); what was the unit and scale of data collection used (e.g. individual, organizational, local, regional, national etc.); how were the data summarized, presented, categorized and grouped in the original data set, how was this reached, and how compatible are they to the present researcher's categories and purposes?
- what ethical issues need to be addressed in using secondary data, for example, anonymity, informed consent (which may not be a problem as identifying data may not be included in the original data, and data may be aggregated so as to render individuals invisible or non-traceable, but may still be a problem inasmuch as the givers of the original data may not have given consent to the data being used for purposes other than those at the time).

One should not be put off by this formidable list of cautions. Rather, they direct the researcher to examine the compatibility of the original data and research with the present research, and the reliability and validity of the original research, so that its usefulness for the present research can be validated.

Researchers working with secondary data need to be clear on how they are going to analyse the data (e.g. by subject, topic or theme; by groups of people; by institution; by year; by region), and many databases enable the researcher to interrogate data by these different variables.

Yorke (2011) gives the example of using data from the National Student Survey to identify several cautions in using secondary data for research. Included in these are that the original data may not fit the kinds of data that the researcher would have preferred to collect (p. 257), and that the researcher has to decide whether the data are 'good enough' ('satisficing') for the present research, as 'good enough' for one purpose may not be so for another. He advocates a risk analysis, to judge the acceptability of using data gathered for one purpose

to serve another purpose, and from one context to another, and he notes that the researcher should make clear any compromises made and limitations encountered by changes of purpose and context.

Yorke advises that secondary data have to be checked for their quality and to avoid assuming that they are free from error (e.g. in data entry). Indeed he notes that earlier versions of data (e.g. student records) may be overwritten by later versions. Further, he notes that errors in categorization might feature in the original data (he cites the example of the Higher Education Statistics Agency in the UK in respect of degree classification), and that these errors may only be found when one is actually working with the data, i.e. when 'implausibilities become apparent' (2011, p. 259). With regard to categorization, he makes the point that the categories and categorizations used in the original data may not be compatible with contemporary categorizations or researcher's needs.

Yorke also questions just how 'national' some data are. He gives the example of trends in honours degrees in the UK's national statistics that omitted Scotland because its honours programmes differed from those in the rest of the UK, and programmes in some subjects did not use an honours classification system, i.e. a definitional, classification problem.

Yorke advises researchers to be prepared to spend time reformatting original data for analysis, and he provides examples of this, for example, how subjects are aggregated in publicly available data in the National Student Survey. This echoes Windle's (2010) comment that using secondary data analysis may not be as time-saving as researchers first imagine, as time must be spent understanding the original research, for example, its conceptual framework, research purposes and questions, contexts, design, methods, definitions, strengths and weaknesses etc. (p. 323). This is a useful caution for those researchers who might think that secondary data can save time overall or that they can be automatically used in the original format in which they were accessed. Also different levels of analysis may exist in the original data, and this may be a definitional problem.

In working with secondary data, we suggest nine practical steps that researchers can take:

Step 1: Identify your own research purposes and research questions. Search and select possible secondary data sets and data for suitability for your own research. Were you part of the original primary research?

Step 2: Familiarize yourself as much as possible with the original research and data that you have selected. This involves attention to: conceptual and theoretical frameworks; design; instrumentation; sampling and populations; variables included; definitions used; data-collection instruments and methods; completeness, accuracy and missing data (for both qualitative and quantitative data); validity and reliability of the original data set; whether the original data set included primary and/or secondary data; data organization and levels of organization; data analysis and weightings; reporting; limitations and errors.

Step 3: Assess and evaluate the data to see if they are amendable to secondary analysis and suitable for your present research: sufficient, valid, relevant, appropriate, reliable, in sufficient detail and depth, and if their scope and coverage are adequate.

Step 4: Check if there are restrictions (and copyright) on how the data may be used, analysed, disseminated, shared and published.

Step 5: Check that ethical issues have been addressed (e.g. what consent was given in the original study, how to address non-traceability and anonymity, how to address any conditions required in the original study).

Step 6: Check the fit and congruence between the original study and your own study: (a) its conceptual and theoretical framework; (b) its socio-cultural, temporal, locational and political contexts; (c) its research purposes, design and research questions; (d) the variables that it included; (e) its population and sampling; (e) the definitions and categories that it used; (f) its data types and coverage; (g) the units of analysis and levels of analysis that it used.

Step 7: Prepare your data: reformat the data if necessary to fit your purposes; select the cases and variables of interest from the original data set; weight the cases (if desired) and recode the variables if necessary (creating new variables if necessary); decide how to take account of missing data.

Step 8: Analyse the data to address your research purposes and research questions. Analyse groups and sub-groups of cases if required.

Step 9: Decide how you will report the secondary analysis and its findings (including reference to the original study/source and its data).

Using these nine steps can guide researchers to evaluate the existing data using several criteria to ensure suitability for their present research. Secondary data are

a valuable source for researchers. As Johnston (2014) remarks, given that we live at a time of massive amounts of data being collected, compiled and archived and made accessible, the time is ripe for secondary data analysis (p. 626).

28.7 Conclusion

Secondary data are a valuable and often easily accessible resource for researchers. Whilst they have many attractions, they also bring several challenges and we advise researchers to be very aware of these and to work out how to address them. Often they cannot be used in their original form, and researchers must be prepared to put them into a format suitable for their own research and examine the sources, definitions, validity, completeness and reliability of the data etc., and take into account the contexts that gave rise to the original research and data. As with all research, using secondary data raises several ethical issues, and we advise researchers to be mindful not only of ethical issues more generally but particularly of those that feature strongly in this form of research. Fitness for purpose and match between the original research and the present research should be sufficiently close to render the use of secondary data valid.

Researchers working with secondary data might need to consider: costs; feasibility; meta-analysis (if original microdata are available); and replication. Readers may also find it helpful to go to Chapter 16 on historical and documentary research.

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Personal constructs

CHAPTER 29

Richard Bell

This chapter discusses the following:

- strengths of repertory grid technique
- working with personal constructs
- grid analysis
- examples of the use of the repertory grid in educational research
- competing demands in the use of the repertory grid technique in research
- resources

29.1 Introduction

Personal constructs are the basic units of analysis in a complete and formally stated theory of personality proposed by George Kelly in his book *The Psychology of Personal Constructs* (1955). Kelly's own clinical experiences led him to the view that there is no objective, absolute truth and that events are meaningful only in relation to the ways that are construed by individuals. Kelly's primary focus is on the way individuals perceive their environment, the way they interpret what they perceive in terms of their existing mental structure and the way in which, as a consequence, they behave towards it. In *The Psychology of Personal Constructs*, Kelly proposes a view of people actively engaged in making sense of and extending their experience of the world. Personal constructs are the dimensions that we use to conceptualize aspects of our day-to-day world, and, as Kelly writes, people differ from each other in their construction of events. The constructs that we create are used by us to forecast events and rehearse situations before their actual occurrence, and are sometimes organized into groups which embody subordinate and superordinate relationships. According to Kelly, we take on the role of scientist seeking to predict and control the course of events in which we are caught up. For Kelly, the ultimate explanation of human behaviour 'lies in scanning man's [*sic*] undertakings, the questions he asks, the lines of inquiry he initiates and the strategies he employs' (Kelly, 1969, p. 69). Education, in Kelly's view, is necessarily experimental. Its ultimate goal is individual fulfilment and the maximizing of individual potential, capitalizing on the need of each individual to question and explore.

Kelly's theory was very formally constructed, with a 'fundamental postulate' and eleven corollaries that followed from this. Later, even in Volume II of this work, but more obviously even later (Kelly, 1969), he moved away from this very formal statement. Butt (2008) provides a good introduction to this broader view of Kelly and his theory. Nevertheless, the formal statement provides the model for the repertory grid. The fundamental postulate is:

> *A person's processes are psychologically channelized by the ways in which he or she anticipates events.*

One key component in the above statement is *the ways in which*. For Kelly, these *ways* are called constructs. The person's repertoire of constructs is the basis by which the person construes or understands their world and makes predictions about the future. What is to be construed or understood are the *events*. What are these events? It is rather an ambiguous term. In one sense they really are events such as 'going to a party' or 'teaching a class', but Kelly uses the term much more broadly to encompass all psychological objects such as 'ideal self' or 'teacher I looked up to'. In the repertory grid technique, these objects are termed *elements*.

A repertory grid then is simply a representation of the relationship between these elements and constructs. As such it provides information we can use to understand *how* 'a person's processes are psychologically channelized by the ways in which he or she anticipates events' (Kelly, 1955, p. 46). Figure 29.1 shows a simple grid layout for collecting data.

Kelly's theory then has a number of corollaries to this fundamental postulate that relate to the constructs. An important one from a repertory grid perspective is that constructs are essentially bipolar, that is, capable of being defined in terms of polar adjectives (good–bad) or polar phrases (makes me feel happy–makes me feel sad). Other corollaries can also affect the ways in

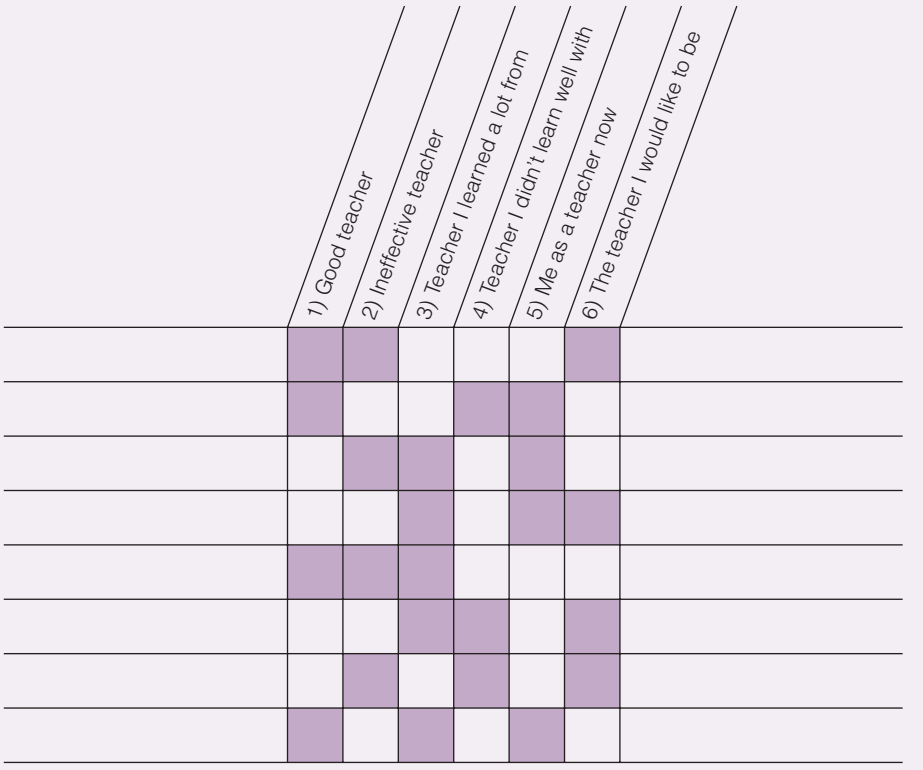

FIGURE 29.1 Simple grid layout

Instructions: Consider the three figures represented by the shaded cells in each row. Which two are more alike and by the same token different from the third? Enter the quality of the similar pair on the *left*-hand side of that row, and the quality that differentiates the third person on the *right*-hand side.

which we can use the repertory grid technique, as we shall see later. In addition to the corollaries there are other formal aspects of the theory that play roles in relating constructs to behaviour. Fransella (2003, pp. 455–7) provides a concise summary of all components of the theory.

A number of different forms of repertory grid technique have been developed since Kelly's first formulation. They have the two essential characteristics in common that we have already identified, that is, constructs – the dimensions used by a person in conceptualizing aspects of his or her world – and elements – the stimulus objects that a person evaluates in terms of the constructs she employs. In Figure 29.1, we illustrate the empirical technique suggested by Kelly for eliciting constructs and identifying their relationship with elements in the form of a repertory grid.

Since Kelly's (1955) original account of what he called 'The Role Construct Repertory Grid Test', several variations of repertory grid have been developed and used in many different areas of research. In a chapter entitled 'Some Uses to Which Grids Have Been Put', Fransella *et al*. (2004) provide an annotated bibliography of a wide range of areas including 'working with children', 'teachers and teaching', 'construing of professionals' and 'those with learning difficulties'.

29.2 Strengths of repertory grid technique

The repertory grid technique draws its strength from two particular features. The obvious one is that it is an individualized technique where the respondent provides the framework as well as the responses. For example,

Suto and Nádas (2009) used grids with two principal examiners to identify features of examination questions that differed in the difficulty of marking. The other, perhaps more important, strength derives from the two-way nature of the data where elements are related to constructs. This enables relationships between elements to be assessed, since there is information about each element provided by the set of constructs. Conversely, the relationships between constructs can be examined through the information provided for each construct by the set of elements. Even if the individuality of the grid is restricted by the use of provided constructs or elements (as discussed below), the two-way data allows for within-respondent analyses to be carried out.

29.3 Working with personal constructs

Choosing elements

The key issue in choosing elements is that they should be a homogeneous set to ensure that the constructs elicited from some of them will also be relevant to other elements. Yorke (1983) and Wright and Lam (2002) draw attention to problems that can arise when this requirement is not met.

In Kelly's original technique, elements were usually chosen by the client to fit 'role titles' provided by the clinician. Some role titles allowed no choice ('me as I am now'); some allowed a possible choice ('your mother (or the person who filled that role in your life)'); and some allowed wide choice ('a teacher you admired'). Some research (Bell *et al*., 2002; Haritos *et al*., 2004) suggests that value-laden role titles such as the teacher role above or 'a girl you did not like' tend to polarize the grid by making constructs subsequently elicited more similar to one another than when role titles are neutral, such as 'a significant person in your life'.

Eliciting constructs

Kelly originally suggested six ways in which constructs could be elicited from elements, the most familiar being to choose three elements and ask the participant to specify *some important way in which two of them are alike and thereby different from the third*. The way in which two were alike formed one pole (the similarity pole), the way in which the third differed formed the other pole. Another way involves asking the participant for the opposite to the similarity pole. Another way suggested by Kelly was to always have the 'as I am now' element always included. This is more widely used in psychotherapy settings since it ensures that all constructs are relevant to the self.

The task of triadic comparison is cognitively demanding at it has been found that simply using two elements is better for children (e.g. Salmon, 1976) or those with learning difficulties (Barton *et al*., 1976).

'Elicited' versus 'provided' constructs

One form of repertory grid technique now in common use represents a significant departure from Kelly's original procedure in that they provide constructs to subjects rather than elicit constructs from them. Eliciting constructs from individuals follows from Kelly's *individuality corollary*: *Persons differ from each other in their construction of events*. Supplying constructs contravenes this, though Kelly also posited a *commonality corollary*: *To the extent that one person employs a construction of experience which is similar to that employed by another, his or her psychological processes are similar to those of the other person*. This suggests that there will be constructs which are common to a number of individuals.

Can the practice of providing constructs to subjects be reconciled with the individuality corollary assumptions? Despite much research, the answer is still unclear and of course is further clouded by the more recently discovered effect of value-laden role titles in elicited constructs. As Fransella *et al*. (2004, p. 48) point out, however, '[c]onstructs have to be supplied in a group context if group data is required'. Bell (2000) has shown how the commonality corollary may be simply tested by examining each supplied construct in turn for unidimensionality of the element ratings.

But the issue of supplied or elicited constructs is not necessarily an all-or-none situation. Bannister and Mair (1968) support the use of supplied constructs in experiments where hypotheses have been formulated and in those involving group comparisons. The use of elicited constructs alongside supplied ones can serve as a useful check on the meaningfulness of those that are provided, substantially lower inter-correlations between elicited and supplied constructs suggesting, perhaps, the lack of relevance of those provided by the researcher.

Allocating elements to constructs

In Kelly's original technique participants were allowed to classify as many or as few elements at the similarity or the contrast pole, giving a very lopsided construct. Originally this was seen as a problem since measures of association between constructs could be affected by this (e.g. Bannister and Mair, 1968, p. 59) and strategies were proposed to overcome it. These strategies had problems of their own, in that they forced the participant to allocate elements to constructs in a fixed fashion, as removed from Kelly's individual focus as

are supplied constructs. More recently Bell (2004a) has shown that lopsidedness is associated with the super- and subordinate relationships implied by Kelly's organizational corollary. The common method now of allotting elements is the 'rating form', which tends to lessen the tendency to locate elements on a construct in a lopsided fashion. Here, the subject is required to judge each element on a multi-point scale, where one extreme (say, 7) is aligned with one pole ('notices when I am having problems') and the other extreme (1) is aligned with the other pole ('doesn't notice when I am having problems'). The rating form is illustrated in Figure 29.2.

As with most rating scale formats, questions arise as to the meaning of a mid-point rating (when an odd number of rating points are specified). Another of Kelly's corollaries was the range corollary: *a construct is convenient for the anticipation of a finite range of events only*. In a rated grid, then, does a mid-point rating mean neither or both poles are relevant? Or more generally, does a grid allow missing data? Kelly's range corollary would suggest 'yes' but the computation of summary measures to represent grids would usually say 'no'. In practice this problem can be ameliorated, if not overcome, by the careful nomination of a homogeneous set of elements. The mid-point issue remains intriguing. Winter *et al.* (2010) found in a psychotherapy study that constructs where either 'self now' or 'ideal self' was located at the mid-point were associated with more complex cognitive structures in the grid.

Other techniques: laddering and pyramid construct elicitation and other forms of grids

The technique known as 'laddering' arises out of Hinkle's (1965) linking of the notion of implication with the organization corollary: *each person characteristically evolves for his or her convenience in anticipating*

	1) Good teacher	2) Ineffective teacher	3) Teacher I learned a lot from	4) Teacher I didn't learn well with	5) Me as a teacher now	6) The teacher I would like to be	
Quiet	1	5	2	2	3	1	Loud
Sociable	4	1	5	5	1	2	Aloof
Open	2	4	1	3	1	2	Private
Creative	2	4	1	5	5	1	Follow set plans
Independent	1	5	1	3	5	1	Dependent
Listens	1	5	1	5	3	1	Doesn't listen
Reject ideas	5	1	4	1	3	5	Accepts
Strict	1	3	1	5	5	2	Lax

FIGURE 29.2 Completed grid

Instructions: Consider how the qualities in each row apply to each of the six figures. To the extent that the quality on the *left* applies more to the person, give a rating closer to *1*. And to the extent that the quality on the *right* applies more to the person, give a rating closer to *5*.

events, a construction system embracing ordinal relationships between constructs. Hinkle's innovation was to replace 'anticipation' with 'implication'. The linking of implication with ordinal relationships enables logical relationships to be specified between poles of different constructs. 'Laddering' is an exploratory technique using implication to move from a pole of a given construct to a pole of an as yet to be elicited construct. It usually proceeds by asking the participant to indicate which pole of the given construct is preferred. (This is linked to Kelly's *choice corollary*: *a person chooses that alternative ... through which he anticipates the greater possibility for the extension and definition of his system*.) Having identified the preferred pole, the participant is then asked 'Why?'. The response to this forms one preferred pole of the higher-order or implied superordinate construct. The construct can then be completed by asking the participant for the contrasting pole of the new construct. In turn the participant can then be asked for the preferred pole of this new construct and again asked 'Why?' to produce the first pole of the next higher-order construct. Although he never published his development of the technique of laddering, it has been used widely in many fields, particularly in research into consumer perceptions (Reynolds and Gutman (1988) provide practical advice in using this technique in the context of laddering from product properties to consumer values).

Laddering is a technique for eliciting constructs in terms of a single element, the self ('Which pole do you prefer and why?'). Pyramiding, a similar procedure developed by Landfield (1971), also uses a single element. Respondents are asked to think of a particular 'element', a person, and then to specify an attribute which is characteristic of that person. Then the respondent is asked to identify what kind of person would not have that characteristic. The researcher then returns to the first characteristic and asks 'What more can you tell me about a person who has that characteristic?' and again 'What is the opposite of that characteristic?' The enquiry is then repeated similarly for the opposite pole of the first characteristic. According to Landfield the enquiry then proceeds to similarly enquire of the four construct poles thus elicited. Landfield termed this a 'pyramid' since it starts from one element to produce two construct poles which in turn produce four construct poles and finally eight construct poles. This kind of enquiry asks for elaborations (What more can you say?) rather than implications (Why?), and thus does not identify superordinate relationships between constructs as does Hinkle's procedure.

Landfield saw his technique as purely qualitative and informing the psychotherapeutic process. Hinkle (1965), however, went on to develop an Implication Grid or Impgrid, in which the subject is required to compare each of his constructs with every other to see which implies the other. Table 29.1 illustrates Hinkle's laddering technique with an example from educational research reported by Fransella (1975).

Exchange grids are procedures developed to enhance the quality of conversational exchanges. Basically, one person's construing provides the format for an empty grid which is offered to another person for completion. The empty grid consists of the first person's verbal descriptions from which his ratings have been deleted. The second person is then invited to test his comprehending of the first person's point of view by filling in the grid as he believes the other has already completed it. Various computer programs ('Pairs', 'Cores' and 'Difference') are available with the Rep Plus package to assist analysis of the processes of negotiation elicited in exchange grids.

In the 'Pairs' analysis, all constructs in one grid are compared with all constructs in the other grid and a measure of commonality in construing is determined. 'Pairs' analysis leads on to 'Sociogrids', in which the pattern of relationships between the grids of one group can be identified. In turn, 'Sociogrids' can provide a mode grid for the whole group or a number of mode grids identifying cliques. 'Socionets' which reveal the pattern of shared construing can also be derived.

Grid administration

The way in which a grid is administered depends in part on the purpose and nature of the research. Where the researcher wants detailed information from few respondents, then administration is best carried out with one-on-one interviews. This has the advantage of allowing the researcher to monitor the constructs elicited for duplication or difficult-to-understand pole labels. Such administration usually begins with some discussion of the area the grid will relate to and a simple trial run of two or three constructs elicited from half-a-dozen elements not related to the main task. Clarifications can be sought, and the preferred pole identified as the constructs are elicited.

Grids can also be collected in group testing. This usually requires a somewhat smaller grid (the study of Haritos *et al*. (2004) used this approach) and a pro forma form that allows spaces for element and construct labels as well as grid ratings, and uses shading or some other method of identifying which elements are to form the triads (see Figure 29.2). Here overheads or PowerPoint are needed to illustrate how the grid is to be completed.

TABLE 29.1 LADDERING DIALOGUE

Okay so **good teacher** and **teacher I learned a lot from** are alike in that they are both 'alert' while **an ineffective teacher** is … *'has his mind on other things'*	The opening construct dialogue
So if you had to choose between 'having your mind on other things' or 'being alert', which would you choose *obviously I'd choose being 'alert'*	Choosing the preferred pole
Why? *well, 'being alert' means you can pick up on where each kid is at in their work but having your mind on other things means you just see the class as a whole*	Laddering up to next higher construct
Why is it important to 'pick up on where each kid is at in their work'*?* *Because kids don't all learn in the same way or at the same rate … they're…* They're individuals? *Right*	Laddering up again to next higher construct. Notice the interviewer doesn't look for the opposite pole of this construct
Why is important to treat them as individuals? *So they can each reach their potential*	Notice the interviewer doesn't look for the opposite pole of 'individuals' but keeps laddering from this pole
Why is that important? *It's important because that is why I want to be a teacher – to enable kids to realize their potential*	The interviewer stops here, sensing perhaps that this is far enough up this ladder for the moment
Can I just go back to what you said as the opposite of 'pick up on where each kid is at in their work', you said 'just see the class as a whole' *Mmm*	The interviewer now goes back to the contrast pole of the first laddered construct
What do you think seeing the class as a whole implies? *You mean about a teacher who does that?* Yes *I guess it means that they don't really care about the kids*	Laddering up to next higher construct from this contrast pole
And what would that mean? *They would be thinking about themselves – it might be temporary like some problem at home – or it might be that they want an easy life, not have to work as hard*	Laddering up to next higher construct. Notice the respondent gives two consequences
Yes, I guess there are times when temporary problems affect our work. But what about wanting an easy life – what does that imply? *Unambitious – I don't mean about promotion or things like that, but not being ambitious about being a good teacher*	The interviewer chooses one to ladder from
And the opposite of 'not being ambitious about being a good teacher' is? *Being ambitious about being a good teacher*	Here the interviewer switches attention across from this negative pole to the contrast positive pole
Is that important to you? *Yes*	And checks that it is the preferred pole
Which is more important to you: 'enabling kids to reach their potential' or 'being ambitious about being a good teacher'? *They're the same thing really; a good teacher is one who enables kids to reach their potential*	The interviewer now draws the higher-level positive poles together
And the 'being ambitious'? *Yeah, it's also important to try to improve your teaching.*	The interviewer notices that part of one of the poles has been left out and draws that in

Where grids are to be collected with supplied elements and constructs (perhaps following on from some individually elicited grids, as in Reid's and Holley's (1972) study of choice of university), the grid data can be collected in a simpler questionnaire-type format. Should the ratings be collected construct by construct, rating each element in turn, or element by element, rating each construct in turn? Evidence (Bell *et al*., 2002; Neimeyer and Hagans, 2002) suggests that it does not matter.

In this century it is to be expected that computer administration is to be a major way in which grid data is collected. A web version can be found at http://webgrid.uvic.ca for the Gaines and Shaw program Webgrid Plus that allows relatively simple grids to be elicited. Idiogrid (at www.idiogrid.com) is a freeware program that allows quite complex grid elicitations to be structured and subsequently used to collect data from respondents. Both of these resources provide for data analysis of the grids collected.

29.4 Grid analysis

Before we analyse the grid data, we need to be aware that the orientation of the data in the grid will be a function of the way in which the constructs were elicited. If the two elements that are alike are both positive figures (e.g. 'ideal self' and 'best friend') then the pole corresponding to their similarity will reflect this (e.g. generous). If the two figures are negative ones (such as 'person I dislike' and 'worst teacher') then the pole corresponding to their similarity (e.g. stingy) will reflect this – and the correlations with other constructs would be opposite.

A preliminary step in analysing a grid should often be to make all the constructs similarly aligned. This can be done by asking the respondent to indicate their 'preferred' pole. (This is also done in a related personal construct technique called laddering.) Another way of doing this is when the grid contains the element 'ideal self'. Whichever pole of each construct is aligned with the 'ideal self' is the preferred pole. Of course, this may not be of any use when the 'ideal self' is located at or near the mid-point. There is also an automatic way of doing this. We can analyse the correlations between the constructs and identify those constructs which generally correlate negatively with other constructs, and reverse these constructs.

How do we extract information from a repertory grid? There are a number of ways we can look at the numerical information in a grid, and these are discussed below.

Looking at relationships between elements and between constructs

Even in an individual grid, there is replicated information for elements (across constructs) and constructs (across elements). We can use this to make comparisons between constructs or between elements, or create indices to represent these comparisons. One of the oldest of these is Bieri's (1955) index of cognitive complexity/simplicity. This was originally a matching coefficient calculated for each pair of constructs and summed for the whole grid. These days it is usually based on the average correlation among constructs. If this is a large value, then it means all constructs are highly correlated and relate to the elements in much the same way. The person might thus be said to be construing their world in a simple way. If the average correlation is low, then the constructs are differentiated and the person might be said to be construing in a complex fashion. We can also compute such averages for each construct to determine which constructs are like the others and which are different. Figure 29.3 shows the average (root-mean-squared) correlations for each construct in the same grid. This output was obtained from the comprehensive (and easy to use) free web-based repertory grid analysis OpenRepGrid on Air package (www.onair.openrepgrid.org) (Heckmann, 2016).

Except where otherwise noted, all analyses shown in this chapter were produced with this package. In this example it can be seen that the construct '*sociable – aloof*' is least related to other constructs, while overall there is a consistent and substantial similarity in the ways these constructs are applied. Of course the construct correlations that form the basis of this index can also be analysed in other ways, such as with principal components. Figure 29.3 shows that the component loadings can be used to show where the poles are reversed with respect to the orientation of the other constructs. All construct loadings have positive signs except for '*sociable – aloof*' and '*rejects ideas – accepts*'. While the latter construct poles can easily be seen to be unaligned with the others (where the left-hand pole is the positive quality), *sociable* rather than *aloof* would normally be seen as positive. For this grid, however, *aloof* is perceived as the more positive quality in a teacher.

Cluster analysis is another way of depicting relationships in a matrix of measures of association among elements or constructs. Figure 29.4 shows element Euclidean distances and a hierarchical clustering of these. *Good teacher* and *ideal teacher [teacher I would like to be]* are similar, while *teacher I learned a lot*

```

FIGURE 29.3 Grid summary measures

from is also similar to these two. *Me as a teacher now* is weakly associated with an *ineffective teacher* and somewhat less associated with *teacher I did not learn from*.

Particularly useful elements where grids involve the self as an element are the elements *self now* and *ideal self*. The discrepancy between these two can be taken as a measure of self-esteem or used to generate a self-identity plot (as in Figure 29.5, taken from the Idiogrid program) where self and ideal are reference axes against which are plotted the other elements.

Looking at the overall grid

In the 1960s Patrick Slater introduced a technique that he called 'principal components' and which we now know as singular-value-decomposition that enables both elements and constructs to be represented together. There have been a number of different ways of representing the constructs and elements in these maps. Elements always appear as points in the map. Constructs, however, are shown in different ways. The construct data is like a principal component solution with two columns of coordinates which define a point in the space. However, representations differ. Often the point is reflected back through the origin to make a line symmetric about the origin, the two ends of which represent the construct poles. Other representations (such as that originally used by Slater) show the construct poles as points on a circle encompassing the elements. Figure 29.6 shows a spatial representation of our sample grid with elements shown as square points and constructs shown as vectors (lines) symmetric about the origin. The longer the line, the more important the construct. The horizontal dimension separates better and poorer teachers, with constructs similarly aligned, while the vertical axis is aligned with the isolated construct *aloof – sociable* distinguishing principally between *teacher I didn't learn well with* and *me as a teacher now*.

The analyses described above all focus on variation within a grid. For many research purposes, the unit of analysis is the person (the subjects of the experiment) and consequently the focus is on between grid differences. This issue is explored later in this chapter.

29.5 Some examples of the use of the repertory grid in educational research

Jones (1999) used repertory grids alongside interviews and participant observation to elicit headteachers' views of their roles and agenda in changing times. While the study found an increase in their management activities (one construct), it also found that not only did their changing role not lead to their de-professionalization but also their core values were rooted in their values in, and views of, education (a second construct). The superordinate constructs for the primary headteachers were child-centred and management, in that order, i.e. the management systems were there to serve the

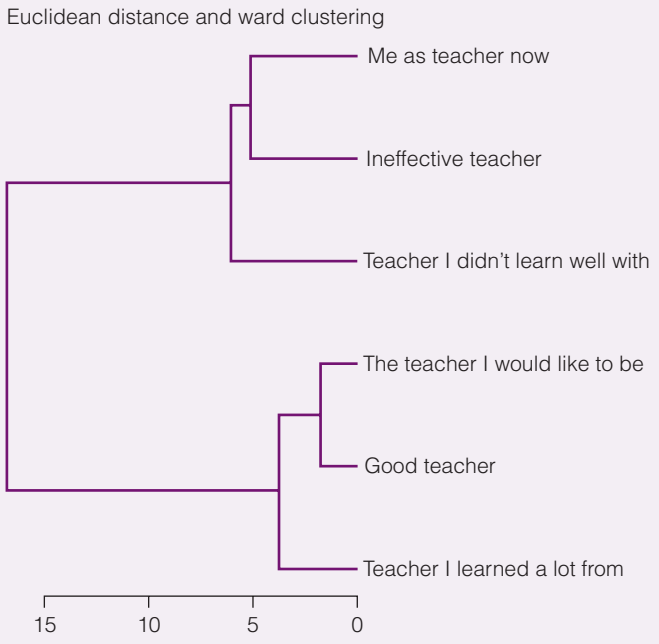

FIGURE 29.4 Grid cluster representation

child-centred values and vision. Constructs elicited included: child-centred problem solving, implementation policy, evaluation, involving other agencies, problem solving and paperwork.

Bezzi (1999) used repertory grids to explore the perceptions of the images of the geosciences, held by a university geology lecturer and five undergraduates at the beginning and end of the academic year. Participants were provided with six names of science subjects (e.g., physics, geography, geology) as elements and fifteen constructs were elicited by Kelly's triadic method separately at the beginning and the end of the year. Construct labels were treated as qualitative data and were classified into five categories by the author: (i) nature of science (e.g. *objective/subjective*); (ii) aspects of investigation (e.g. *use of maps or charts/no such use*); (iii) application of science and its professional aspects (e.g. *more employment opportunities/less*; *modifies environment/preserves environment*); (iv) affective aspects (e.g. *like/dislike*; *difficult/easy*); and (v) characteristics of the courses (*with lab/without lab*). Bezzi (1999) found constructs to be predominantly of the first two kinds, that is, dealing with the scientific essence of the disciplines. He used principal component representations of both elements and constructs (as in Figure 29.6) to identify constructs associated with the elements 'geology' and 'geography' both before and after the course of instruction for each of the five students and the lecturer to show how their perceptions of these two subjects had shifted over the year. Bezzi (1999) was able to conclude that simply studying the content of science did not lead to a greater understanding of the role of science in society or how to make good public decisions about scientific issues confronting society.

Lui and Lee (2005) showed how repertory grids could be incorporated into a learning programme in an examination of conceptual understanding in computer-mediated peer discourse. Twelve graduate students rated each of six database design methodologies on eleven supplied database design concepts. The course instructor also completed this task. Use of supplied elements and constructs enabled the researchers to feed back information to students about conflicts between their perspectives and for the students to take these differences into account during a week of online unstructured discourse in which students were required to reach a consensus perspective. Following this, students again completed the grids, and it was found that student concepts became significantly more aligned with the instructor's perspective. Lui and Lee (2005) conclude by suggesting that the methodology could be extended to using student-derived constructs, although this would require more complex procedures.

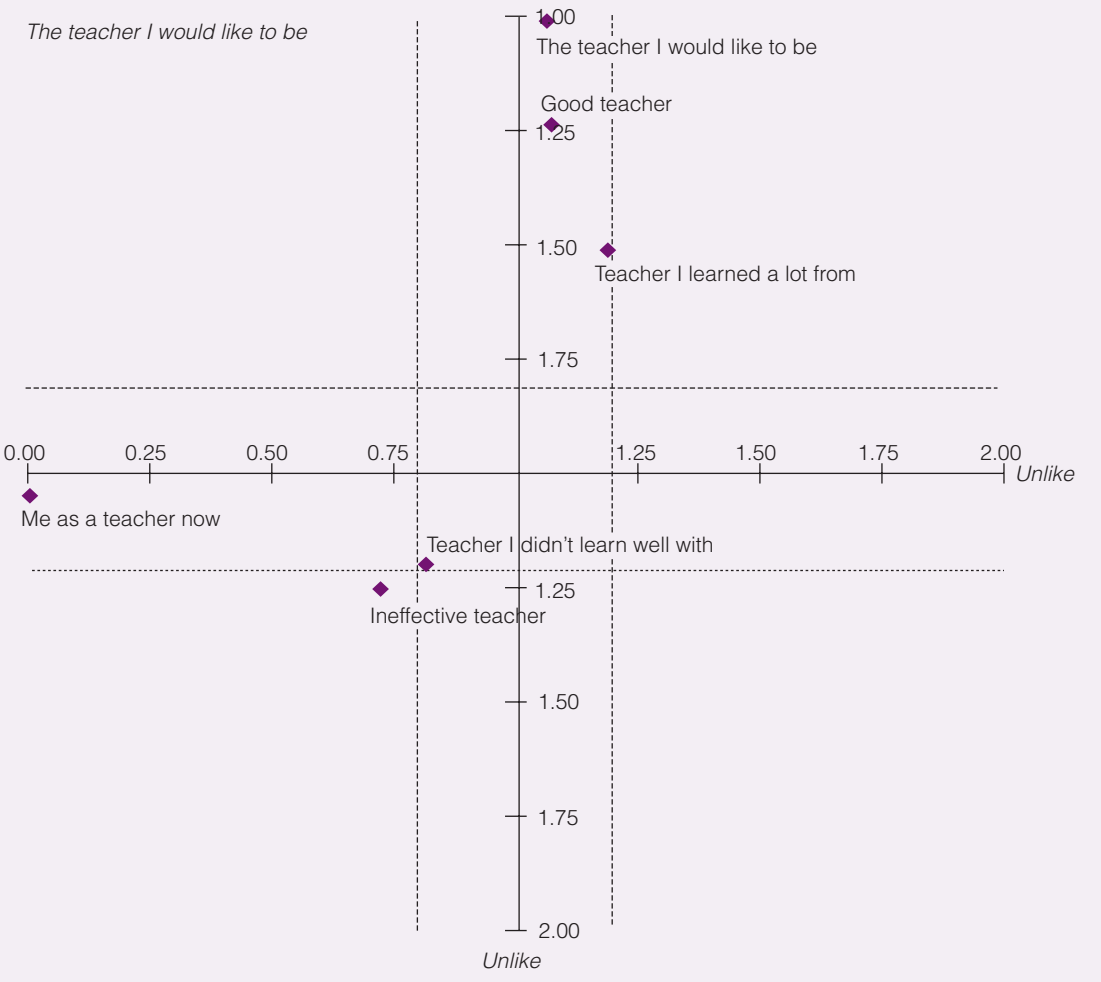

FIGURE 29.5 Self-identity plot

Yeung and Watkins (2000) employed the repertory grid technique to investigate how student teachers in Hong Kong developed a personal sense of teaching efficacy. A pilot study was used to generate elements such as 'self-efficacy', 'teaching practice', 'teaching practice supervisors', 'pupils' and 'lessons'. Constructs were individually elicited from twenty-seven students using the triadic procedure with cards. Yeung and Watkins (2000) matched constructs between student teachers to identify core constructs and create networks of similarity among student teachers using the Repgrid software of Shaw and Gaines (an earlier version of their current package, discussed above).

They found that third-year students' perceptions were more homogeneous than those of first-year students. Teaching efficacy was defined in terms of the dimensions of concern for instructional participation and learning needs of pupils, communication and relationships with pupils, academic knowledge and teaching skills, lesson preparation, management of class discipline, teaching success, teaching commitment and a sense of self-confidence. Experiences of teaching practice, pupils and teaching practice supervisors (Electives) were the major sources for the development of a sense of teaching efficacy.

Suto and Nádas (2009) used repertory grids to investigate why some GCSE examination questions in mathematics and physics were harder to mark accurately than others. Two highly experienced principal examiners generated constructs of question features for triads of ques-

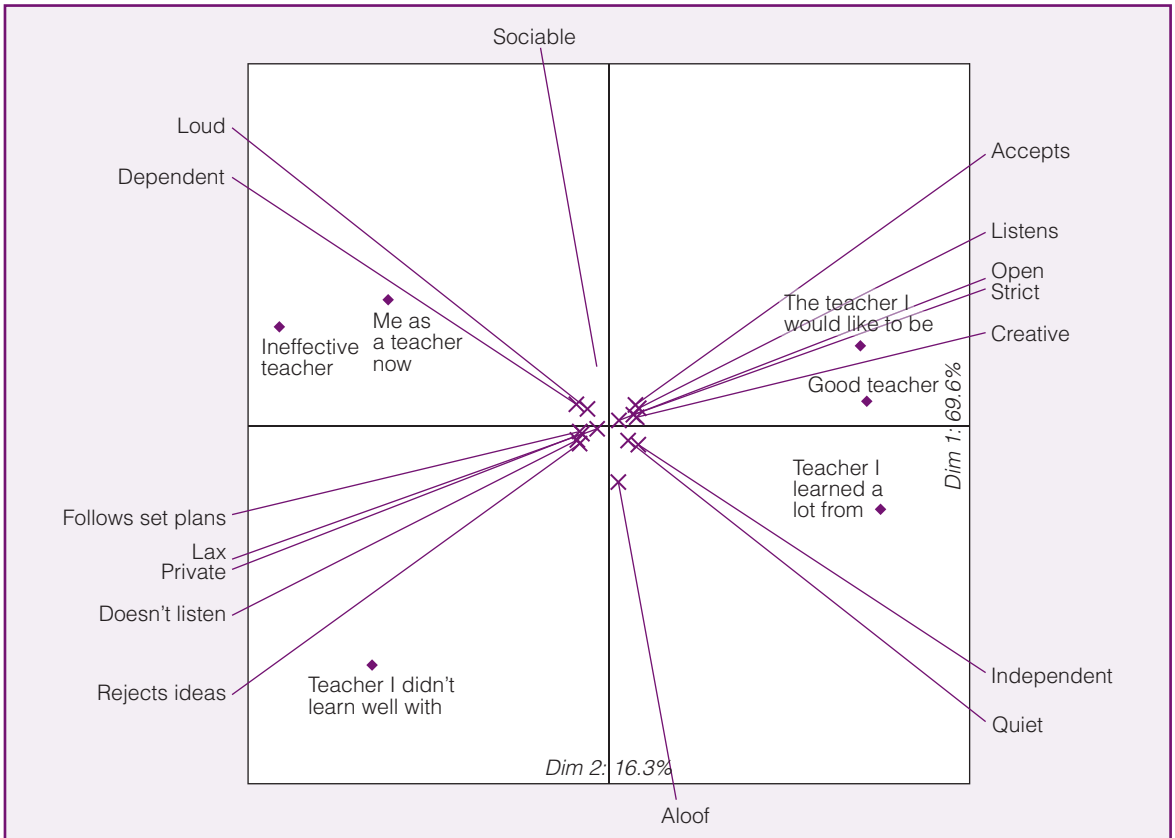

FIGURE 29.6 Spatial representation of elements and constructs

tions (elements) and rated each question (i.e. the elements) on these constructs. The study examined the constructs generated in detail and related this to marking accuracy. In a similar vein, Johnson (2008) used the repertory grid procedure with assessors of vocationally related portfolios to elicit constructs of differentiation among portfolios. Six assessors generated 131 constructs over six assessment objectives. There was general agreement between the assessors about the qualities of the commonly identified constructs, but Johnson (2008) did identify some potentially problematic linguistic issues, usually between the notions of quality and quantity.

Crudge and Johnson (2007) used the repertory grid to elicit a set of constructs relevant to web search engines (such as Google) from ten information science undergraduates. They then used laddering to determine the reasons for a construct's importance within the user's mental model. Using standard qualitative techniques they identified three hierarchical strata that conveyed the interrelations between basic system description, evaluative description and the key evaluations of ease, efficiency, effort and effectiveness. Two additional layers related to the perceived process and the experience of emotion are also discussed. They concluded that their model of key evaluations with the conjunctions of procedural elements provided a framework for further research to evaluate search engines from the user perspective.

In another use of laddering, Voss *et al*. (2007) used two laddering techniques (personal interviews and laddering questionnaires) to identify desired qualities of lecturers in a sample of eighty-two business management students. They found that personal interviewing led to more complex ladder structures with more components. Among the substantive findings they found that students' academic interests motivated them less than the vocational aspects of their studies.

Madill and Latchford (2005) explored identity change in four medical students over their first year of medical training, particularly in relation to their experience of human dissection. Each participant completed two repertory grids (one oriented towards their identity

construction, the other drawing out their experience of human dissection) at two time points, early in term one and towards the end of term three. The identity constructs elicited involved three common themes: dedication, competence and responsibility, as well as negative reactions, such as feeling driven and stressed. Three major themes were apparent in their experience of human dissection: involvement, emotional coping and ability. Complex patterns of relationships between the grids and between occasions led the authors to see a development of a vulnerable sense of professionalism alongside a frustration at potentially losing out on wider aspects of personal development.

29.6 Competing demands in the use of the repertory grid technique in research

The major overarching issue in repertory in research is the tension between individuality and commonality. A grid which is elicited wholly from the respondent is the most valid representation of that person's construing. Research, however, demands replication across subjects, so that for some purposes there needs to be commonality across respondents. Where the researcher's interests are qualitative, then individual grids form a useful way of collecting qualitative data. Some studies in the previous section provide examples of this feature.

When the structure of the grid data is of interest, the quantitative aspects of the grid become important. When these are specific to an individual because of the individualized specification of elements and elicitation of constructs, the quantitative component of an individual's grid cannot be related to that of others. In such situations the only traditional way these individualized grids could be compared is through the use of grid summary measures, such as 'cognitive complexity' or self–ideal discrepancy across constructs. When grids have some aspects in common, for example, role-specified elements or supplied constructs, it is possible to analyse the common aspects of such grids (see Fransella *et al.*, 2004, pp. 98–101). A recent development for data analysis in the individualized construct situation discussed above makes it now possible to carry out analysis at the level of construct. This can take account of within-grid variation at the simplest level, but where constructs can be commonly (across grids) qualitatively categorized, the categories can then be used as a factor in the analysis. Heckmann and Bell (2015) have recently shown how this can be carried out with free web-based software.

There are also some issues with aspects of grid elicitation, particularly relating to the issue of bipolarity in the grid. When only one pole of the construct is used, unwarranted inferences about constructs' polar opposites may be made. Yorke's (1978) illustration of the possibility of the researcher obtaining 'bent' constructs might suggest the usefulness of the opposite method (Epting *et al.*, 1971) in ensuring the bipolarity of elicited constructs. There is also the previously mentioned uncertainty about the meaning attached to mid-point ratings. Value-laden element role titles (such as 'A teacher I disliked') can affect the structure of the grid (see Haritos *et al.*), as can the orientation of construct poles. A number of practical problems commonly experienced in rating grids are identified by Yorke (1978):

- variable perception of elements of low personal relevance;
- varying the context in which the elements are perceived during the administration of the grid;
- halo effect intruding into the ratings where the subject sees the grid matrix building up;
- accidental reversal of the rating scale (mentally switching from 5 = high to 1 = high, perhaps because '5 points' and 'first' are both ways of describing high quality). This can happen both within and between constructs, and is particularly likely where a negative or implicitly negative property is ascribed to the pair during triadic elicitation;
- failure to follow the rules of the rating procedure. For example, where the pair has had to be rated at the high end of a five-point scale, triads have been found in a single grid rated as 5, 4, 4; 1, 1, 2; 1, 2, 4, which must call into question the constructs and their relationship with the elements.

Laddering also presents problems, both in process (Butt, 1995) and in the hierarchical implications that follow (van Rekom and Wierenga, 2007).

Another problem is the continuing tension between theory and method in the repertory grid. Major works devoted to the repertory grid technique (Bannister and Mair, 1968; Fransella and Bannister, 1977; Jankowicz, 2003; and Fransella *et al.*, 2004) have all been written from a personal construct theory perspective and emphasize the importance and relevance of Kelly's theory to the usage of the technique. Yet most research with the repertory grid is carried out with the grid being used in a purely methodological and a-theoretical fashion that is content with a passing reference to Kelly as the originator of the grid. As this chapter demonstrates, the theory can be used to understand what is happening in the grid, but of course it is not essential to its use. The real drawback to the personal construct

theory background of writers in this area is often with the jargon employed, particularly for indices or measures developed to summarize structures in the grid. For example, the average correlation used to summarize relationships between constructs was originally termed 'intensity' by Bannister (1970) and is often referred to by that name.

29.7 Resources

It might be thought that the repertory grid is unchanging. However, there has been continuing research to inform the technique itself (some details of such developments have been mentioned in this chapter) as well as new measures that can be derived from grid data (for example, Bell (2004b) devised a new index of inconsistency in ratings in the grid) that could have applications in educational research. Most, if not all, of these developments occur through the work of researchers identified with personal construct psychology. Such researchers tend to work alone or in small groups across the globe and use the web as a means of communication. There is a very general and comprehensive site maintained by the George Kelly Society with many resources and links to groups, publications and computer programs located at www.kellysociety.org/resources.html.

The major computer programs for the analysis of grid data through SPSS can be found on the Kelly Society website (http://kellysociety.org).

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Role-play and research

CHAPTER 30

Carmel O'Sullivan

This chapter introduces role-playing as a research technique, and discusses issues such as:

- role-play pedagogy
- what is role-play?
- issues to be aware of when using role-play
- role-play as a research method
- how does it work?
- strategies for successful role-play
- a note on simulations
- examples of research using role-play

Role-play is very valuable for researching questions such as 'what if', 'how', 'why', 'if–then', 'what are the effects of', 'what are responses to', 'what are the challenges in', 'what happens if', 'what are the key issues in'. They can examine individual and group behaviour in controlled and less controlled environments, in safe environments and in particular situations. They are useful in studying complex situations, interactions and evolving decisions, and in which issues capable of different interpretations, negotiations or potential conflicts are included.

30.1 Introduction

Erving Goffman (1969, p. 78) famously claimed that '[l]ife itself is a dramatically enacted thing', and although he recognized that 'all the world' is not a stage, he argued that 'the crucial ways in which it isn't are not easy to specify'. The perception of people playing some role or other in their everyday lives is a common theme in literature. The Irish playwright Oscar Wilde similarly advanced the argument that life and drama are closely connected:

> Actors are so fortunate. They can choose whether they will appear in tragedy or in comedy, whether they will suffer or make merry, laugh or shed tears. But in real life it is different. Most men and women are forced to perform parts for which they have no qualifications. … The world is a stage, but the play is badly cast.
>
> (Oscar Wilde, *Lord Arthur Savile's Crime*, 1891)

It is undeniable that drama, in some form or other, touches most people's lives, typically in society today through watching television soap operas, going to the movies or attending the theatre. However, drama has been recognized for many years as a useful training method in the fields of business, health sciences, industrial psychology, law, sociology, political science and education. Harriet Finlay-Johnson (1912) and Henry Caldwell Cook (1917) were using dramatic play in schools as a teaching and learning method in England at the turn of the twentieth century, while Jacob Levy Moreno (1908) was similarly exploring its use with children in Vienna, before later developing its application in therapeutic procedures known as psychodrama (Moreno, 1939).

Owing to the immediacy of its impact, drama can affect people in powerful ways, and historically it has been viewed unfavourably by ruling hegemonies wishing to suppress its ability to move audiences and mould attitudes (Banham, 1995). As is the case with all art which has the power to 'move people', the educational use of drama has the potential to connect with people both emotionally and cognitively, resulting in what we might call 'felt understanding'; a type of knowing which results in people taking a personal interest in issues and wanting to effect change. This potentially subversive power has been recognized throughout the ages by different ruling elites and oppressive regimes, who sought to diminish or eradicate its power through banning or severely censoring it.

Fearing the connection between political radicalism and social unrest, and the powerful role of theatricality in everyday life (Nicholson, 2015), censorship of the theatre and dramatic performativity in people's daily lives remained active throughout most of the twentieth century. However, recent archival and other evidence reveals that bureaucratic regulation, prohibition and state control in right-wing dictatorships, post-colonial regimes, communist systems and western democracies continue to censor drama and theatre performances in the twenty-first century (O'Leary *et al.*, 2015).

In spite of this, drama's potential as a valuable educational method has endured, and with the publication

of Maier *et al*.'s training manual for role-playing in 1957, an ever-increasing number of researchers have been motivated to use role-play in their research design. Described as 'a pioneering attempt to portray industrial conflicts in role-playing format' (Mee, 1957, p. 135), the authors (Maier *et al*., 1957, p. xi) recognize that understanding the 'principles of human behavior has little value unless it is supplemented with skill practice'. Maier *et al*. (1957) describe one of the benefits of using role-play as being able to demonstrate the gap between thinking and doing. The innovative approach was well received at the time by researchers in a number of applied areas, including sociology, education, management science and industrial relations (see Berg, 1957; Borgatta, 1957; Mee, 1957; Argyris, 1958), and researchers recognized in this fusion of case study method with role-playing techniques a rich potential to analyse aspects of social behaviour and social interaction implicit in ordinary living.

In the succeeding sixty years, role-play has been widely used in education and training, and increasingly in the field of corporate training, where it is used to explore such issues as change management, negotiation skills, communication skills, leadership skills, entrepreneurial attitudes, team building, presentation skills, management training, public speaking, assertiveness training, performance management, customer service, interview skills, stress management, appraisals training and media training.

Role-playing, gaming and computer simulation are three related strands of activity in this wider field, but it is beyond the scope of this chapter to explore the last two categories in detail (but see Chapter 23 of the present volume), and the focus here is on the use of role-play as a technique in educational research. Similarly, the area of online role-play and game-based learning is currently burgeoning, with many people beginning to research the areas of socialization and social identity theory as key constructs underpinning learning in massively multiplayer online role-playing games (MMORPG) (see Liang, 2012; Moon *et al.*, 2013). These experiences, while usually recreational, can also offer valuable social and educational outcomes. Moser and Fang (2015) refer to the value of narrative structure and decision-making points as improving participants' experience of online role-playing games.

Prosocial behaviour and skills, absorption and empathy are also positively identified with online role-playing games (Rivers *et al.*, 2016). Research is indicating that role-playing can be effective in online language learning and teaching (Ashraf *et al*., 2014; Zhang *et al.*, 2016). The developing research area of how to respond to 'unexpected events' also currently features as a key characteristic of digital game-based learning. The creation of immersive virtual worlds which facilitate participants' realistic interactions and enhance their experiential learning of human-related issues, such as teamwork, communication and collaboration, is attracting much attention in the literature (Maratou *et al.*, 2016; Sampson *et al.*, 2014) (see Chapter 23 of the present volume).

30.2 Role-play pedagogy

Education systems worldwide are constantly reinventing themselves in the twenty-first century in an effort to keep pace with the exponential growth in digital learning and media. Technology is dramatically changing the nature of learning, training and education, and voraciously demanding rapid sectorial and societal responses. Terms such as project-based learning, STEM/STEAM, blended learning, flipped classrooms, inquiry-based instruction, mLearning, T-learning, microlearning, social learning, gamification, Tin Can and personalized learning, all feature as the latest buzzwords in the field of learning and development.

Experiential learning is quickly becoming an umbrella term for many of these ideas where the emphasis is on active and creative forms of learning that provide learners with experiences through which they can acquire, experience and develop new knowledge and skills (on- or offline). It is within this context that the idea of ownership and 'owning learning' has resurfaced in education as a response to technology-assisted learning and the changing profile of many learners globally.

There is a common theme running through much of the recent literature in education which reflects the idea of empowered, autonomous, active, participatory and creative teaching and learning practices for lifelong learners in the new millennium, and role-play is being called into service as a way of encouraging engaged, enjoyable and deep learning from early years to adult education. With the current emphasis on experiential learning, role-play is seen as motivational, helping to develop student confidence and facilitate graduate skills acquisition (Waters, 2016).

Recent studies across most disciplines are reporting greater success in inviting learners of all ages to engage in role-play, and it is increasingly featuring as a core teaching, learning and assessment strategy across all levels of the education and work systems. Terms such as role-play pedagogy are regularly cited (Shapiro and Leopold, 2012; Gordon and Thomas, 2016), and it is explicitly associated with pedagogic aims placing

students in real-world contexts and encouraging them to explore the complexities of decision making, reflecting on issues and the views of others (Smith, 2016). Reflection features consistently in the literature on role-play, and Wadensjö (2014) found it effective as a method to encourage examiners to reflect on role-play as an assessment instrument in examination sessions (see also Johansson *et al.*, 2012).

In keeping with the emphasis on what are loosely termed twenty-first-century skills, many of which are associated with social and emotional learning, role-play is increasingly being used in multiple formats:

- to 'stand in the shoes of someone else' (role-switch: to learn from the inside out);
- acting (practising a skill); and
- 'almost real life' (experiencing something as close to the real-life example as possible) (Rao and Stupans, 2012).

This aligns closely with the current emphasis on social skills, metacognition and lifelong learning, particularly with 'millennials' and the newer 'generation tap', who are born in a digital age where vast amounts of information are available at a touch, but where many learners need to learn how to use, critically interpret and apply it.

Ideas such as adding variety, interest and involvement in learning, increasing students' sensitivity to feelings and the attitudes of others, enhancing the authenticity of experiences, giving students insight into the dynamics of interpersonal interactions in relationships which cannot be gained from other methods, were commonly associated with role-play in the 1950s and 1960s (Buxton, 1956; Shipman, 1964) and are making a strong comeback as part of the twenty-first-century suite of skills, which arguably is connected to role-play.

Although role-playing is increasingly featuring in the literature in many subject areas as a creative and participatory teaching and learning strategy, it has had mixed success to date as a research method, much of it owing to a persistent lack of clarity about what it is and how to use it, as revealed in an early report from the *British Medical Journal* in Box 30.1.

We begin by taking a closer look at drama and role-play in order to increase our understanding of what it is and how it works.

30.3 What is role-play?

Deriving its theoretical basis from the field of psychodrama, role-play is a 'spontaneous, dramatic, creative teaching strategy in which individuals overtly and consciously assume the roles of others' (Sellers, 2002, p. 498). Sellers argues that it involves 'multi-level communication' (p. 498), and as a powerful teaching strategy is capable of influencing participants' attitudes and emotions, whilst simultaneously promoting higher-order cognitive skills. This definition supports the claim that role-play is an effective strategy for learning because it encourages participants to think about the person whose role is being assumed, is connected to real-life situations and promotes active, personal involvement in learning (Billings and Halstead, 2009). Errington (1997, p. 3) defines role-play as 'a planned learning activity designed to achieve specific educational purposes'. He suggests that it is based on three major aspects of the experiences that most people have of roles in everyday life:

- role-taking (the roles we hold in accordance with social expectations and in social circumstances, i.e. how police officers should act) (Goffman, 1976);
- role-making (the ability to create, switch and modify roles as required) (Roberts, 1991);
- role-negotiation (negotiation and social interaction with other role holders) (Hare, 1985).

For educational researchers, these categories offer a wealth of possibilities for accessing and exploring people's behaviour and responses to situations and stimuli in a diverse range of contexts and settings. For example, a researcher investigating a new coaching and mentoring training approach for senior managers in schools may involve participants in varying aspects of role-taking, role-making and role-negotiation as part of his overall research design to gather relevant data.

Role-play consists of three major stages: briefing, acting and debriefing. The first stage focuses on introducing the participants to the activity by clarifying the learning objectives and 'setting the scene'. In the second stage, the educator must encourage the participants to 'act out' the role in a spontaneous, accurate and realistic manner. Debriefing, the final stage, allows participants to discuss, analyse and evaluate the role-play and insights gained (Billings and Halstead, 2009).

Working in drama involves stepping into an imagined world, a fictional reality, and in order to make this imaginary world more meaningful and purposeful in an educational research context, it must have aspects of the real world in it. Thus, human relationships are a central component of role-play situations, and exist in the form of:

1. relationships between people;
2. the relationship between people and ideas; and

BOX 30.1 A ROLE-PLAYING EXPERIENCE

It's Wednesday morning again, and time for our clinic sisters' teaching session. Anybody who thinks this gives me a relaxing two hour break from the rigours of outpatients is sorely deluded. Seeing a hundred patients seems quite a soft option compared with facing our four most senior sisters, exercise books open and pens poised to take down my every word.

Thinking up suitable topics is not easy. But harder is the actual task of teaching. British medical training provides ample case studies in how not to teach, and I've wasted many hours trying to find a comfortable sleeping position while a well intentioned lecturer starts on yet another new piece of chalk. Surely I can do better than that?

So I've put away the blackboard. And I've got the chairs rearranged in a circle. Dividing up for group work is tricky when there's only five of us all together. 'Brainstorming' with the flip chart is a bit of a non-starter with a group that's as talkative as a bunch of Trappist monks. But for today's session, on AIDS counselling, there is only one possible option. I must introduce them to the joys of role-play.

After a prolonged discussion about counselling in general, we kick off with a simple scenario. I am heading the bill with a stirring performance as Sipho, a young Zulu man who will need to be told that he is HIV positive. I have been rehearsing my lines for sometime, and I am all ready to bring the audience to its feet with my impassioned soliloquy. Sister Gumede has bravely volunteered to star in the lead role as, well, a clinic sister. After all, it is the first time they have ever done role-play, and I don't want to put them off.

So I reel off my performance, standing up, gesticulating, groaning, and clutching my head as I hear the bad news. Only the glycerine tears are missing. But the audience is not moved. They watch with bemused perplexity, and take copious notes. Sister takes her cue, and improvises her lines deadpan: 'Sipho, your HIV test is positive. We don't have any cure for AIDS so you are going to die.'

Now I have real cause to groan and clutch my head. What sort of a way is that to counsel someone who is HIV positive? Where are the open ended questions, the active listening, the non-verbal communication? My Balint colleagues in Lisson Grove would throw up their hands in horror.

But this is Africa, not north London. Maybe sister's performance is the one that should win the Oscar. After all it is exactly the way most of the sisters talk to patients, and probably the way that patients expect to be spoken to. And whoever saw a Zulu man behaving anything like my performance? Maybe this role-play business is not so simple. Maybe teaching is not so simple. So next time, sisters, bring your pillows; I am going to write notes on the blackboard.

Duncan Curr, Medical Officer, Mosvold Hospital, Ingwavuma, South Africa

Source: Curr (1994, p. 725)

3 the relationship between people and the environment (O'Toole and Haseman, 1992, p. 3).

These categories provide a useful framework for researchers interested in using role-play to identify who and what their research should focus on. Thus a researcher who wishes to explore whether teenagers empathize with bullied peers may use role-play to determine the extent to which young people:

1 discuss the issue among themselves, and if/how they would approach the subject with a peer in school who they know is being bullied;
2 engage with training sessions and resources they have received in school on the issue of bullying, and if/how they put these into practice;
3 demonstrate an awareness of their role in the creation of a culture that does not accept or tolerate bullying in their school environment and wider social community.

Taking on roles allows participants to set up and explore the different dynamics of the relationships cited above, but differs from traditional understandings of theatre in that the role-taker is not required to demonstrate elaborate acting skills, rather, simply to represent a point of view. Ideally, the role should be portrayed honestly and without elaborate costumes or props, where participants place themselves 'as if' they are that person, temporarily identifying with and exploring a set of attitudes and values, which may not identify closely with their own. It is therefore important that

participants respect the role being played, as it represents another person's perspective or point of view (O'Toole and Haseman, 1992, p. 3). Lowenstein (2016) describes role-play as a versatile technique which focuses on the actions of the characters, their attitude to the situation, and not on their acting ability. The role-play must be lived at life-rate (i.e. in that moment), and aim to create a living picture of life, which provides a learning opportunity for the participant as much as for any onlookers, including the researcher.

The more realistic the role-play, the better the outcomes, according to Dennison (2011), who found in her study that using theatre studies students as patients was not as realistic as using a more traditional approach to role-playing where the social work students played the role of the patients themselves.

Role-play is improvisational in nature and increasingly unscripted, although role-cards may be supplied to provide sufficient background information to participants to enable them to comfortably 'step into the shoes' of another, and feel what it might be like to be that person in that situation for a little while. Wagner (1998, p. 60) defines improvisational drama as taking on 'a role in a particular moment in time and creating with others a plausible world'. She argues that when working in role, as in all learning contexts, participants make meaning by connecting their prior experiences to the challenge of the moment (see Bradshaw and Hultquist, 2017). However, using a non-parametric test, Osborn and Costas (2013) found no statistically significant difference in the development of counselling skills between students improvising their own role-plays and using scripted role-plays.

30.4 Why use role-play in research?

Cabral (1987, p. 470) describes role-playing as a valuable technique that 'has been broadly adapted for use in academic research and applied settings'. Before presenting the arguments related to the particular use of role-play in research contexts, it is worth taking a brief look at the general educational claims made in its name. In their aptly titled book *So You Want to Use Role-Play?*, Bolton and Heathcote (1999) provide six major categories which summarize the use and value of role-play in education.

1. Behaviour modification. It is a concrete form of learning, and particularly suitable for giving participants practice in behavioural procedures (for example, training reception staff or police officers to handle particular situations according to an established procedure).
2. Acquiring information.
3. Using information.
4. Training in seeking information.
5. Attention to detail (role work can generate in participants a disposition to attend to detail, an alertness to particulars).
6. Fostering a change in values, perceptions or attitudes.

(Adapted from Bolton and Heathcote, 1999, pp. 178–85)

The arts, and role-play in this particular discussion, work by revealing truths about people and the world they live in, and they do this through the creation of a fictional situation, a make-believe world, but one that is closely connected to reality. This is the difference between fiction and fantasy, and in most research situations where role-play is used, the emphasis is on working in and through fiction: uncovering and exploring truths about reality, and about how we respond individually to such situations, as we each construct our own understanding of experiences. Bolton and Heathcote (1999, p. ix) are concerned with broadening the traditionally perceived use of role-play, away from a strictly behavioural emphasis to the communication of meaning. Thus, an educational researcher interested in investigating social skills education with children with an autistic spectrum disorder may use role-play to create a baseline assessment of participants' 'theory of mind' (i.e. their ability to perceive and understand the thoughts of others) through placing the children in role as detectives, observing a crime as it unfolds and trying to predict what the characters are thinking at that time (see O'Sullivan, 2015).

There are many uses and types of role-play, but the single criterion underpinning all role-play activity, according to Bolton and Heathcote (1999, p. 57), is that it demands participants to step into an 'as if' fiction: a fiction that has been 'conceived of by a tutor, teacher, or researcher in terms of *learning*'. It poses a unique challenge to participants, as it involves 'embracing knowledge', an act which is not just a matter of instruction or absorption, but is achieved by entering the fiction in such a way as to make the required knowledge one's own. Thus, role-players are not just receiving or acquiring knowledge as in a typical instructional context; they are making it, practising it and embodying it: they know what they know (Bolton and Heathcote, 1999, pp. 57–8). This highlights the importance of accurately setting up and structuring the role-play to record these truths and attitudes, and thereby increase the reliability and validity of the data retrieved.

Roslyn Arnold (1998, p. 111) claims that the arts, and in particular drama, uniquely explore the dynamics between affect and cognition, two significant aspects of human existence. The use of role-play in research contexts is a rich source of insight into the role and function of such dynamics. Thus, when participating in role, we articulate both physically and verbally, and this active engagement promotes 'emotional, cognitive, social and ego development. We are, metaphorically speaking, sitting on a research gold mine' (Arnold, 1998, p. 111).

One of the main reasons for considering the use of role-play in research is because of its ability to help participants consider ideas from different perspectives, to think of possibilities. Role-play is concerned with representing and exploring different people's points of view, and different points of view forge different types of knowledge. It places participants at the centre of the learning experience, and allows them to build their own bridges of understanding. As a result of this informed consideration, they are better able to resolve problems and issues. For example, role-play as a research method has been successfully used with young people in a designated disadvantaged school to elicit the extent to which they use an elaborate or restricted linguistic code (public versus private use of language), and whether, through the use of role-playing, they can explore and develop different linguistic registers and codes as appropriate to a range of communication contexts (Heeran-Flynn, 2010).

The following list identifies the range of possibilities in which role-play can be employed as an effective research method. Specifically, role-play can allow participants to:

- experience how people behave in particular circumstances by exploring a variety of social situations and social interactions;
- explore a range of human feelings and responses to situations;
- explore choices and moral dilemmas;
- make decisions which are tested out in the role-play and later reflected on;
- develop a sense of responsibility and confidence as decision makers and problem solvers;
- improve the social health of their group and foster improved relationships with peers or colleagues;
- interact with peers and learn to compromise in order to sustain and develop activities;
- extend, enrich and prompt the use of authentic language use in simulated real-life contexts where language use arises out of a genuine need to communicate;
- explore the skills and processes involved in conflict, negotiation and resolution of difficulties and problems in their environment;
- develop personal creativity;
- develop agency and an increased awareness of self;
- improve visual and spatial skills through responding to a range of stimuli and situations.

Role-play situations as described above can be observed by the researcher, and/or digitally recorded, and replayed to participants to elicit their responses and perspectives according to predetermined or emerging research themes and issues, thereby assisting in the triangulation and interpretation of data. Such an approach was used when investigating social skills education with children and young people with Asperger's syndrome. Role-play was used as a core research method in a longitudinal study to initially create a baseline measure of participants' literal and metaphorical language competencies, and then to assess the extent to which improvements in participants' social skills were revealed and practised during subsequent role-play episodes (see O'Sullivan *et al*., 2009).

Role-play operates in a 'no-penalty zone', where people are freer to explore and try out a range of solutions to problems and issues, without having to worry about the outcome. Such an approach was adopted in a recent study designed to explore the impact of role-plays on primary school children's awareness and knowledge of bullying in an all-boys school (Donohoe and O'Sullivan, 2015). Using the *No Blame Approach* (Maines and Robinson, 1997), within the framework of a role-play-based *Bullying Prevention Pack* (BPP), a standardized survey instrument (Olweus Bully/Victim Questionnaire – Revised, OBVQ-R) revealed a 53 per cent reduction in reports of victimization at the research school.

Drama functions as a way of making the world simpler and more understandable. It can be a kind of 'playing at' or practice of living in real-life situations. It enables participants to put into practice skills they have learnt in the fictional context of the drama world. It is a tool that can affect participants' fundamental reactions to everyday situations. Augusto Boal (1979, 2002) refers to this type of dramatic activity as a 'rehearsal for reality'. In professional disciplines, such as health care, education, engineering and social care practice, both pre- and in-service education models rely on problem-based and enquiry-based approaches to teaching, learning and research. Role-play offers enormous potential in these areas to enhance case study method and facilitate research on models of best practice.

The notion of learning through play tends to be associated with early years education, and opportunities for imaginative and dramatic play decline as a child progresses through the school system and into adult life. An unfounded belief that academic content standards cannot be met through creative and imaginative activities still persists, and has caused playful methods of learning to virtually disappear from classrooms (O'Sullivan, 2016a). The following is a brief summary from the literature reflecting the use of role-play in research on a continuum of lifelong education.

- Role-play facilitates participatory research in case study method (Carte and Torres, 2014).
- Role-play provides rich opportunities to assess communication skills and language use in simulated training sessions (Stokoe, 2013, 2014).
- Role-play is an effective strategy in exploring ethics (Strohmetz and Skleder, 1992; Doron, 2007; Kraus, 2008; Roos, 2011).
- Within a socio-linguistic constructivist approach, role-play can help learners access and communicate abstract ideas in science (McEwen *et al*., 2014; Braund *et al.*, 2015).
- The integrated nature of role-play allows for individual differences in development (Frost *et al*., 2008).
- Role-playing is a popular teaching method with students, and encourages participation, engagement and active learning (Stevens, 2015; Waters, 2016).
- Role-play activities help participants create more informed opinions and stimulate critical thinking and argumentation skills (Agell *et al*., 2015).
- Effective classroom management strategies can be explored through role-play in teacher education programmes (Niemeyer *et al.*, 2014).
- Online role-play is effective in language instruction and the development of collaborative argument (Zhang *et al*., 2016).
- Complex human–environment relations and environmental governance issues can be explored effectively through role-play (Schnurr *et al*., 2014, 2015; Agell *et al*., 2015).

30.5 Issues to be aware of when using role-play

Much of the early history relating to the use of role-play in research settings was mired in controversy and notoriety, mainly relating to issues around deception in experimental social psychology (see Milgram's obedience to authority experiments, 1974; Mixon's role-playing replications of the Milgram experiment, 1974), and to overt/covert forms of research. Bolton (1996, p. 187) discusses the case of James Patrick (a pseudonym), a young teacher at an approved school who in the late 1950s obtained entry into a Glaswegian gang for four months, in order to record and analyse how a city gang functions (see Patrick, 1973). He made friends with a pupil in his school called Tim, and through this acquaintance, joined his pupil's gang. In deciding to open his teacher's eyes to gang life, Tim understood the risks more clearly than Patrick did. Tim was extremely well-behaved when in school, but at weekends he participated fully in the violent incidents that regularly erupted at a moment's notice (Douglas Home, 2007). After having been placed in several uncompromising situations, Patrick left Glasgow quickly when the violence became too severe and he felt threatened by it. As he was so afraid of the gang members, he didn't publish his research until many years later.

Bolton (1996) describes this act of infiltration and deception as a blatantly unethical form of inquiry, although a researcher may well have to ask themselves whether the same information could have been gained by overt means. In contrast to this covert approach, William Foote Whyte (1993) conducted a similar research exercise in a poor Italian district in Boston from 1937 onwards called 'Street Corner Society' (see also Chapter 35 of the present volume). He was interested in the activities of the adolescent boys who hung around street corners and got involved in gang activities. However, his research approach was not covert, and he began almost as an observer, having informed the group that he was writing a book about their activities (Whyte, 1993). Perhaps one of the most controversial examples of a study involving the use of role-play is the well-known Stanford Prison Experiment carried out by Philip Zimbardo in 1971 (2000, 2007a, 2007b, 2008; see also Haney and Zimbardo, 1998), a brief overview of which is given in Box 30.2.

The Stanford Prison study raises uncomfortable questions for researchers. On the one hand, it violated the principle of 'do no harm' (see Chapter 7 of the present volume), exposing the 'prisoners' to cruel behaviour, suffering and sadism, to psychological torment and distress, to the removal of freedom and self-control, to degradation, to the loss of identity in the prisoners, to physical abuse, embarrassment (e.g. strip searches), harassment, public humiliation, to feelings of helplessness and despair, to emotional breakdown and to some longer-term trauma. As one participant said, years later: 'It is still a prison to me. … It harms me.'

On the other hand, the participants were volunteers who had undertaken diagnostic psychological screening

BOX 30.2 THE STANFORD PRISON EXPERIMENT

The study was conducted in the summer of 1971 in a mock prison constructed in the basement of the psychology building at Stanford University. The subjects were selected from a pool of seventy-five respondents to a newspaper advertisement asking for paid volunteers to participate in a psychological study of prison life. On a random basis, half of the subjects were assigned to the role of guard and half to the role of prisoner. Prior to the experiment subjects were asked to sign a form, agreeing to play either the prisoner or the guard role for a maximum of two weeks. Those assigned to the prisoner role should expect to be under surveillance, to be harassed, but not to be physically abused. In return, subjects would be adequately fed, clothed and housed and would receive fifteen dollars per day for the duration of the experiment. The outcome of the study was quite dramatic. In less than two days after the initiation of the experiment, violence and rebellion broke out. The prisoners ripped off their clothing and their identification numbers and barricaded themselves inside the cells while shouting and cursing at the guards. The guards, in turn, began to harass, humiliate and intimidate the prisoners. They used sophisticated psychological techniques to break the solidarity among the inmates and to create a sense of distrust among them. In less than thirty-six hours one of the prisoners showed severe symptoms of emotional disturbance, uncontrollable crying and screaming, and was released. On the third day, a rumour developed about a mass escape plot. The guards increased their harassment, intimidation and brutality towards the prisoners. On the fourth day, two prisoners showed symptoms of severe emotional disturbance and were released. On the fifth day, the prisoners showed symptoms of individual and group disintegration. They had become mostly passive and docile, suffering from an acute loss of contact with reality. The guards, on the other hand, had kept up their harassment, some behaving sadistically. Because of the unexpectedly intense reactions generated by the mock prison experience, the experimenters terminated the study at the end of the sixth day.

Source: Adapted from Banuazizi and Movahedi (1975)

before being admitted to the experiment, and they were provided with long-term follow-up support for many years. Further, its findings had, and continue to have, important implications: 'ordinary' everyday people have the potential to become sadists and to become highly emotional; the 'power of the situation' can exert extreme effects on people's behaviour beyond what might have been imagined, and indeed overtakes the power of the individual; the pathology of prisons is exposed clearly; and control and domination have rapid and powerful effects on all participants (e.g. prisoners and guards). In other words, the benefits to society were immense, and indeed spawned research into shyness and shyness therapy. Decades later, the experiment's director, Zimbardo (2007a) indicated how the 'Lucifer Effect' (his term) continued to operate in contemporary situations (e.g. in the US military's treatment of prisoners). The role-play provided findings which might not have been possible otherwise. The dilemma for researchers using role-play here raises awkward questions: Is the benefit worth the cost? Does benefit to the many override the harm to a few? Does the end justify the means? Further, for researchers, the Stanford Prison Experiment demonstrates very clearly the power of role-play as a research technique.

In discussing the Stanford Prison Experiment, Bolton (1996, p. 188) argues that the disregard of ethical standards in this research results from 'the tacit permission that role-playing a power-position gives', and not from deception. Although the researchers anticipated the risk of physical abuse and changed the rules to reflect this, they failed to predict the pleasure that some guards might derive from employing psychological abuse, 'even when they could perceive … the genuine discomfort of their victims' (Bolton, 1996, p. 188).

Early enthusiasts of role-playing as a research methodology cite experiments such as the Stanford Prison Experiment to support their claim that where realism and spontaneity can be introduced into role-play, then such experimental conditions do, in fact, simulate both symbolically and phenomenologically the real-life analogues that they purport to represent. Such advocates of role-play would concur with the conclusions of Zimbardo and his research associates that the simulated prison developed into a psychologically compelling prison environment, and they, too, would infer that the dramatic differences in the behaviour of prisoners and guards arose out of their location in different positions within the institutional structure of the prison and the social psychological conditions that prevailed there, rather than from personality differences between the two groups of subjects (see Banuazizi and Movahedi, 1975; Stokoe, 2013).

Bolton (1996) expresses concern that the use of role-play in such circumstances can appear to give permission to participants to behave outside their normal moral constraints. Grumet (1998) acknowledges that taking on a role is complex and provocative, and when working in role, researchers should be aware of 'the power of a role to extend or constrict meaning and exploration' (p. 8). If we accept the Latin word for role as *dramatis personae*, there is a danger that the participant may hide behind the mask of a role, taking on 'actions and ideas that would be difficult to assume within his or her daily identity' (p. 8). Thus, playing a role in this context may result in behaviours and attitudes that extend imagination and expression beyond the individual's usual capacity, and 'the imaginative extension of ego into role' might have the effect of constraining rather than enlarging understanding (p. 9).

On the other hand, Grumet (1998, p. 9) argues, when a role is used in a naturalized scene, untrained participants may 'fail to fill it with the complex and multiple possibilities that a real life situation' would demand, choosing instead to adopt a more stereotypical action in the improvisation than might exist in real life. The researcher must therefore look for opportunities to break the often powerful grip of a scene and role, and encourage critical reflection on the choices that are being taken in the role-play. The aim is to shift, alter, interrupt and possibly distort the focus of the role-play (during it if necessary), to allow participants to explore and experience different aspects of the situation under consideration, thereby 'avoiding a reductive metonymy that would substitute the improvisational situation for the world', with its infinite colour and myriad possibilities (p. 9). This can often be achieved by following step 8 (the hidden objective) as described in Box 30.3.

Wagner (1998, p. 58) suggests that working in drama requires the same intelligence it takes to live one's life in the real world, in order to be able to cope with the many possibilities, choices, decisions, ambiguities, changes, etc. that face people on a daily basis. The challenge in drama is to engage with those issues without losing the capacity to analyse situations responsibly and carefully, choose between alternatives that are not always clear, 'act on those choices and live with consequences. In other words, to think before, during, and after one acts' (p. 58). For the researcher interested in exploring the intricacies and complexities of life, the key is to set up and organize the role-play event so that it accurately reflects, not mirrors, the situation under scrutiny (see the guidelines provided in Box 30.3). When working with medical students, Joyner and Young (2006) highlight the importance of defining the learning objectives and setting the ground rules from the outset if a role-play is to be effective.

In using role-play in research trials such as the Stanford Prison Experiment, where none of the preliminary documentation given to participants refers explicitly to the act of role-playing, or provides them with information or guidance on how to safely 'enter a role', 'step into the shoes of another person' and behave as if they are that person for the duration of the activity (see www.prisonexp.org for copies of the original documentation), there is an implicit assumption that the person in charge of organizing the game is taking on ultimate responsibility for what might happen. Bolton (1996, p. 188) suggests that this effectively provides temporary release to the participants to regard the experiment as 'only a game and, what's more, someone else has asked us to play it'. However, he makes an interesting observation when he claims that this seeming release from responsibility rarely extends to breaking the rules of a game, and he recommends that researchers interested in using role-play may need to pay particular attention to this by 'delineating participant goals and delimiting strategies' (p. 188). It may have been a very different prison experiment had the responsibility been altered during the role-play by telling the warders that they had been nominated for promotion within the prison service on the basis of their ability to combine authority and respect in their dealings with prisoners (p. 188). The flexibility of role-play as a research method can provide a researcher with valuable opportunities to shift variables and explore other angles/perspectives, all within the framework of the existing role-play, thus saving time and resources (with due attention being paid to ethical issues and constraints as relevant).

In High Fidelity Patient Simulation (HFPS), which uses interactive computerized mannequins, priority is given to safety when teaching about complex clinical situations that mimic reality (Jarzemsky *et al.*, 2010; Munshi *et al.*, 2015). Clear measurable objectives are set for each simulation, and conclude with debriefing and reflection opportunities.

There is recognition that all acting is, by definition, 'not real'. The extent of the illusion is reflected in the different versions of reality and humanity portrayed, and in role-play it is possible to show both the inner and outer voices of a participant. This is referred to as the self-spectator, where participants are able to monitor their performance in the role, and are not overwhelmed by it (O'Neill, 2014). They are empowered through the initial setting up of the exercise to be able to maintain a dual personality: they are watching themselves as they play the role, and can learn from the

experience. This is particularly useful for researchers as it allows them to gather data from a dual perspective, i.e. what it was like for participants to play the role of someone else, and to compare that experience to participants' own realities. Such data can be used by the researcher to inform and create a multilayered approach to the research.

In the Stanford Prison Experiment, however, the participants appear to have been fully submerged in the role, or as Sartre (1976, p. 162) might put it, 'devoured by the imaginary'. This led to its own consequences, as presented in Box 30.2, and serves to highlight the necessity of thorough planning and preparation for the use of role-playing in research contexts, particularly in the field of social psychology. O'Neill (1995, p. 70) suggests that anyone who publicly takes on a fictional role changes in response to the alteration in interpretive attitude of the viewer to the viewed. They become simultaneously 'more' than themselves in a state of metaxis, acquiring what Roland Barthes (1972, p. 49) calls a 'corporeal exemplarity'. A role can protect and conceal a participant within the dramatic world, and they can be simultaneously 'both more and less than themselves. They embody both present meaning and future possibility' (O'Neill, 1995, p. 144). For this reason, role-play can provide an experimental setting in which questions of identity and the power and limitations of the roles we inhabit may be explored (O'Neill, 1995).

A further example of ethical dilemmas in role-play are the experiments by Stanley Milgram on obedience to authority (Milgram, 1974). In a series of studies from 1963 to 1974, Milgram carried out numerous variations on a basic obedience experiment which involved individuals acting, one at a time, as 'teachers' of a 'learner' (who was, in reality, a 'confederate' of the experimenter). The researcher explained to the participants that the experiment, though initially advertised as a study of memory, in fact was a study of the effects of punishment on learning: if 'learners' made errors in learning they were 'punished' by receiving what the 'teacher' believed were electric shocks. In fact, the teacher – the member of the public who was a participant in the research – did not know that the electric shocks were not real but were simulated by the learner (an actor who had been briefed by the researchers to complain, shout and scream as the supposed electric shocks were administered).

The experiment was not actually about the effects of punishment on learning at all; it was about obedience to authority, as the 'teachers' were urged strongly by the research director (an authority figure: a man dressed in a laboratory coat) to persist with the experiment even if they had serious reservations about administering increasingly powerful electric shocks.

'Teachers' were required to administer electric shocks of increasing severity every time the learner failed to make a correct response to a verbal learning task. Over the years, Milgram involved over 1,000 subjects in the experiment – subjects, incidentally, who were drawn from all walks of life (rather than, for example, from undergraduate psychology classes). Summarizing his findings, Milgram (1974) reported that typically some 67 per cent of his 'teachers' delivered the maximum electric shock to the learner despite the fact that such a degree of severity was clearly labelled as highly dangerous to the physical well-being of the person on the receiving end.

A role-play can involve scripted and/or unscripted elements. The 'confederates' might be given scripted comments in order to ensure some 'controls' in the role-play. For example, in this study the 'learner' was a confederate who gave scripted responses to different levels of electric shock, which were standardized across the different 'teachers', and the laboratory-coated director gave scripted responses to 'teachers' who were questioning the state of health of the 'learner' or who were reluctant to continue with the study.

Again, the research raises uncomfortable ethical questions for researchers using role-play. On the one hand, the research involved deception, telling lies about the purpose of the experiment, making the 'teachers' believe that they were administering electric shocks, making them feel very uncomfortable about administering these, putting them in a conflict situation and putting them under pressure to continue with the experiment despite their reservations, challenges and discomfort (Baumrind, 1964; Mixon, 1974).

Objections to the use of deception in experimental research are:

- Lying, cheating and deceiving contradict the norms that we typically try to apply in our everyday social interactions. The use of deception in the study of interpersonal relations is equally reprehensible. In a word, deception is unethical.
- The use of deception is epistemologically unsound because it rests upon the acceptance of a less than adequate model of the subject as a person. Deception studies generally try to exclude the human capacities of the subject for choice and self-presentation.
- The use of deception is methodologically unsound. Deception research depends upon a continuing supply of subjects who are naive to the intentions of the researchers. But word soon gets round and

potential subjects come to expect that they will be deceived. It is a fair guess that most subjects are suspicious and distrustful of psychological research despite the best intentions of deception researchers.

On the other hand, the participants were all volunteers. Moreover, they had the right to withdraw at any time or not to administer the electric shocks, they were debriefed at the end of the experiment so that they knew that no actual harm had been done to the 'learner', and neither Milgram nor any of the psychologists whom he had consulted before the experiment thought that the 'teachers' would persist in applying the electric shock of such high voltage, and indeed the participants indicated subsequently that, though they had been stressed, they were pleased to have taken part in the experiment (Dixon, 1987). Further, the experiment showed clearly the huge power of an authority figure to compel obedience – people simply follow orders and rules.

As with the Stanford Prison study, the Milgram role-play experiment, though it is unlikely that it would be approved by ethical regulation bodies nowadays, provided findings which might not have been possible otherwise. The dilemma for researchers using role-play again raises awkward questions: Is the benefit worth the cost? Does benefit to the many override the harm to a few? Does the end justify the means? Further, for researchers, the Milgram obedience to authority study demonstrates very clearly the power of role-play as a research technique.

30.6 Role-play as a research method

The approach to role-play advocated in this chapter represents a move away from a strictly behaviourist system to one which emphasizes process, and is involved in the creation and communication of meaning. Thus, role-play as presented here offers particular advantages to a researcher who is interested in exploring and analysing data which may not be easily accessed through other methods. It is a unique blending with case study method, and offers a rare opportunity to critically examine aspects of social behaviour and social interaction in relationships between people, ideas and the environment.

Using role-play in research allows researchers to:

- explore the principles of human behaviour in real-life settings, lived at life-pace;
- access and assess how people make sense of their lives, and the structures of the natural world;
- prioritize the process of engagement;
- explore different points of view, and forge different types of knowledge;
- adopt multiple viewing points within a data set;
- study multilevel communication;
- identify and explore the development and manifestation of participants' attitudes, decisions, strategies, values, higher-level cognitive and affective thinking skills, and emotions;
- shift and alter variables as the research unfolds, to explore subtleties and nuances in human interactions and situations, in an uncomplicated and undemanding manner, without having to schedule additional sessions or devise alternative methods to collect the data required;
- provide planned or spontaneous physical, emotional, personal, social or intellectual prompts and stimuli to participants, in comparison to the use of predominantly intellectual prompts in other methods such as interviews and questionnaires;
- engage with a fully diverse research population through the use of an inclusive method to explore and access relevant data;
- explore meanings and the ways in which people understand things;
- investigate patterns of behaviour;
- provide a somewhat objective lens through which to interpret the material, and thus distance themselves from the topic of inquiry, facilitating an objective mode of analysis;
- examine ready-made, visually and narratively rich research data, which evoke layers of meaning through reflection;
- capture visual data, adding immediacy and authenticity to the research;
- involve participants as co-researchers;
- engage in meaningful interaction with participants.

30.7 Role-play as a research method: special features

Role-play as a research method has several special features:

- Participants are actively involved in the research process through the three major stages of briefing, acting and debriefing. The use of role-play in a well-structured research process has the potential to create a reciprocal relationship, a valuable learning experience for both researcher and participant, which may ultimately impact upon the quality of resulting data.
- It helps participants to consider ideas from different perspectives. It can place participants at the centre

of the research experience, and allow them to construct their own bridges of understanding. As a result, they are often better able to respond to questions and comments from researchers about the experience.

- It supports participants during the research process, owing to the group and social nature of the activity. It tends to be much less isolating than completing a questionnaire, for example.
- Engages the whole person through the process, and reduces the danger of intellectual speculation or 'navel gazing' (what I would do if I were in that situation…). It places participants '*in situ*', at that moment, and demands a holistic response.
- The role-play can be structured to become incrementally more challenging or complex as participants are eased into the activity and prepared to engage with the issues under examination.
- It is an enjoyable activity and fosters positive relations between the researcher and participants.
- It is a spontaneous, dramatic, creative research strategy in which participants overtly and consciously assume the roles of others.
- The role-play may stimulate related memories and experiences, and can be used as a naturally occurring springboard to explore other relevant experiences or situations without the researcher probing too deeply or overtly.
- It can both relax and poise participants simultaneously, who may respond more openly and freely without overt direction from the researcher.
- It can be controlled by participants, and they can stop, pause or extend the activity at will.
- Debriefing and de-roling activities can increase reflection, and provide rich data that is not easily accessed using other methods, or within such an economic time frame.
- It can provide an added dimension to the research in that participants are engaged in reflexive praxis; they are learning and doing at the same time, i.e. research as a combination of both experience and reasoning.
- Like other forms of empirical data, role-playing may not provide researchers with unbiased, objective documentation, but it can show characteristic attributes that are often missed in other forms of data collection.

30.8 A note of caution

Like much research in the qualitative tradition, role-playing as a research method caters for issues concerning moral responsibility, individuality, freedom and choice, resulting in the collation of rich and personal data. While quantitative research is characterized by presupposed outcomes, qualitative analysis encourages an organic development, with much more flexibility offered to the overall process (see Bartlett and Vavrus, 2016). However, it is important to note that role-playing is always context-bound and localized. It does not lend itself easily to mass generalization, unlike quantitative techniques. The conclusions are usually derived from intensive, small-scale experiences drawing on a rich and deep data set, but they may be highly selective depending on the researcher's objectives. In this approach, the researcher turns away from statistical analysis in favour of in-depth analytical accounts of human behaviour.

If using role-play as a research method, the researcher must ask herself, what impact does the interplay of art with reality have? In addition to those issues identified in the previous section, Ginsburg (1978) summarizes the argument against role-playing as a device for generating scientific knowledge when he notes that:

- role-playing is unreal with respect to the variables under study in that the subject reports what she *would do*, and that is taken as though she did do it;
- the behaviour displayed is not spontaneous even in the more active forms of role-playing;
- the verbal reports in role-playing are very susceptible to artefactual influence such as social desirability; and
- role-playing procedures are not sensitive to complex interactions.

Ginsburg's (1978) critique relates to a form of practice that underpins a behaviourist approach to role-playing. It is noteworthy that many of his concerns have been addressed in the intervening years through the development of a systematic approach to role-play methodology as described in the following sections.

30.9 How does role-play work?

Maier *et al*. (1957, p. 14) state that leading role-playing is not a difficult task, and does not require special training by the trainer. However, this is disputed by Argyris (1958, p. 321), who claims that role-playing requires skilful leaders who have a high degree of self-awareness, confidence and self-worth. As alluded to earlier, the shift in role-play from a typical transactional model of passing on of knowledge to the 'making' of it, 'calls on one's humanness in a way not normally

associated with an instructional context': it can be both demanding and revealing (Bolton and Heathcote, 1999, p. 58).

This was evident in the response of the participants in the Stanford Prison Experiment, and the challenge for researchers is to get the balance right between maximizing opportunities for research and protecting participants. If one over- or under-protects, it may stifle learning. Many people are nervous about role-play, and associate it with being required to 'act' in front of their peers or colleagues. Taking on a role is like an actor working to create a character in a play or film. However, whereas the actor is required to build a complex personality through a process called characterization, the role-player focuses only on:

1. the purpose of taking on the role;
2. the status or level of power of the role – high, low or equal status in relation to the others in the role-play;
3. the attitude of the role; and
4. the participant's motivation in the role-play (O'Toole and Haseman, 1992, pp. 7–13).

The researcher should determine these in advance according to the questions or themes being investigated, and brief participants fully on these four points before they engage in the role-play (cf. Rao and Supans, 2012). This will facilitate transparency about the research exercise, and ensure greater clarity and depth in the activity itself, thereby improving the reliability of the data by more closely reflecting the real-life situation and reducing any tendency to superficiality. Using a variant of conversation analysis called the conversation analytic role-play method (CARM), Stokoe (2013, 2014) highlights the value of using animated audio and video recordings of real-time, actual encounters which differ from traditional role-played interactions, which do not always mimic and prepare participants for the real situations and events they are designed for.

Unscripted or improvised role-play increases flexibility, encourages varied discourse and allows for natural turn-taking in a conversational exchange, but educators and researchers should be aware that a loosely structured role-play places more demands on participants, and thus requires greater preparation in advance. A more structured, scripted role-play may also be used, but it does not allow for the same level of discourse and flexible response as improvised role-play. Occasionally, the educator or researcher may play a role (often called Teacher-in-Role in the literature), but usually most roles are assumed by participants. Cowley and Stuart (2015) report positive results of using a practitioner in role in their study of helping political science students understand the role of the whips in British parliamentary politics.

Although no set method or standardized approach exists for role-play, Waters (2016) suggests that where careful planning, implementation and management of the role-play is enacted, it helps to build learner confidence, enables deeper learning and assists graduate skills acquisition. The educator or researcher's ability to convey confidence to participants is key to ensuring a productive encounter. The eight principles outlined in Box 30.3 are designed to support the researcher as she endeavours to plan for a rich and well-designed role-playing episode. Without adhering to some general guidelines, a simulation or role-play is in danger of becoming stereotypical, overacted, simplistic and may skew resulting data. Such an activity may also peter out after a few moments if participants lack sufficient information about the situation or the characters they are playing. Depending on the researcher's objectives, it is possible to alter some of these principles below to elicit, monitor and assess a specific response. The following guidelines are useful to encourage active participation in most role-play situations, and should be attended to during the initial planning stage of the research, and communicated to the participants, either orally, much as a narrator in a film or play might do at the outset to fill in missing information, or through the use of written briefs or role-cards (which are commercially available or written by the researcher in accordance with her objectives).

30.10 Strategies for successful role-play

Inserting dramatic tension and awakening participants' self-spectator

Irrespective of the many types and genre of drama, one of its key defining characteristics is dramatic tension. Role-play, devoid of any tension, is sometimes used in educational and research contexts, and results in little more than rote learning or drill practice. While a behaviourist mode of training is appropriate in some areas, it can ignore the intricacies of real life where interactions with other people occur. If, as is suggested, dramatic tension is a key feature of successful role-play, then Heathcote (1991, p. 34) argues for the importance of focusing on the *quality* of dramatic tension, and by this she is not referring to 'huge terrifying events such as earthquakes, mutinies, armies and so on' which can characterize some forms of drama, but rather to localized incidents operating at a subtle level within a human circumstance. Tension is often manifest in situations where

BOX 30.3 MANAGING ROLE-PLAY EFFECTIVELY

1. *Set the scene*: when the participants are settled, the researcher should introduce the activity and outline what is going to happen during the session.
2. *Narrate the dramatic frame*: describe the context and background to the fictional situation by outlining any necessary information, i.e. what has happened up to this point in the story, where is this scene set, who is present, when does it take place, etc. It familiarizes the participant with the context, and removes some of the awkwardness associated with starting a role-play 'cold'.
3. *Provide a 'second dimension' for each role*: the researcher must provide adequate information about each of the characters in the role-play in order to 'flesh out' their profile sufficiently for the role-player to be able to 'step into the role' safely, confidently and with integrity. The 'first dimension' of role specifies only the character's broad profile, such as being 'a father', 'a teacher', 'a prisoner', 'a doctor', but does not indicate what kind of doctor is to be represented, what training she has had, what are her dominant personality traits (kind, generous, short-tempered, even-handed) etc. Talk about 'the character' as if you know her (it will increase participants' interest and investment in her situation).
4. *Dilemma*: the researcher must outline the dilemma or problem which is to be explored (and/or resolved) in the scene (usually consisting of conflicting choices where decisions have to be made and consequences dealt with). In planning the research, the dilemma or problem selected for inquiry may be of a personal nature (my family comes before my job), social nature (everyone goes to the nightclub at weekends), or of a moral nature (if we restructure the company in this manner, many workers will lose their jobs).
5. *Dramatic tension*: all drama, by virtue of its definition, relies on dramatic tension to propel the action forward. Tension may occur as follows: in relationships; as a result of a task that has to be undertaken; in not knowing what is going to happen (surprise and/or mystery); or in exploring ways of behaving not typical in participants' every daily lives. A successful role-play must have dramatic tension to sustain character belief and investment in the situation ('as if it could be real'). A well-chosen dilemma will lead to dramatic tension in the scene.
6. *Objective*: the researcher must ensure that *each* participant in the role-play has an objective. For example, as Human Resources Manager, invite the union representative to lunch, and your objective is to find out who is driving the proposed work stoppage among the workers. The person playing the part of the union worker may be given a different objective, possibly one that counters yours (i.e. reveal nothing), or operates at a more divisive or subtle level (provide misleading information, or play along with the game). Selecting the right objectives will impact on the focus of action in the scene, and thereby facilitate the researcher to gather data on his/her area(s) of interest. It will also impact upon the mood generated by the participants in response to their attempts to achieve their objectives, which may further alter or intensify the dramatic tension as a result.
7. *Constraint*: the researcher must formulate appropriate and purposeful constraints for each participant in the role-play before it begins. Constraints help to make a scene more realistic, and slow the action down, allowing for greater opportunity for negotiation and interaction. To be meaningful, constraints must be related to the dominant political, economic, historical, social or personal realities in the scene. For example, in the scene above, the union representative may be aware that he is being 'pressed' for information, but has to maintain a calm and vaguely pleasant demeanour as he is aware that greater harm could result if he were to have an outburst at a lunch table with the HR Manager. The constraint for the HR Manager could be that she is not allowed to ask the union rep directly about staff members' activities, and has to exercise caution in how she gently probes over a long and leisurely lunch. Without effective constraints, a role-player may ignore the social and professional 'niceties' in the scene above, demand the required information and conclude the scene rather swiftly, thereby missing out on the learning possibilities that this activity has to offer.
8. *Hidden objective*: while the information in principles 1–7 should be shared with all role-play participants openly, the researcher may decide to add additional information or instructions to complicate, enrich or develop a scene. It involves giving a piece of information or instruction to one participant in the role-play, and giving a different piece of information or instruction to the other role-player(s). This information is not shared with the full group but delivered privately, and thus when the characters come together to improvise

continued

continued

the scene, their objectives may clash overtly (or covertly) as set up by the researcher. A hidden objective can be used successfully to re-play the same scene, but altering some of the detail in the second and subsequent runnings. For example, in a re-run of a scene between a marriage guidance counsellor and a client, the researcher may call the counsellor to one side of the room to additionally inform her that this client has already seen another counsellor in the same organization, and made an official complaint about her. The client is not aware of this additional information being applied to the scene, and it would be interesting to gather data from both participants, comparing how the two scenes may (or may not) differ. It is possible to give a hidden objective to both parties, which can result in a lively interaction when the scene re-commences.

there is an incomplete task with a deadline looming, and related to power games and status in relationships. Inserting low-level or insipid dramatic tension into a role-play can motivate participants, build investment in the fictional situation and 'has the effect of making the most hackneyed situations spring into new focus and create new awareness' (Heathcote, 1991, p. 34).

Being cognizant of the fact that role-play operates in a fictional realm, and employs the art form of drama as its vehicle to achieve new insights, participants must not be allowed to become emotionally and intellectually consumed by a situation, or it will reduce the possibilities for reflection on their actions and related consequences. In addition to good planning for role-playing episodes, the concept of the 'self-spectator' (see Bolton and Heathcote, 1999; O'Neill, 2014) is closely linked with protecting participants in drama, and allowing for greater reflection and deepening of the experience. The concept implies that participants are observing themselves when in role, are aware of what they are doing and of what is happening to them, and do not become overly immersed in the action. This is achieved by monitoring their emotional and cognitive responses to the dramatic stimulus, so that they are aware that they are playing a part. They are simultaneously themselves and also representing a character.

Self-spectation implies becoming the critical audience of your own performance, and facilitates an ability to change if required. Failure to monitor one's participation in a role-play may result in missed learning opportunities, reduced flexibility in responding to a situation and increased risk of dangerous emotional engagement (i.e. getting carried away with the action). Regular moments of reflection both during and after the role-play are important to allow for self-spectation to be activated and employed. These can be facilitated by researcher interventions during the activity, such as questioning, judicious use of praise and encouraging participants to be responsible and to look for implications and consequences of their actions at all times. It is important to encourage the participants to document their experiences of the role-play, whilst in- and/or out-of-role. It can allow for the emergence of important insights and form the basis for later reflection and evaluation. Writing or drawing whilst inside or outside the dramatic situation can facilitate the formulation and expression of both private and public responses, and also further stimulate self-spectation.

Protection into role and protection into emotion

Emotion is the underlying currency of drama, because any imaginary act is necessarily accompanied by emotion (Davis, 2014). It fosters participant investment where the characters begin to care about the situation, and work collaboratively towards exploring creative and meaningful solutions. There are many ways to categorize and discuss emotion, but in educational drama and role-play we are broadly concerned with the notion of first- and second-order emotions. The former describes raw emotion as experienced in real life, and the latter refers to filtered emotion, as may be experienced in art (see Witkin, 1974; Best, 1992). It is widely agreed that first-order emotion has little or no place in art, as it is transitory and fleeting, and may at times be overwhelming and uncontrollable. But the advantage of using the arts in educational research is that they allow us to slow down time, pausing and dwelling a little on experiences that might otherwise be lost to us. This can be a useful approach in gathering valuable data for research. For example, when working with children who were prone to public release of inappropriate behaviours, such as tantrums or meltdowns, a role-play methodology was employed to investigate whether such children could learn to mediate and manage their emotional state using an experiential rather than a behaviourist intervention (O'Sullivan, 2016b).

In drama and role-play, the aim is not to protect participants *from* emotion, but *into* emotion, in order to maximize engagement and extend learning opportunities. There are several highly effective strategies, including the aforementioned self-spectatorship and second dimension of role, which serve to maintain and increase the objective distance between participants'

real lives and the fictional scenario they are working in. The challenge is to induct people comfortably and carefully into role to ensure that they are equipped to play that part safely and responsibly.

Whereas a professional actor will develop a whole technique to assist him in safely 'stepping into the role' of someone else (being careful to ensure a distance is maintained at all times between his real life and the 'role' he is playing), role-play facilitators and researchers who use this methodology typically just ask participants to 'be a…' (pensioner, sales rep, waiter, taxi-driver, prisoner) with little or no preparation for what it might mean to 'be a…', and little understanding of the consequences and associated responsibilities of asking someone to assume the role of another. Without adequate preparation, participants may have little or no option but to revert to a stereotype, as they have been given nothing else to work from. Thus, if asking young children 'to be pirates', they tend to rely on stereotyped images from film and television to base their representation on. The use of context and second dimension of role (and the principles discussed in Box 30.3) can considerably reduce this risk, and in this case encourage the children to explore what type of pirate they are role-playing. In building an initial profile, children can be encouraged to think about what they might have done (as a pirate) to be outlawed. Preliminary discussion to elicit information about what type of people pirates are, how and why they found themselves following that way of life, and what it means to be a pirate historically and in today's world, are effective strategies to:

a build belief and investment (i.e. 'I know about and care about this role');
b protect participants into taking on that role, leading subsequently to an emotional engagement with the role; and
c activate their self-spectator.

Attention to detail and thoughtful, responsible planning should always incorporate these strategies in order to simultaneously challenge and protect participants when engaged in role-playing. Supporting the idea that preparation and participant information are key to success in role-playing, Biziouras (2013) found that depending on the reading materials which his students were given before they undertook the role-playing simulation (i.e. different theories on international relations), different decisions and responses were evident in how the students behaved during the simulation activity.

Paying careful attention to how we induct people safely and responsibly into a role will elicit more reliable and ethical data. It would appear that while every effort was made to organize the research component in the Stanford Prison Experiment (via consent forms and university ethical approval), a major weakness in the design was evident in the lack of attention paid to the practicalities of using role-play as a research technique in this case study.

Box 30.4 sets out practical points to consider when setting up a multiple role-playing procedure.

The 'debriefing' stage of the role-play

A key element of a role-play for researchers is the debriefing. Debriefing involves sharing, discussing, reviewing and reflecting on experiences during the role-play, evaluating these and integrating them into the minds of the participants. The debriefing can be descriptive, evaluative, reflective and formative. It serves many purposes:

- to safely close a role-play and allow the participants to resume their normal roles and return 'to themselves';
- to review the contents of the role-play (what happened);
- to make sense of what happened (e.g. what were the key features);
- to share experiences and perspectives on the role-play (people's views and experiences will differ);
- to make meaning of what happened;
- to link the role-play to 'real life';
- to discuss and correct any errors in participants' knowledge, analysis and performance;
- to identify further learning development needs.

For the researchers, the main purpose of the debriefing is for participants and the researcher to learn. The comparison of role-play experiences of different groups can be part of the learning experience.

In this stage the role-play participants are also given feedback on what happened. For example, in the Milgram studies of obedience to authority, mentioned earlier, they were told what the experiment was for and that in fact no electric shocks had been administered to the 'learner', and steps were taken to ensure that they (the participants) suffered no after-effects or trauma. Further, it is in the debriefing stage that the researcher can also obtain further research data, for example, on the participants' feelings about, reactions to, views on, actions and behaviours in, thoughts about, reflections on what was happening in and what had happened in the role-play/simulation, the outcomes of the role-play/simulation, and so on.

Caution has to be exercised: too little debriefing and the role-play/simulation loses its purpose. Too much debriefing and it loses its impact. The researcher can plan the timing and duration of the debriefing carefully (a rule

BOX 30.4 PRACTICAL POINTS WHEN SETTING UP A MULTIPLE ROLE-PLAYING PROCEDURE

1. If the researcher is using 'a multiple role-playing procedure', where there are a number of pairs or groups conducting the role-play in the same space at the same time, begin by organizing the groups according to the number of people required in the scene (i.e. 'get into groups of three please').
2. Using the eight principles of role-play outlined in Box 30.3, give the group the requisite information and instructions for the ensuing role-play. Ask them to take a moment to discuss who is going to be whom and what the characters' names are (if this has not already been predetermined). It is a good idea to write the names of the characters on a clearly visible flip chart which participants can refer to if they forget, without stopping the action.
3. Ask the participants to find a space in the room and organize it in preparation for the role-play (i.e. loosely demarcate it as an office space, a shop, a university classroom, etc. according to easily identifiable and available objects and resources). Invite them to use a chair or bag to section off their space. This helps to establish belief in what they are doing and makes their space semi-private so that they can focus on the task in hand.
4. Inform them that the role-play will begin at the same time for all groups, and that when theirs has run its natural course, they should remain *in situ*, and quietly observe until the other groups have finished. On average, role-plays will run for between five and ten minutes if they have been well set up.
5. Where the role-play begins with all players *in situ* (i.e. sitting opposite each other in an office-type setting), the researcher should invite them to adopt an appropriate position for their role, such as scanning through a list on the desk, fiddling with a watch to signal nervousness, or concluding a phone call. Ask them to place their eye contact on an object rather than on their partner(s), freeze this gaze and their physical action for a moment, and on a clearly audible count of 1, 2, 3 from the researcher, all groups begin at the same time. It is a good idea to provide the first line or opening words of the scene, such as, 'Now then, Mr Hayes, why did you come to see us today?' which all groups can recite to get them started. It reduces tension and any nervousness that may be present, and can usefully serve to focus the direction, the tone and the mood of the role-play.
6. If the role-play begins with one person entering a room and the other(s) already *in situ*, ask the person entering to stand about a metre away from their role-play partner(s), to lower their gaze as if preparing to knock on a door and enter on a given signal by you. In this situation, the person/people inside the room should adopt an appropriate action and eye gaze, away from the imaginary door and their role-play partner standing 'outside', and wait for the facilitator to count aloud and knock physically on a table or wall on everyone's behalf. The opening words provided here may be something like: 'Come in please', or 'One moment please, I'm on the phone/finishing off a document', etc. Deciding to leave a person waiting outside an office door for 10–20 seconds can create an interesting power dynamic that will impact upon the remainder of the role-play as it unfolds.
7. Allow the role-play to run its natural course, and if most pairs/groups are finished, you can gently intervene by inviting those still going to finish up shortly.
8. Reminding the participants that they are 'back to themselves', provide an opportunity for the pair/group to reflect and discuss initially, and then open up the discussion as a whole group exercise. This will be structured according to the individual research requirements. Participant diaries can be a useful tool to gather participant perspectives.
9. Scenes can be re-played as required, giving participants a different experience by shifting or altering any of the principles outlined in Box 30.3.

of thumb is that a debriefing may take up a quarter of the total role-play/simulation time at most, and much less if it (e.g. a simulation) has run over several sessions).

The researcher will need to decide whether to conduct the debriefing in a plenary session and/or with individuals or groups (the latter can be time-consuming).

If the debriefing takes place immediately after the end of the role-play (which is a good idea), it is advisable to have a few minutes break, so that the debriefing clearly marks a new stage of the role-play.

It is useful to consider the physical layout of the space for debriefing: a circle or semicircle/horseshoe is desirable as everyone can see everyone else, and there is little issue of 'status': all are equals, with the Chair simply managing the discussion or interjecting with feedback and/or questions.

It is essential for the researcher to prepare the debriefing, as the debriefing is a guided discussion, not a 'free-for-all'. The debriefing must strive to be positive, with the Chair showing empathy rather than being judgemental (unless there is a point of correction to be made). Sensitive and productive debriefing is a skill, an art, requiring an ability to tolerate ambiguity and difference.

The researcher must consider many questions in preparing for the debriefing:

- what are the purposes of the debriefing (and tell the participants);
- what points *must* be addressed;
- what questions can be posed (e.g. to promote discussion and feedback);
- what feedback must, should and may be given, and about what;
- what data the researchers wishes to collect;
- what and how to summarize;
- how to involve and receive feedback from observers (if there were any);
- how to manage the debriefing:
  - what are the ground rules, for example: the Chair nominates or identifies the speaker (or places several volunteer speakers in a sequence)
  - nobody interrupts a speaker
  - speakers are polite and respectful, even when raising points of criticism
  - nobody may speak for more than three or four minutes
  - each speaker must keep to the point, i.e. avoid redundant or irrelevant material
  - each speaker should build on, or link to, the previous speaker where possible;
- how to affirm participants and be positive about comments received;
- how to promote participation in the debriefing;
- how and when to give feedback from observers/experts.

Opening the debriefing session

The Chair indicates what will happen in the debriefing, what are its purposes, how it will be managed, the importance of keeping to the point, and that there may be no right answer or no single solution to issues being raised. Then the following can take place:

- Invite participants to volunteer their views on how they feel about the role-play (a general question to see if this promotes a response to 'break the ice').
- Invite participants to volunteer their views on what happened, what they did and why, what they felt went well and less well, and why.
- Invite participants to comment on their roles, interactions and reactions to others, how effectively they operated in these and why/why not.
- Invite participants to share their *feelings* about the role-play, for example, which parts they enjoyed, which parts excited them (or the opposite), what surprised them, and why, and what were their feelings. Gain reactions of others to the same point/situation being made.
- Which parts did the participants find challenging, difficult, easy, and why?
- Where did they feel they were most/least effective, and why?
- What would they do differently next time, and why?

Continuing the debriefing

- Invite participants to identify *key features* of the role-play and what they *learned* from it (e.g. the topic, themselves, the interactions, the relationships, their roles, conducting a role-play).
- Why did people (themselves and others) behave in the way that they did? Are there other interpretations of what happened?
- In what ways was the experience of the role-play beneficial and worthwhile?
- What aspects do they need to learn more about?

Concluding the debriefing

- Receive feedback from observers/experts.
- How to apply their learning in the 'real world'; what were the key points of application.
- End the debriefing on a positive note.

For some reticent participants, the Chair must judge whether to invite their direct participation.

30.11 Examples of research using role-play

As noted earlier in the chapter, role-play appears to be making a strong comeback in the broad field of education and training. It is no longer being given a cursory mention in research studies, but is beginning to feature as a key teaching, learning and assessment strategy in many publications across a diverse range of academic and professional disciplines. While there is still more work to be done in terms of encouraging researchers to consider its use as a valid and valuable research method, Table 30.1 provides a brief summary (illustrative only) of some recent reports on role-playing, both as a research technique and as an effective approach to teaching and learning.

TABLE 30.1 EXAMPLES OF THE USE OF ROLE-PLAY IN THE LITERATURE

Article	*Use of role-play*	*Major findings*	*Issues for consideration*
Seiler, S. N., Brummel, B. J., Anderson, K. L., Kim, K. J., Wee, S., Gunsalus, C. K. and Loui, M. C. (2011) Outcomes assessment of role-play scenarios for teaching responsible conduct of research. *Accountability in Research*, 18 (4), pp. 217–46.	As a form of summative assessment to teach responsible conduct of research (RCR) to graduate students in science and engineering.	Results suggest that role-playing might promote a deeper appreciation of RCR by shifting the focus away from wanting to simply 'know the rules'.	The authors also used a *think-aloud* case analysis approach to assess participants' case analysis performance.
Johansson, J., Skeff, K. M. and Stratos, G. A. (2012) A randomised control study of role-play in a faculty development programme. *Medical Teacher*, 34 (2), pp. 123–8.	To investigate the impact of role-playing as an instructional technique for facilitating change in teaching behaviours.	Data from 48 hospital physicians indicated significantly greater positive changes in teaching behaviour among faculty who attended the standard course (with role-play) as compared to those in the alternative course ($p = 0.015$).	This study validates a commonly held view in health sciences education that role-play is a useful instructional method for improving teaching.
Stevens, R. (2015) Role-play and student engagement: reflections from the classroom. *Teaching in Higher Education*, 20 (5), pp. 481–92.	To elicit feedback from 144 history students about their experience of a role-play activity, identifying what they gained from the activity and if it encouraged them to learn more about the topic.	A large majority found the role-play activity beneficial, but a small minority reported gaining little from the exercise. The author argues that role-play may be less beneficial for weak or unprepared students.	It is acknowledged that although role-play may be a popular teaching method, the manner in which the teacher/facilitator sets it up and prepares the students can impact upon learning outcomes.
McEwen, L., Stokes, A., Crowley, K. and Roberts, C. (2014) Using role-play for expert science communication with professional stakeholders in flood risk management. *Journal of Geography in Higher Education*, 38 (2), pp. 277–300.	To explore role-play pedagogies and evaluate participant perceptions of their learning experiences in learning and communicating about flood science by flood risk management professionals in local government.	Results suggested the development of analytical and strategic use of flood science skills, and increased confidence in science communication.	The negative impact of prior role-play experiences affected participants' attitudes to learning, and learner diversity affected co-learning.
Browning, T. R. (2014) A role-playing game for teaching about enterprise process integration. *Journal of Enterprise Transformation*, 4 (3), pp. 226–50.	To examine the impact of a role-playing game that helps teach process integration in a more streamlined, customer-oriented manner.	Playing the roles of owners of various enterprise processes who must coordinate their input–output relationships, participants' awareness was raised to the challenges and potential of integration at the enterprise level.	The role-playing game led to fruitful discussion and negotiation, to successfully bridge the gap between poor understanding of the motivations and methods for successful integration.

Article	*Use of role-play*	*Major findings*	*Issues for consideration*
Carte, L. and Torres, R. M. (2014) Role-playing: a feminist-geopolitical analysis of the everyday workings of the Mexican state. *Gender, Place & Culture*, 21 (10), pp. 1267–84.	Examining in detail the implementation of role-play as a research method in a case study with Central American immigrants.	Role-play was shown to be very useful in revealing immigrant daily experiences as they try to assert their rights.	The authors report that role-play is particularly suited to revealing immigrant women's experiences due to its encouragement of creativity and facilitation of discussion around challenging subject matter.
Guilfoyle, N. and Mistry, M. (2013) How effective is role-play in supporting speaking and listening for pupils with English as an additional language in the Foundation Stage? *Education 3–13*, 41 (1), pp. 63–70.	The study investigated how role-play supports the development of language skills for young EAL learners.	The authors found that role-play promoted the use of a wide range of key strategies for language learning.	Role-play is well adapted for use in early years language pedagogies.
Deaton, C. C. M. and Cook, C. (2012) Using role-play and case study to promote student research on Environmental Science. *Science Activities: Classroom Projects and Curriculum Ideas*, 49 (39), pp. 71–6.	To investigate the use of an integrated role-play and case study approach in developing critical thinking skills, communication skills and learning communities.	Students were actively engaged with a scientific issue through a case study approach, and took on the role of a case study character to research environmental science.	This integrated approach successfully combined the gaming features of role-play with the narrative of case study.
Maratou, V., Chatzidaki, E. and Xenos, M. (2016) Enhance learning on software project management through a role-play game in a virtual world. *Interactive Learning Environments*, 24 (4), pp. 897–915.	Using an immersive multi-user virtual world, the role-play game aims to enhance experiential learning of human-related issues such as communication and collaboration with other team members, which the authors indicate are not easy to teach through other methods.	Participants evaluated the game positively in terms of overall game experience, enjoyment and learning impact, commenting on the successful challenge of interacting with other online players.	The instructor is able to observe the players, intervene when needed, and significantly alter specific game scenario parameters to modify the level of challenge and difficulty for players.

30.12 A note on simulations

The difference between role-play and simulations

Simulation is a commonly used term in research, and increasingly is used almost interchangeably with role-play. However, traditionally, to simulate meant to imitate, to pretend, to copy, and was typically associated with a person 'pretending' to be in a different situation (often as themselves). It was regarded as a powerful form of active learning and engagement, allowing participants to experience and possibly rehearse/practise other situations within the domain of 'real life'. Simulations are often used in games and training scenarios, such as for medical personnel, pilots, engineers, construction workers and military personnel.

Simulations differ from role-play in several key respects, but principally in terms of the degree of engagement with the role assumed. Role-play can be more demanding and generally requires greater imagination and preparation on the part of the role-player to successfully 'get into' the role and 'take on' more of the depth, complexities, subtleties, nuances and challenges associated with temporarily 'being' that person, in that situation. Simulations require participants to take decisions in response to their assessment of the situation they have been placed in, and to evaluate and monitor their performance and its impact on others, while role-play is more exploratory and may not lead to decisions but to further exploration of problems in a spontaneous enactment.

In recent years, there appears to have been somewhat of a merger between the two ideas, and researchers often refer to role-playing simulations, where they have combined the elements of both concepts to create an interactive and dynamic approach. The use of online role-play simulations in particular has burgeoned in the last five years and is proving effective as a training intervention and research strategy in such areas as suicide prevention using emotionally responsive avatars (Bartgis and Albright, 2016), and developing transnational global competencies for engineering students entering an international workforce (May *et al*., 2014).

Simulations

Educational simulations involve a sequence of events which typically involve or lead to decision making, and in which the environment or situation is set up by the researcher (Hertel and Millis, 2002, p. 15; Cheng *et al*., 2014). In these, participants take on roles and the sequence of activities evolves, sometimes planned and sometimes unplanned, as the simulation rolls out over time. They often involve problems and many differences between participants, for example, in terms of attitudes, agendas, perceptions, powers, voice, status, values, sympathies and agendas, i.e. in which the potential for conflict or disagreement features strongly. Simulations are designed to put participants in a realistic representation of a situation, environment and issue, recognizing and building in the complexities of these, within which interactions should occur, leading to an outcome (e.g. a decision, a compromise, an action, a statement, a change of view) (Shaw, 2010, p. 2).

In setting up the simulation, researchers must ensure that the scenario design has the hallmarks of realism (e.g. situational, physical, emotional, conceptual, interpersonal), i.e. that it could really happen in the 'real world', and that participants understand the situation and what is required of them (Cheng *et al*., 2014).

It is important for the researchers to choose a topic that is interesting, topical, real-world, relevant and engaging (cf. Livingstone, 1999; Goedert and Rokooei, 2016). In choosing a topic, particularly for a simulation, it is often useful to select one that will enable different perspectives, interest groups (maybe conflicting interests) and agendas to be included, and this will enable different groups of participants to take on the roles/interests/agendas of these different groups. It may be useful to take a controversial issue, an issue on which there is dissensus and maybe strong feeling, a conflict or problematic situation, one that is not susceptible to simple solutions, or one in which there are different interests at play. It may be helpful to identify an issue on which there are many perspectives and differences of opinion, and then construct a scenario around this. Or the role-play/simulation may focus on a crisis situation, or a sensitive, delicate matter, or a situation in which there is no single or correct answer. By choosing a current issue for a role-play/simulation, this gives some immediate relevance to the topic.

Simulations:

- are 'real-world' and focus on 'real-world' issues, but in a safe learning environment;
- are based on reality, and focus on those parts of that reality which are deemed to be relevant for the case in hand; they are representations of reality;
- simplify a complex reality to focus on key issues;
- are participatory;
- hand over significant autonomy, responsibility and power to participants;
- use active, interactive and collaborative methodologies, promoting collaboration as well as competition;
- focus on the processes as well as outcomes;

- develop interpersonal, team-working and leadership skills;
- develop decision-making skills and include opportunities for prompt feedback to be given and received;
- focus on key issues and 'design out' distracting and extraneous matters;
- accelerate and condense certain events;
- develop negotiation and bargaining skills;
- develop abilities to look at a situation from many perspectives.

They typically have several defining features:

- key objectives are stated explicitly;
- simulations are carefully structured and timed, and are based on the key objectives;
- participants take on roles and act in role in the given setting/context of the simulation;
- there are interactions between the participants in role;
- the interactions are rule-governed;
- the outcomes of the simulation follow from the simulation itself and its participants;
- success criteria for the achievement of the objectives are made explicit;
- there are often no simple or single solutions to the problems set out in the simulation.

Simulations have the potential to create complex, dynamic and evolving political processes and interactions, thereby enabling participants (including the researcher) to investigate and examine participants' (individually, by group, party etc.) motivations, constraints on behaviour, attitudes and values, and interactions among the actors in the situation.

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Visual media in educational research

CHAPTER 31

The chapter suggests an agenda for attention in using visual media and what practical considerations researchers can address in this enterprise: who provides the image; photo-elicitation and how to work with it; strengths and weaknesses of different kinds of visual media for research; how to interpret artefacts and images (and the issue of multiple interpretations); the importance of reflexivity. It suggests that visual data, whilst being useful as free-standing data sources, are also useful in conjunction with other kinds of data.

We are surrounded by visual data; knowledge comes in various forms and is not reducible to language alone (Eisner, 2008, p. 5). Visual methods can provide data that word-based data cannot (Clark *et al.*, 2010, p. 86). Visual data are increasing in educational research (e.g. Wall *et al.*, 2012) and this chapter introduces how researchers can use visual data, addressing a core of issues in the planning and conduct of data collection using visual media of different types. The chapter raises a series of issues concerning:

- photographs and still images
- video and moving images
- artefacts
- ethical practices in visual research

This chapter should also be read in conjunction with Chapter 36 on the analysis of visual data.

31.1 Introduction

Educational researchers can draw on a host of visual media in their research. These include, but are not limited to: film, video, photographs, television, advertisements, pictures, artefacts, objects of fine art, memorabilia, advertisements, moving images, still images, media images, maps, graphs, drawings and sketches, illustrations, graphical representations, cartoons, artefacts and everyday objects, deliberately non-commonplace objects, family photographs, and so on. In short, anything we see, watch or look at counts as a visual image. They are the stuff of ethnographic and anthropological educational research (witness, for example, the attention given to artefacts and visual images in studying organizational culture, and the messages about the organization that are conveyed in such images, discussed later in this chapter).

Using visual media concerns the production of the image, the image itself and the audiences of the image. Visual media are not neutral; they give messages, deliberately or not, and we interpret them in many different ways. They have their own forms and effects (e.g. compositions and technical properties, and these have an effect on the viewer). They are constructions of social events and perspectives, of power and power relations, of social relations and social difference. More than this, we look at them in different ways, i.e. we bring our own values, biographies, cultures and background to bear on images (Rose, 2007, p. 11). Images, then, must be viewed in the social and cultural contexts of their production (Banks, 1995, p. 2) with consideration of who are the audiences, intended or otherwise, of the image. An essential feature of an image is its audience and the way in which the audience views and 'reads' the image (Fiske, 1995). As Berger (1972) made clear, we have different 'ways of seeing'.

Images are made, kept and displayed in different places, from museums, cinemas and galleries to each person's home, each of which confers its own required social behaviours and audience reactions (as Bourdieu and Darbel (1991) indicated: middle-class, educated visitors to art galleries stand in quiet contemplation of paintings). Some visual media have texts, others do not.

A constant feature is the subjectivity of the producer and selector of the images. A professional photographer can use images to persuade, to project an agenda. A documentary maker can select video clips to press a point, and this becomes an ethical issue. A researcher can decide which photographs to use in a photo-elicitation technique, or how to brief children-as-photographers in creating their own images. The issue of bias has a high profile in image-based research, and the researcher's reflexivity is a key issue here.

An image is the product of *technologies* (oil paintings, video production, photographic materials, computer software), *compositional features* (visual form,

material form, presentational form, structure, colour (e.g. hue, saturation, lightness/darkness), texture, abstraction, expressive content, spatial arrangement, symbolism etc.) and *social contexts* (cf. Rose, 2007, p. 26). Some images balance colour and content harmoniously; others scream at us. Some are close up, some are distant or wide-angle. Some shots are deliberately taken from an elevated, low, side or frontal position; some are posed; others are snapshots taken as the opportunity arises. Some are in focus; others are not. Some are geometrically structured (e.g. with perspective); others are free of geometric form. Some images are meticulously planned; others are fleeting snapshots taken on the spur of the moment. Some are part of a series or a collection; some stand alone. Some are part of a recognizable genre; others are not. Some are made by amateurs; others by professionals. Some are deliberately designed to give messages; others are not. Some are reflections of culture and society; others are in the vanguard of social and cultural change. Some are part of normal living (e.g. food); others are deliberate constructions that are out of the ordinary (the oil painting). Some are faded and fuzzy (the 'materiality' of the image (Rose, 2007, p. 234)); others are crisp and sharp. As Rose (2007, p. 26) remarks, visual images are never innocent; they are wrapped up in many layers of meaning and interpretation. They are not only 'reproductions of reality' (Flick, 2009, p. 240) but, rather, 'presentations of reality' which themselves are then interpreted by viewers. All of this renders images difficult to interpret and capable of multiple interpretations.

Huge proportions of the population can take still and moving images with conventional and video cameras, with both of these on their cellphone. Cameras can present an immediate, comprehensive and holistic image of situations, objects, people, events, lifestyles, contexts, conditions and so on, that happen very quickly or suddenly (maybe too quickly or with too many details or with too great a level of complexity for conventional observational recording to be able to catch). Such images are easy to transport, and enable the researcher to review them repeatedly (particularly useful for fleeting, short-lived and ephemeral moments) and indeed to have their reviews checked by a third party. Further, images can be taken non-intrusively, reducing observer effects and reactivity (cf. Denzin, 1989, p. 203; Flick, 2009, p. 241).

It may be the researcher who takes the image, or researchers can ask participants to take images, maybe even providing them with the camera so that they can decide what they consider to be important to be kept as a still or moving image (Flick, 2009, p. 242). Research that uses images may be both collaborative and participatory in involving participants as partners in the creation, production and discussion of images, both still and moving (but setting up a concealed camera is far from collaborative (Banks, 1995, p. 3)). As online communication increases, so the ability to share images has become part of everyday life. Indeed Banks (1995) argues that the dichotomy between the researcher and participants, the observed and the observer, is collapsing (p. 1).

The researcher can provide the already-taken images (and use them as a starting point for discussion), or ask the participants to bring images that they have and which they have or have not taken themselves (e.g. family photographs), and which can be used as starting points for interviews or as main elements of interviews (the 'photo-elicitation interview' (Harper, 2000, p. 725)). Here consideration has to be given to the taking of the image and the derivation of data from the image (cf. Denzin, 1989, p. 210).

In considering visual images, Denzin (1989, pp. 213–14) indicates that whilst cameras report what they see and what really happens (rather than the selective observation of the human observer), nevertheless images are selective, in that the image maker has already decided what to include or not, what to focus on and what not to focus on (Becker, 1986, pp. 241–2), where to point the camera and where not to point the camera. Images create their own representational and symbolic forms and they are time-bound; they catch a particular moment (or several). Given this, it is wise to regard visual images as telling a story – a discourse – rather than being a singular objective reality. Indeed it is commonplace to have written text – a commentary or analysis – accompanying the image, and this text, too, tells a selective story or has a selective focus.

Visual data catch and store a wealth of data in a single image or video sequence and, like other forms of observational data, they are selective in their focus and contents (e.g. deriving from the researcher's agenda, interests, research questions etc.). This presents issues of data overload, selectivity and manageability. Whilst this may present problems in the stage of data analysis (the problem of bias in being unavoidably selective), visual data can be one of a range of different types of data (e.g. written, aural, oral, observational) in a research project. Rather than standing on their own, visual data are one element in triangulated data and, as we mention in Chapter 36, can employ analytical techniques used with other kinds of data, as well having their own methods of analysis.

In contemplating images the researcher has to consider how much they are natural, contrived, arranged, posed or staged. In this respect there is an argument for

covert research and/or a fixed camera as it leaves the natural situation undisturbed.

31.2 Who provides the images?

Prosser and Loxley (2008) identify four main kinds of visual data: found data; researcher-created data; respondent-created data; and 'representations'. At issue here is who provides the data, for example, who are the photographers, who selects the photographs or edits the video?

Whilst it is commonplace for the researcher to provide the image (Prosser and Burke, 2011), there is a growing recognition that, in educational research, asking children to provide the images – either images they have taken or created themselves, or that they have collected or brought (e.g. family photographs, Internet images, magazine images, collages) – is a way of empowering participants and building rapport, not least in situations where, for example in researching with children, there are differences of age, status, power and language and explanatory abilities (cf. Hatten *et al*., 2013; Torre and Murphy, 2015). Researchers and participants become equal partners in the co-construction of meanings (Torre and Murphy, 2015, p. 6). In the case of participant-provided images, the researcher will need to brief them and provide an agenda and guidelines. Smartphones enable children to take still or moving images easily; they are digital natives.

Further, enabling children to create their own images is a doorway into their worlds and cultures in their terms, which researchers otherwise might not be able to enter or understand. Visual images enable children to present their worlds in *their* terms, meanings and perspectives. Children's worlds are highly visual and central to researchers' understandings of childhood; indeed, Harper (2002, p. 13) suggests that, in human evolution, visual processing evolved before verbal processing and is located more deeply in the human brain, evoking 'deeper elements of human consciousness than do words'.

31.3 Photo-elicitation

Photo-elicitation, a term penned by Collier (1957) when researching environmental influences on stress and mental health, has a history reaching back to anthropological studies in the late nineteenth and early twentieth centuries (Hatten *et al*., 2013; Torre and Murphy, 2015). Elicitation concerns disclosure of the 'core definitions of the self' (Harper, 2002, p. 13), 'ideas that they don't usually talk about' (Barton, 2015, p. 179), 'surfacing the taken-for-granted ideas about the social world' or other aspects of lives which might be easily overlooked (p. 197).

There are several types of photo-elicitation (Hurworth, 2003; Karlsson, 2012; Mills and Morton, 2013; Mitchell, 2012; Barton, 2015; Elliot *et al*., 2016), for example:

- *autodriving*: the researcher and/or participants can provide the photographs but participants take the lead;
- *reflexive photography*: participants take the photographs and then, at interview, are asked to reflect on these;
- *photo novella*: participants take photographs which tell a story about part/all of their lives;
- *photovoice*: participants photograph those parts of their society/community/environment (widely defined) which have meaning for them or which they feel need to change (i.e. the appeal to critical research);
- *photo-observation*: photographing real objects, events, activities and discussing them;
- *photo-interviewing*.

Photographs enable people at interview to talk about issues that word-based approaches alone cannot do; they stimulate discussion, provoke a response and enable the researcher to work collaboratively with participants (Richard and Lahman, 2015; Elliot *et al*., 2016). They can elicit information which researchers cannot directly observe: participants' ideas, emotions, inner feelings, perspectives, opinions, meanings and ways of thinking (Richard and Lahman, 2015; Elliot *et al*., 2016). Photographs may be the starting point of an interview (an 'ice-breaker') (Prosser and Burke, 2011), a supporting part or means of opening up an issue. They make concrete those abstract concepts or issues that are difficult to put into exact words, particularly for participants (e.g. children) who may not have sufficient linguistic or abstract thinking skills, or who may find it difficult or uncomfortable to talk about issues, or who need a safe environment in which to disclose information or intense feelings (Pyle, 2012; Hatten *et al*., 2013; Richard and Lahman, 2015). Photographs can trigger feelings (suppressed or forgotten), recollections, understandings, attitudes and opinions; they are evocative and often ambiguous and polysemic, and this can stimulate discussion and reflexivity (Harper, 2002; Pyle, 2012). Indeed Barton (2015) suggests that participants may find it harder to lie about their reactions to photographs because photographs have 'emotional salience' (p. 197).

Photographs, taken by the researcher, participants or other parties and brought to an interview, help

participants to focus, clarify, illustrate and explain an issue, to judge the importance given to the issue or the personal meaning and significance attached to it by participants. They help to elicit tacit or abstract knowledge that participants may be unable to or unwilling to share; they may bring an emotional dimension to the interview or matters in hand; they may facilitate conversation between relative strangers (researcher and participant(s)) and they give power to the participants (Meo, 2010; Hatten *et al*., 2013), bridging the gap between researchers, educators and students (Torre and Murphy, 2015). Photo-elicitation empowers participants and can build rapport and trust between them and the researcher, enabling the researcher to see the world and the situation through the eyes of the participants, and thereby give greater validity to the data and the participants' responses (Meo, 2010; Pyle, 2012; Elliot *et al*., 2016).

Photographs carry meanings that words alone, spoken or written, cannot. They convey real life, flesh and blood (witness Sutcliffe's nineteenth-century photographs of the fishing port of Whitby in the UK and everyday lives that he photographed, or the photographic work of Forsyth in the poor districts of twentieth-century Newcastle-upon-Tyne in the UK). Photographs evoke meanings and reflections as well as information and factual data. They catch the texture, the mood, the atmosphere, the 'feel' of real life and different places, emotions and flesh-and-blood drama. They frame how we think; they can mirror our thoughts or stimulate them. They are both *emic* and *etic*. They carry documentary and interpretive meanings, posed or natural. They can support and supplement other sources of data and text, or they can stand alone. They are less time-consuming to study than film footage or video materials. Indeed they are time-efficient and researcher-efficient, as they can convey far more in a single image than many pages of text ('a picture paints a thousand words').

A photograph can be of a real situation, an image – concrete or abstract, contextualized or decontextualized – which is a metaphor that is subsequently interpreted at interview, a representation of something, a symbol, a real event or an interpretation etc. (Richard and Lahman, 2015; Elliot *et al*., 2016).

In using photographs, researchers can take photographs and ask the participants to comment on them, or the researcher can ask participants either to take their own photographs (and the researcher might supply the camera) or to bring along to an interview (e.g. individual or group) one or more photographs that have meaning to them, to discuss them or provide a commentary on them. Such interviews or textual material can then use conventional methods of data analysis, for example, analysis of transcripts, field notes, software packages, coding, content analysis, grounded theory approaches, constant comparison of images and codes, looking for patterns and genre, and moving towards generalization where appropriate (see Chapters 32 to 37).

A seven-step sequence can be adopted in photo-elicitation (cf. Torre and Murphy, 2015):

Step 1: The researcher sets the topic for the research or investigation.

Step 2: The researcher identifies and invites suitable participants for the study.

Step 3: The researcher briefs the participants about the purpose, agenda, requirements, operation, ethics, constraints and conduct of the photograph provision, for example:

- the purposes of the photographs;
- what to do and why;
- what to focus on and why;
- who takes/collects the photographs (and individually or in pairs/groups);
- how to take photographs (if, for example, children are unfamiliar with how to handle equipment carefully and take photographs);
- what to photograph, not to photograph, and why;
- when to photograph (e.g. time of day, how frequently, at what intervals);
- where to photograph and not to photograph;
- to whom to show and not show the photographs;
- ethical issues of identification and anonymity, privacy, confidentiality;
- how many photographs (e.g. a maximum or how many to select);
- how to proceed (which might include children being accompanied by an adult);
- how the photographs will be used at the interviews.

Step 4: The researcher and/or participants decide who will take and/or collect the photographs.

Step 5: The researcher and/or the participants take and/or collect the photographs.

Step 6: The photographs are brought to, and form part of, the interview or discussion (see Chapter 25 on interviews – and whether they are individual or group – and their conduct).

Step 7: Data are analysed and the results reported.

Some of these steps may be in a different order or recursive (e.g. Steps 3 and 4) and, indeed, researchers

and participants may negotiate and agree the 'rules of the game' rather than the researcher taking all the decisions alone.

In the photo-elicitation technique, the photograph, or set of photographs, or sequence of photographs, is used to invoke, prompt and promote discussion, reflections, comments, observations and memories (Banks, 2007, p. 65). The interview or meeting between the researcher and participant(s) can start with photographs, what they show, who took them, when, where, what is the story behind them, and so on. Photographs can break down differentials of power between the researcher and participants (Prosser and Burke, 2011; Pyle, 2012; Torre and Murphy, 2015).

An image can mean different things to different people, there is no one 'correct' or meaningful interpretation of what it says about the world. A photograph of a child sitting at a desk can be seen as, for example: hard work; commitment; punishment; loneliness; struggle to learn; boredom; enjoyment of solitude; examination pressure; motivation; an outdated pedagogical strategy; delight in reading etc. The researcher has to ascertain what the image means for the participant, what significance it has, i.e. to respect the 'positionality' of the participants (Hatten *et al*., 2013) (see also Chapter 15).

Using photographs in an interview can overcome awkward silences or maintaining direct eye contact (Banks. 2007, p. 66), as this can be intimidating for some participants (e.g. children), not least because of the potential power and status differentials between the researcher and participants. The potential discomfort of face-to-face contact is alleviated by shared face-to-photograph contact. Further, having a focus on a photograph or different photographs can offset any feelings that the interview is some kind of 'test' or 'grilling' for the participants (p. 65), particularly if the photograph comes from, or has been taken by, the participant(s). Having a common/shared focus in the photograph introduces a 'neutral' third party (the photograph) into the interview (p. 66).

During the interview in which the photographs are used, participants may be asked to select some photographs and explain why they chose them, what the photograph(s) is/are about (different meanings and perspectives). They may be asked to sort and group photographs and explain their grouping criteria, or to arrange them in an order or along a continuum, for example, what they like best to least, what is most/least like them, what is closest or truest to their own lives etc. Such sorting can elicit the participants' conceptual categories: how they think and group items, and why (Barton, 2015). As in other interviews, the researcher must be ready with prompts and probes (see Chapter 25), helping participants to explain and crystallize their and the photographer's thoughts, meanings, perspectives, feelings and psychological states.

Whilst the researcher can strive to have high-quality photographs and reproduction, this is not always possible: old photographs fade over time; they can become damaged and fuzzy. On the one hand, this may impede the interpretation of the photograph; on the other, it may give added authenticity or poignancy to the photograph.

In deciding which images to use, the researcher can ask participants to select images from their own or researcher-provided images, or the images may be selected on the basis of sampling techniques, for example, random stratified sampling of images, representative sampling, convenience sampling, probability and non-probability sampling from a given population, and so on. Strict sampling may not be possible if the still images are in very short supply (e.g. only one or two images are available). Nonetheless, as with other forms of data and participants, the selection of which images to use is subject to specification of criteria; the selection may be made on objective grounds (e.g. researcher-specified criteria or those which derive from the research questions), or subjectively from the participants themselves (e.g. their preferences or selections). The researcher/participant should specify and justify the selection made. Further, it is important for the researcher to elicit a narrative from participants, to explain the photograph (including, for example, factual and non-factual matters), as a single photograph may contain multiple messages (Elliot *et al*., 2016).

Researchers can consider several further questions in using photo-elicitation (cf. Barton, 2015; Richard and Lahman, 2015; Elliot *et al*., 2016), for example:

- what instructions to give to participants about taking and interpreting photographs, their focus and purposes;
- how 'provocative or disruptive' (Barton, 2015, p. 198) to make the photographs, when provided by the researcher;
- how to select the most suitable set of photographs: who decides and on what grounds;
- when to use the photographs (the most suitable time);
- how deep an impression the photographs may make on the participants;
- what difference it makes to the research and its outcomes if the researcher and/or participants take and choose the photographs;

- how to avoid doing harm to participants in photo-elicitation (e.g. evocation of intense negative memories);
- how important are the photographs in the research;
- what is the place of the photo-elicitation in the overall research and in large-scale (e.g. quantitative) data collection;
- how to combine a photograph with a narrative (the researcher's and/or the participants');
- who will see the results and in what form (e.g. publication).

31.4 Video and moving images

Taking and viewing moving images (film, video) are part of the everyday lives of everyday people, be they members of a family, the public, researchers, security and surveillance services or others. Video catches real-time sequences and behaviours in a clear chronology, often in close detail with high granularity, and can be stored and shared easily (e.g. with smartphones) (Blikstad-Balas, 2016). As with photographs, it may be the researcher or the participants who create the video, the latter being an instance of participatory research (Jewitt, 2012). Indeed the advantages of authenticity, ownership and empowerment claimed for having participants create photographs apply equally to participants creating videos, and having participants create the video can enable the researcher to gain access to their lifeworlds (Jewitt, 2012, p. 8).

Video has the attraction of recording 'naturally occurring' behaviour and events (Jewitt, 2012, p. 4), and, as with photographs, it has considerable evocative potential, re-awakening memories and events in participants, heightened by the multi-sensory, colour-rich moving image, i.e. creating or restoring a feeling of what it was like to be there. Further, the researcher can watch and re-watch the video, pause and freeze-frame, edit, remove or restore the sound, and focus in close-up detail on items.

Video material catches the non-verbal data that audio recordings cannot, which may be particularly useful, for example, in detailed case study data collection (e.g. of children at work, at play, interacting with each other and with adults). Video material is live and is useful for recording evolving situations and interactions, details that the observer may miss, and non-verbal matters (e.g. facial expressions, aggressive behaviour) (Greig and Taylor, 1999, pp. 66–7). It allows for repeated viewing and checking, though this takes time to watch, re-watch and analyse. The construction and consumption of video, as a meaning-laden resource, can promote 'reflective, dialogical and dialectical' thinking (Hadfield and Haw, 2012, p. 323).

Flick (2009, p. 249) reports the use of video for catching: (a) natural social situations; (b) contrived situations, for example, experimental conditions and situations, events and activities as recorded by the participants themselves and/or the researcher; (c) posed situations (such as video diaries); (d) special events; or (e) commissioned materials (e.g. a celebration or commemorative activity).

As with photographs, the researcher has to be aware of the selective bias inherent in moving images, i.e. the images recorded are a function of the focus and location of the camera, as well as the editing of the material. Hence the researcher must consider not only the images themselves and where, how, why, for whom, how and under what conditions they were produced, but also the interpretations that he or she (or indeed others) make or may make of the moving images, and how these interpretations are influenced by the interpreters' own backgrounds, values and purposes, i.e. the issue of reflexivity.

Moving images are powerful in many kinds of educational research, from experiments to ethnography. They can catch both the everyday routines and practices of participants and also special events. On the one hand, they are rich in detail, and on the other hand, this raises problems of how to analyse complex and detailed, often superfluous multimedia data, in ways that do justice to the different media (sound and vision) both separately and together.

Video data are rich but they are also selective, shaped by decisions of the video maker (Jewitt, 2012, p. 8), and this risks bias. The video material depends on the focus and angle of the camera, whether it is a fixed camera (the 'eye in the classroom'; see Chapter 26) or moved round the location and focused by an operator, a wide-angle lens or a lens with close-up focus, and indeed it depends on when and for how long the camera is taking the moving images. Whilst videos are rich in detail, this presents issues of how to conduct and write up the data analysis. Flick (2009, p. 250) also draws attention to important legal and ethical matters of permission, data protection, privacy, covert research (on the public and on identified persons) and permission to film (see the discussion below on the ethics of taking and using visual data).

A fixed camera in a classroom is not neutral; it has its field and focus predetermined. A wide-angle lens might catch gross behaviours but miss important detail – an eye movement, a facial expression, a small hand movement, a finger gesture. A fixed camera may be less intrusive, as it does not need the presence of an

operator and, indeed, may be located in a ceiling-level corner of the classroom. However, people move in and out of the field and focus of a fixed camera. Sometimes the video camera might be supplemented by a microphone situated on the table(s) at which children/participants are seated. It is important, therefore, in using a fixed camera, to decide where to locate it and focus it, whether there will be a camera operator or whether the camera will run automatically.

Having a moving camera that is operated by a person *in situ*, whilst it may catch close-up detail, may be highly intrusive and artificial (though Blikstad-Balas (2016) suggests that reactivity may be overstated, particularly if the camera is present for a longer period of time). In taking moving images, the researcher will need to consider the location, height, visibility and intrusiveness of the camera, the field of focus, the lighting in the area to be filmed, when to start and stop the recording (and whether the recording will be continuous or intermittent), how may cameras to use, whether to have a fixed or moving camera, who will operate it and who will create/edit the video (Jewitt, 2012).

Given their selectivity, researchers often use videos in conjunction with other kinds of data (triangulation). Indeed Flick (2009, p. 252) advocates the use of video material as part of a wider database and methods rather than being stand-alone. Data from moving images can be used for discussion (e.g. in subsequent interviews), to ask for video participants to reflect on the material, to corroborate data from other sources and to exemplify and illustrate themes, issues and events.

In using video, Blikstad-Balas (2016) notes the importance of addressing three challenges:

- balancing attention to close-up detail and the broader context, so that the broader context is not lost;
- avoiding data overload ('death by data') (p. 6), particularly magnifying events or details which might not be meaningful or important to participants;
- representing data, ensuring that audiences are able to judge if inferences that are made from the video are plausible (p. 5).

Because video data are complex, it is difficult to make sense of them and to represent them (p. 7), as video material is selective (and indeed can be edited by the video's creator) and therefore inevitably omits certain details or events. Even if one has more than one video camera trained on an event (e.g. inside a classroom), this does not overcome problems of interpretation and representation, as video data are inherently ambiguous and can sustain multiple interpretations. What the video frames is a selection only (p. 8), and attention to micro-matters, one of the advantages of video, might too easily overlook macro-settings. Many videos typically record short events and interactions (Jewitt, 2012, p. 8); they are not feature-length documentaries. Even though they tend to record short events, activities or behaviours, Jewitt (2012) notes that the risk of data overload is serious in video research, overwhelming the researcher, and this can weaken the research, rendering it descriptive rather than analytical (p. 6).

As with photographs, it is essential for the researcher (and indeed the participants) to accompany the video with the construction of a narrative that makes meaning of the video, as, without this, there is no evidence of intentionality, what is in the minds of the researcher/participants, opinions, significance, interpretations, motives of participants, i.e. all those points which a material, observable image cannot include.

Useful sources for using moving and still images in research can be found in: Heath and Hindmarsh (2002); Flick *et al*. (2004); Knoblauch *et* al. (2006); Banks (2007); Pink (2007); Rose (2007); Konecki (2009); Heath *et al*. (2010); Mitchell (2011); Jewitt (2012); and Blikstad-Balas (2016). For online guidelines on conducting video research more specifically in education, we refer readers to the companion website.

As with still images, in deciding which moving images to use, the criteria for selection (sampling criteria) should demonstrate fitness for purpose, fairness and defensibility. Moving images may focus on, for example, critical incidents, turning points, key events, representative behaviours, extreme examples, and so on. The criteria for choosing video clips must be justified. As with still images, the moving image clips may be selected by the researcher or the participants, and, as with still images, strict sampling may not be possible if the moving images are in very short supply (e.g. only one or two videos are available). The researcher should specify and justify the selection made.

The use of video raises serious ethical issues, as posting videos in the public domain – the sharing of the video – is very easy, raising issues of privacy, confidentiality, anonymity, protecting people from harm, ownership of the image, informed consent (and for what). We discuss these below.

31.5 Artefacts

As with other visual data, objects/artefacts can convey messages, even if those messages are unclear. Artefacts include, for example, objects in interior design and equipment (Higgins and McAllaster, 2004), children's toys, reading materials, DVDs, clothes etc. (which can

give indications of gender stereotyping in young children and how such stereotyping occurs and how boys and girls are inducted into differently gendered worlds (e.g. Francis, 2010)).

Artefacts have been widely used in educational research (e.g. Boston, 2008; Francis, 2010), ethnographic, anthropological and historical research, and studies of organizational culture (Schein, 1992), for example, studying dress codes, architecture, status symbols, signs, furniture, office areas, space, technology, mission statements and physical premises (Buch and Wetzel, 2001). Schein (1992) considers artefacts to be one of the three main levels and manifestations of organizational culture. Artefacts are the observable level of organizational culture (the other two levels being values and deep-seated norms); they are the outward manifestations of culture, for example executive rooms, dress codes, level of technology utilized (and where it is utilized), the physical layout of workspaces, the objects provided or observed in the workplace. All may be visible indicators of culture, but they are difficult to interpret; artefacts may suggest what a group is doing, but not why.

For example, consider a dull, dark, sparsely fitted classroom with no real amenities or decoration, with a few dried pot plants in a corner and no surplus ornaments or displays. Contrast this with the brightly lit, interesting, multi-equipped classroom with notices, displays, samples of students' work and the latest computing equipment in use. The objects can make a point here very tellingly, but what is that point? Is it that:

- some classrooms are dull, dispiriting places whilst others are energizing and interesting;
- some schools don't care about the teaching room whilst others take pains to present a stimulating environment;
- some schools are financially poor whilst others are rich;
- some classrooms exude a focus on learning from the teacher whilst others emphasize learning from the environment;
- some classrooms do not care about students' emotions whilst others are concerned to make the environment a happy place;
- some classrooms are very old and off-putting whilst others are new and engaging?

Inference from the artefacts alone may be dangerous as they may signify very different or discrepant realities; hence researchers should consider using artefacts alongside other data sources.

Take the example of the school in which the principal's office is private, separated from the main part of the school, large, beautifully carpeted, airy and spacious, with trophies, pictures, gifts, a huge working desk and an ergonomically designed chair, maybe a glass cabinet or two, works of art, a photograph of the family and of a meeting with an important dignitary, an up-to-date computer and colour printer, and a personal bathroom. Contrast this with the working space of the staff, who each have a small cubicle as part of a large room which has been sectioned off into workspaces for a dozen or more staff, with eye-level partitions like a typing pool, a small chair and desk, no room to put anything personal, with workstations squashed into an egg-crate arrangement and with no personal space, no superfluous ornaments, not a picture in sight, bare walls except for notices, shared equipment, and piles of books in each cubicle waiting to be marked. The messages – the not-so-hidden curriculum – of power, status, care and respect for people and humanity are very clear.

Or take the example of a school staffroom which may be untidy, with piles of books strewn around in different places, unwashed cups all over the room, notices peeling off the notice boards, cushions crumpled up on chairs, boxes of sports equipment lying in the corners, box files piled up alongside tables, comfortable chairs in very short supply and pieces of computer equipment cluttering up several tables. What can the researcher infer from this scene: that staff are extremely casual and careless or that they are extremely busy? Very different interpretations can be made of the same scene and artefacts.

As with other visual materials, artefacts can give messages but, like other visual objects, they are easy to observe but difficult to interpret, and there are multiple interpretations. In some cases artefacts may be easy to interpret, for example, the images presented in children's books may indicate sex role stereotyping, or may portray positive images of some groups and negative images of others.

Artefacts can be seen, heard, smelt, touched, felt, even tasted and heard, so the researcher can bring to bear a multi-sensory analysis. They can be used to stimulate discussion (see the comments above about the use of photographs), to glimpse into the past or the present, to reconstruct or help to imagine a scene, to remind people and bring back memories. They can be observed *in situ* (and the location and placing of the object in a spatial context itself carries meaning, e.g. in a home, a museum, at the back of a room, in a dark corner, in a prominent position etc.). As with still and moving images, the artefact may be provided by the researcher or by the participants.

The researcher can examine artefacts on their own or in combination. For instance, in the example of the

messages about the organizational culture of the principal's and staff's office areas, a single object may not say very much, but taken together the objects can make a persuasive case. Objects may also be sorted and grouped into categories, for example, ornaments, books, furniture, space; each category can be examined on its own and/or in combination (akin to the different kinds of coding exercise in grounded theory, where individual codes are combined into categories) and such sorting can elicit the participants' conceptual categories: how they think and group items, and why (cf. the earlier discussion of elicitation) (Barton, 2015).

In investigating artefacts, the researcher can consider the purpose of the production and location of the artefact, what it was used for and by whom, who produced it, when was it made, what materials were used in its making, what was its actual and/or symbolic purpose or function, how has it been preserved and in what condition, and what value it has to the provider or user. This has particular significance in historical, anthropological, ethnographic and archaeological research in educational and social science.

In some research (e.g. on child abuse), artefacts (e.g. dolls with lifelike features or sex organs) can be used to encourage children to speak out about their experiences, displacing the highly sensitive personal threat or embarrassment onto the doll in question. Greig and Taylor (1999, p. 64) advocate the use of familiar artefacts with children – dolls, puppets, drawings, pictures – as this not only sets them at their ease but helps them to make concrete their ideas. This technique is particularly useful with young children, where dolls or puppets can have a series of facial expressions (happy, sad, angry, afraid) and where non-verbal postures can be manipulated on puppets (e.g. dolls, manikins, glove puppets) to enable the researcher to investigate emotions in young children (pp. 120–2). Greig and Taylor indicate how puppets can be used to research situations of conflict in young children. For example, the researcher can ask what puppets A and B want, how they feel, why they are fighting, who is winning, whether the fight is justified, what each puppet should do, what the child would do in a similar situation, why puppet A or B was wrong, how the situation could end, and how the situation could be resolved (p. 122).

How researchers use artefacts depends on their research questions. Similarly, just as one uses sampling procedures to decide, for example, which people to approach to be involved in the research, so one has to consider the criteria to be used for deciding the sampling and selection of artefacts (cf. Lodico *et al*., 2010, p. 164). As with still and moving images, in deciding which artefacts to use, the criteria for selection (sampling criteria) should demonstrate fitness for purpose, fairness and defensibility. This operates with researcher- or participant-provided artefacts and with researcher observation of artefacts (e.g. the objects in a classroom, staffroom, principal's office and so on). The researcher should specify and justify the selection of the artefacts, and, to be faithful to the multiple interpretations that can be made of artefacts, the researcher should provide alternative interpretations of the artefacts where appropriate.

31.6 Ethical practices in visual research

Taking visual images is subject to the same ethical concerns and requirements as other forms of educational research, and we refer readers to Chapter 7 here. In particular, the issue of informed consent may prove difficult in the case of historical images, images of the general public or deliberately covert research. It is important to consider the indiscriminate taking or use of photographic or visual images of children without their consent and that of their teacher, the school, parents, helpers, guardians and staff.

Whilst Clark (2006) and Prosser *et al*. (2008) regard collaborative research (between researcher and participants) as one way of addressing complex ethical issues, this does not cover all situations, and researchers need to consider the ethical principles set out in Chapter 7.

Public places

Permission concerns not only the site of the image itself (e.g. the taking of the photograph, filming in public places), but permission for reproduction (e.g. from individuals, from institutions), indicating the uses to which the image will be put, and indeed for altering the image in some way. In the case of public places (and Prosser *et al*. (2008, p. 6) argue that what constitutes a public place is itself unclear), permission may need to be sought from the official body or party responsible for that public place as well as individuals (e.g. the informed consent of people in the street or in a building). Not only are there issues of legally and illegally taking images (e.g. of military establishments) or storing images, there is the issue of preferred and non-preferred sites for taking pictures (Prosser *et al*., 2008, p. 6), such as police stations, hospitals, schools, leisure facilities, surgeries, even rail stations, airports and libraries.

However, the argument is not only about what is permitted or not permitted in terms of a public place, and what constitutes a public place, but the ethical acceptability of, for instance, taking a photograph of

someone in a public place without their informed consent. What constitutes a public, semi-public or private space is unclear, or what constitutes what the participants may wish to see as a private activity in a public place (e.g. kissing your partner) (cf. Solove, 2004). For example, just because there are no notices in a hospital or a school to saying 'no photographs', does that make it ethical to take such photographs or videos of patients, the public, students and teachers in those sites (cf. Clark *et al*., 2010)?

Anonymity, confidentiality, privacy and identification

Images, for example, photographs and videos, often identify people. This raises significant ethical issues. Identification, anonymization and obscuring of individuals and places relate not only to the ethical sphere but to matters of legal regulation on data protection. On the other hand, some participants may deliberately wish to be identified (Prosser *et al*., 2008, p. 11; Brooks *et al*., 2014, p. 145).

Prosser *et al*. (2008) contend that visual methods raise issues of informed consent, anonymity, confidentiality and dissemination (p. 2). Anonymity and confidentiality may be highly problematic in visual images, as the whole purpose of the image lies in the details of the person, place or institution in question, without disguise or dehumanization (p. 15). If one removes identifying features, one destroys the very detail that might be the purpose of the research.

Whilst informed consent may be one method of addressing this, it is not always applicable (discussed below). Images may be anonymized, for example blurring identifying features, pixilation, eye-blocking (e.g. black bars), voice modification, using pseudonyms, taking the image showing only the back of the person, showing only non-identifying features of people (e.g. their hands), or with shaded, back-lit lighting (see Clark (2006) and Clark *et al*. (2010) for detailed guidance on anonymization).

Copyright and ownership of the image

Visual images may be subject to copyright and intellectual property legislation. Researchers have to be aware of their moral and legal responsibilities concerning intellectual property. For example, if one takes a visual image of a teacher and students in a classroom, who owns the image and the lesson in question (US Department of Education, 2002) – the researcher, the teacher, the students, the parents, the school, or any combination of these – and what rights to usage, distribution and publication does this bring or prevent? What if the image includes a school textbook: does the publisher have ownership rights? What if the students have special needs? What if the class is unruly? What if the lesson is ineffective? How can the data be used, and by whom? Once the image is in the public domain, it is beyond the control of the researcher.

'Images' come under legislation concerning 'artistic works' (Clark *et al*., 2010), with copyright lasting for decades after the artist's death, and the researcher's use of photographs is affected by Data Protection Acts which require informed consent, not least for public release. Informed consent applies not only to taking the photograph or video, but to putting the image into the public domain. This can be particularly problematic, for example, if children or researchers have created images or collages of images using media-created photographs (e.g. from magazines).

Informed consent

Informed consent (see Chapter 7) is complex, as, for example, it may be in the public interest to have a long-lens photograph of a private activity or of a person, without that person's informed consent, i.e. covert research. As discussed in Chapter 7, informed consent also raises issues of who is to give that consent, and for what, and on whose behalf. Clark *et al*. (2010) note that this is a delicate matter, as seeking consent from parents may disempower their children who are the very subjects of the research. Further, practically speaking, it may be impossible to obtain the consent of everyone who appears in the image, for example, a crowded school corridor or playground. Informed consent applies not only to the creation of the image (e.g. the photograph, the video) but to its use, release, publication and audiences. The long-term effect of publication is relevant here: for example, Clark *et al*. (2010) report the case of a researcher who decided not to publish a photograph, because in later years the topic could come back to haunt or negatively affect the person in the photograph. Once an image goes into the public domain, the researcher almost completely ceases to have control over how it will be used.

Prosser *et al*. (2008) give an example of the challenges that visual researchers face with regard to informed consent (pp. 12–14):

- it may not always be appropriate to gain informed consent (e.g. in covert research or surveillance work);
- what 'informed' and 'consent' mean may be different in different cultures or with different groups (e.g. children);
- it is not always clear who is actually in a position to give the consent sought (e.g. in the case of children or teachers);

- it may not be practically possible to gain the consent of those who feature in visual images (e.g. in public places), for instance in the case of photo-journalism;
- it may be difficult to gain the consent of those featured in a visual image if the provider of the image (e.g. a participant) has not gained that consent;
- it is important to ensure that participants know to what they are giving their consent, for example, to the taking of the image, to the reproduction of that image (and where) and for how long;
- it is not always clear what to do with 'found images', where the provenance of the image is unknown or with images which were not originally produced for the purposes used in the research (see the analysis of the photograph in Chapter 36).

In covert research (see Chapter 7), with easy access to photographing and videoing with smartphones, or a range of small video cameras, disguised and tiny, issues of informed consent are highly problematical.

Do no harm

A key principle in image-based research is *primum non nocere:* 'first of all, do no harm'. This issue concerns the sharing and publication of the image, and with whom (Alderson and Morrow, 2011; Hammersley and Traianou, 2012), and researchers have to consider not only legal constraints but ethical obligations. They must ask themselves, and indeed the participants in the research, what might be the negative effects of the image on those included in the image, on the participants and on the researcher, if the image is made public, both now and in the future. What if there is an image of students being unruly or if the teacher is ineffective? What if the image, for example, a photograph or video, is taken covertly? What if a person does not wish to be photographed or videoed or doesn't know that this is happening? How can the data be used, and by whom? Once the image is in the public domain, it is beyond the control of the researcher, and *primum non nocere* trumps benefits to the researcher; this is an overriding precept.

A statement on ethical practice in visual research is provided by the British Sociological Association (2006). This includes: professional integrity; legal considerations (including data protection, copyright and libel laws); ownership of images; images of illegal activities; morally questionable practices; beneficence and non-maleficence; non-breaching of trust; informed consent; relations with and responsibilities towards research participants; sensitivity to local cultures; procedures for sharing images; covert research; researching vulnerable groups; anonymity, privacy and confidentiality; dangers of intrusion into private worlds and lives; working with children and images of children; Internet-based research; relations with and responsibilities towards sponsors and/or funders; and clarification of rights to publish.

The UK's Economic and Social Research Council National Centre for Research Methods (2008) has produced a comprehensive analysis of ethical issues in visual research, including material on frameworks, professional guidance, regulations and legal rights and duties for visual researchers. It covers: ethics; issues of consent; researcher-generated and respondent-generated images; anonymizing and obscuring visual data; photo-elicitation and informed consent; anonymity and confidentiality; photographs and films that identify individuals; images of place and how to anonymize these; the construction and consumption of images; and guidelines for practice. We strongly advise researchers to consider carefully these ethical guidelines, as they indicate the very careful boundaries within which researchers with visual data must work. We provide the websites of these organizations on the companion website, and we also refer readers to Clark (2006), Wiles *et al*. (2008), Prosser *et al*. (2008) and Skåreus (2009).

We summarize key questions in image-based research and visual methods in Boxes 31.1 to 31.4. 'Image' here can refer to photographs, videos, drawings, artefacts etc., i.e. the entire gamut of visual objects.

BOX 31.1 APPROACHING IMAGE-BASED RESEARCH

In the research design

1. How does the use of the image fit with the purpose, focus and design of the research?
2. What research question(s) will the use of images address?
3. Why include image-based research?
4. What are the purposes and importance of creating and using the image in the research?

Preparing the image and its usage

5. What visual medium will you use? What kind of image is it (photograph, video, collage, painting, drawing, graphic etc.) and why choose that kind?
6. Is it an existing or specially created image?
7. How many images?
8. How and why is/was the image created/selected/included?
9. Who creates/created the image?
10. Who provides the image?
11. What is the context of the image?
12. Why and how was the image originally created and obtained?
13. What equipment and training are needed to create the image?
14. What is the source of the image (e.g. book, magazine, archive)?
15. What kind of image is it (e.g. a mirror/real event, a metaphor or symbol, a representation, a narrative sequence, concrete or abstract etc.)? What is the image about?
16. What instructions, preparations and criteria have been given to participants in connection with the image (e.g. creation, usage, selection)?
17. What are possible effects of creating the image on participants and those included in the image? How to address intrusion and reactivity?
18. How to address researcher and/or participant reflexivity in creating and using the image?
19. How to avoid researcher and/or participant bias in creating and using the image?
20. What technologies, compositional and editorial features have been used to create the image, and what effect does this have on the image?

BOX 31.2 USING THE IMAGE IN THE INTERVIEW

Using the image in the interview

1. When and how to introduce the image in the interview, and why?
2. How to use the image to build rapport and trust?
3. How to use the image to promote discussion/data collection (i.e. what to say, how to prompt and probe)?
4. How to respect the 'positionality' of the participants in interpreting the image?
5. What narrative/commentary are you seeking in the use of the image?
6. How to respond to participants' reactions (e.g. emotional) to the image and its use in the interview?
7. How to balance attention to close-up detail with attention to the bigger picture?
8. How to ensure that the points raised about the image at interview are relevant to the participant?

BOX 31.3 DATA ANALYSIS WITH IMAGE-BASED RESEARCH

After the interview

1. How to analyse the images and the interview data?
2. What to focus on the analysis, and why?
3. How to create and include narratives about the image?
4. How to report discussion/interview data, to whom, in what form, and with what protections?
5. How to incorporate image-based analysis with analysis of other data?
6. How to address researcher and/or participant reflexivity in reporting the results?
7. How to avoid researcher and/or participant bias in reporting the results?
8. How to avoid selection bias in what is reported?
9. What are the main messages from the interview/image analysis, and how do we trust these?
10. How to check and make transparent the plausibility of the researcher's interpretations of the image and the interview?

BOX 31.4 ETHICS AND OWNERSHIP OF IMAGES

Ethics and ownership of images

1. How has the ethic of 'do no harm' been addressed in creating and using the image?
2. What informed consent has been obtained, from whom and for what?
3. How have issues of anonymity, confidentiality, privacy, non-traceability and identifiability of people, places, institutions, behaviours and events been addressed?
4. Who will see the image?
5. How will the image-based research empower participants?
6. How to use images in sensitive research?
7. What safety precautions have been taken in creating, using, storing, sharing, disclosing and publishing the image (legal and ethical)?
8. Who owns the image?
9. Where to post images on the Internet/cloud and with what security features?
10. What permissions have been obtained for access to image-creation sites and control of release of the image (including legal requirements)?
11. What copyright issues have been addressed?

Companion Website

The companion website to the book includes PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. These resources can be found online at **www.routledge.com/cw/cohen**.

Part 5
Data analysis and reporting

This part starts with qualitative data analysis and then moves to quantitative data analysis. In qualitative data analysis we take readers from first principles to content analysis and grounded theory, making the point that texts – data – are multi-layered and open to a variety of interpretations. We indicate in practical terms how researchers can analyse, present and report qualitative data, including an introduction to the foundational principles of such approaches and ways of organizing and presenting qualitative data. The material on qualitative data analysis covers kinds of analysis which are not reliant on coding and grounded theory, including conversational analysis, narrative analysis, discourse analysis and autobiographies. We provide many worked examples of each of these, indicating how to approach, conduct and report analyses of different kinds of qualitative data, and the need for reflexive authorship of analyses. We expand the chapter on analysing visual data, including new examples of software for approaching and analysing text, still images and moving images.

In quantitative data we assume that researchers will not only have no experience of statistics but may even be frightened by them! Hence we take readers by the hand from very first principles to more complex statistical processes, how to do them and how to analyse, interpret and report the results. We explain the foundations, principles and concepts underlying statistical procedures, and we indicate 'safety checks' that researchers should follow before proceeding with statistical analysis. We have an entirely new chapter on statistical significance, effect size and statistical power, how researchers can work with these, and some concerns about significance testing. In introducing descriptive statistics we also include new material on missing data.

Following this we introduce correlations, reliability, straightforward inferential statistics, including difference tests, regression and working with standardized scores, and higher level inferential statistics, such as factor analysis. We include new material on cluster analysis and introductory notes on, and examples of, structural equation modelling and multilevel modelling. Given the range of statistics available to researchers, we organize these clearly using charts and tables, so that researchers can see how to select appropriate statistics for their purposes and to fit the kinds of data collected. Finally, this part includes an entirely new chapter entitled 'Beyond mixed methods: using Qualitative Comparative Analysis (QCA) to integrate cross-case and within-case analyses', which is a fitting final chapter as it works with a celebrated approach to moving beyond discrete quantitative and qualitative data analysis. These chapters also contain new boxes indicating the command sequences for using SPSS.

For both the qualitative and quantitative data analysis we provide practical advice – including sample phrases and choice of words – on how to report results and findings. These chapters are accompanied by extensive materials on the companion website, including data files for use with qualitative and quantitative data and PowerPoint slides for each chapter, at: www.routledge.com/cw/cohen.

Approaches to qualitative data analysis

CHAPTER 32

This chapter sets the scene for qualitative data analysis. Subsequent chapters focus on specific techniques and types of data analysis such as coding and content analysis, discourse analysis, narrative analysis and grounded theory. Here we introduce:

- elements of qualitative data analysis
- qualitative data analysis, thick description and reflexivity
- ethics in qualitative data analysis
- computer assisted qualitative data analysis (CAQDAS)

In many instances we deliberately use seminal texts in this field. In-depth consideration of ways of analysing qualitative data is set out in Chapters 33 to 37.

32.1 Elements of qualitative data analysis

Qualitative data analysis concerns how we move from the data to understanding, explaining and interpreting the phenomena in question (Taylor and Gibbs, 2010, p. 1). It includes, among other matters, organizing, describing, understanding, accounting for, and explaining data, making sense of data in terms of the participants' definitions of the situation (of which the researcher is one), noting patterns, themes, categories and regularities, all of which are the task of the qualitative.

Qualitative data analysis is not straightforward. As Patton (2002) remarks, though qualitative data analysis turns data into findings, there is no simple formula or recipe for this (p. 432). There is no one single or correct way to analyse and present qualitative data; how one does it should abide by *fitness for purpose*. Qualitative data analysis is often heavy on interpretation, and there are often multiple interpretations to be made of qualitative data – that is their glory and their headache! It is also distinguished by its merging of analysis and interpretation and often by the simultaneity of data collection with data analysis (Gibbs, 2007, p. 3) in a back-and-forth process (Teddlie and Tashakkori, 2009, p. 251). Indeed, the processes of the analysis also constitute data in themselves. As researchers write down notes, memos, thoughts and reflections in the field or during an interview or observation, these, too, become data. The steps taken in moving from description to understanding to explanation, interpretation and conclusions must be transparent (Gläser and Laudel, 2013) and demonstrate validity.

Qualitative data derive from many sources, for example:

- interviews (transcribed or not transcribed);
- observation (participant to non-participant);
- field notes;
- documents, reports, newspapers, minutes of meetings;
- memos;
- emails and online conversations;
- diaries;
- audio, image-based, visual, video and film materials;
- records of events;
- websites and website data (e.g. online surveys);
- qualitative survey data (e.g. from questionnaires);
- advertisements and print materials;
- pictures and photographs;
- artefacts.

The list is huge. Qualitative data analysis focuses on in-depth, context-specific, rich, subjective data and meanings by the participants in the situation, with the researcher herself/himself as a principal research instrument. It involves: *data reduction* (in order to avoid the often serious issue of data overload, i.e. too much detail and too much material); *data display*; *data analysis and interpretation*; *drawing and verifying conclusions*; and *reporting* the analysis and findings (cf. Miles and Huberman (1984, 1994, who restrict their suggestions to: data reduction, data display and conclusion drawing and verification). Data reduction does not mean disregarding data; rather it means distilling from the complexity of the findings the key points of the phenomenon in question, reducing complexity without violating it, catching the essence of the issue or the situation, enabling the researcher to identify, for example, patterns, key issues, causal processes and sequences (Gläser and Laudel, 2013).

To compound the challenge of qualitative data analysis, as Chapter 15 made clear, meanings and interpretations of situations and data are not singular or unitary – the sole preserve of the researcher(s) – but are several, including those of the participants. In other words, there are many possible analyses and interpretations of data, and care must be taken to avoid indefensibly privileging one interpretation over another equally possible interpretation (e.g. the researcher's) if both are sustainable by the data. The researcher has to catch multiple perspectives on a phenomenon and multiple interpretations of it, and report these.

Qualitative data analysis involves some or all of the following, depending on the approach adopted (e.g. Newby, 2010; Creswell, 2012; Gibbs, 2012; Marshall and Rossman, 2016):

- *preparing and organizing the data*: putting the data into formats, documents, maybe computer files, and an organization system that make for ease of management and analysis. This might involve transcribing and/or summarizing data, and bringing order into the data;
- *describing and presenting the data*;
- *analysing the data*: exploring and making meaning of the data, for example, organizing and categorizing data into key concepts; identifying the units of analysis; coding; inductive processes; identifying and refining key concepts and key points; identifying linkages and relationships between the data; summarizing; thematic analysis; creating typologies (e.g. by combining categories – the qualitative equivalent of factor analysis from variables in quantitative research); case summaries and cross-site analysis; patterning; constant comparison methods; discourse analysis; writing a narrative, conversational analysis etc. In other words, it involves data assembly and re-assembly, recombining them in new ways, synthesizing and integrating data in order to create a meaningful account and analysis;
- *interpreting the data*;
- *drawing conclusions;*
- *reporting the findings*;
- *ensuring accuracy, reliability, coherence, corroboration, validity and reliability* (variously defined, see Chapter 14).

These bullet points overlap and do not necessarily indicate a sequence, indeed analysis and interpretation often occur simultaneously. Rather, the process of data analysis is recursive, non-linear, messy and reflexive, moving backwards and forwards between data, analysis and interpretation. It involves ensuring that all the relevant data have been included and that a fair, coherent and defensible representation of the data and their meaning(s) has been presented, together with conclusions drawn from them.

Data analysis is often an ongoing process that takes place during the research as well as at the end of it. Data collection and analysis may accompany each other (see below: progressive focusing), and this means that analysis is subject to continual modification, addition, refinement, excision, extension and amendment. Some of the analytical tools can be *pre-ordinate* (*a priori*: ideas, themes, codes, key points, analytical framework etc. decided in advance); some can be *responsive* to the emerging data and their analysis and interpretation (*a posteriori*) and what they reveal; indeed a combination of *pre-ordinate* and *responsive* categories, codes, themes, ideas, topics, concepts etc. can be used.

The qualitative data analyst must identify and locate raw data (Gläser and Laudel, 2013, p. 5) and link data to the research questions and the research findings (Thomas, 2006). This involves interpretation, and categories generated can be derived from the data themselves, or from theory, research questions, the researcher herself/himself or any combination of these. Similarly, linkages between data can be in terms of concepts, themes and content, with patterning across data (i.e. more-than-one occurrence of sequences, conditions, processes and outcomes of events), or indeed in terms of conflicting accounts. Such patterns can be integrated or merged where suitable (Gläser and Laudel, 2013, p. 8), ensuring that all the data are included and none forced out, even if this means acknowledging variation within an overall pattern.

Wellington (2015, p. 263), suggests that qualitative data analysis includes: (a) dividing the data into 'units of meaning'; (b) classifying and grouping the units of meaning; (c) including new units of data into these groupings/categories; (d) searching for categories that are similar and/or which can be merged into a single category; (e) reviewing categories that contain large amounts of data to see if they can be split into smaller categories; (f) checking that the categories include all the data and are mutually exclusive (though some data may appear in more than one category); and (g) looking for linkages, contrasts and comparisons between the categories (constant comparison).

He provides a seven-stage model for 'making sense of qualitative data' (2015, p. 267):

Stage 1: 'Immersion' in the data;
Stage 2: 'Reflecting, standing back';
Stage 3: 'Analysing' ('dividing up, taking apart, selecting and filtering, classifying, categorizing')

Stage 4: 'Synthesizing, re-combining' data;
Stage 5: 'Relating to other work, locating' data;
Stage 6: 'Reflecting back (returning for more detail?)';
Stage 7: 'Presenting, disseminating, sharing' the findings.

This sequence is not necessarily linear, and recursion might occur.

In preparing for data analysis, the researcher must immerse herself/himself in the data, read, re-read, reflect on the data, write about the data and what they mean (and what different meanings, explanation and interpretations of the data there may be), how the data are linked or related, how to organize the data and the key points arising from the data, how to analyse the data, how to organize and synthesize the analysis most fittingly and coherently (e.g. Wellington, 2015), and reflect on how the researchers' own biography, values, knowledge, assumptions and experiences shape or inform the data analysis, i.e. reflexivity (Woods *et al*., 2016, p. 387).

Qualitative data analysis as an inductive process

The process of qualitative data analysis is typically inductive (Thomas, 2006). Here the researcher reads, re-reads, reflects on, infers from and interprets the raw data/transcripts/memos etc. From this, without preconceptions or deductions from a pre-given framework (unlike, for example, experimental research or hypothesis testing), the researcher develops interpretations of the data and derives themes, concepts, theories, explanations, understandings, summaries, models etc. which fairly and comprehensively explain the data or phenomenon. As Strauss and Corbin (1998) remark, the theory emerges from the data in the field of study in question (p. 12). This is a bottom-up process, moving from data to explanation to theory (hence the 'grounded theory' approach discussed in Chapter 37) (though Bazeley and Jackson (2013) contest how far it is only a bottom-up process). The researcher can refer to the research questions in guiding induction, though often analysis is data-driven rather than research-question-driven (Thomas, 2006) (but see Chapter 33 here). The inductive process, Thomas suggests, can proceed thus (in practice this is not necessarily a linear sequence): *understanding the research objectives* → *preparation of the raw data* → *reading and re-reading the raw data*, and *reflecting* on the raw data and their meanings → *category generation, revision and refinement* (involving, as appropriate: coding and recoding; creating a hierarchy of codes and categories; checking for consistent use of codes; category descriptions; removing irrelevant data without loss of fidelity to the phenomenon; category labelling; identifying texts/data to put within the category; and identifying links between categories) → *model generation* (which might contain key themes, processes and the category systematization, temporal sequences and causal networks) → *answering the research purposes and questions*.

Many researchers move almost spontaneously into coding. We advocate caution here (see below and Chapter 34). Thomas (2006) suggests that checking for the consistent use of codes can be addressed by:

- *independent, blind parallel coding*, where a second researcher is given the objectives and the raw data, but no codes, and is asked to code the data, after which the two sets are reviewed for consistency, overlaps and discrepancies;
- *checking on the clarity of the categories*, where a second researcher is given the categories and the raw (uncoded) data and is asked to assign the raw data to the categories, which are then checked against the allocation of the data by the first researcher, to look for consistency and discrepancies.
- *stakeholder and member checks*: respondent validation and review in order to establish, *inter alia*, the credibility, transferability, dependability and confirmability of the data and the findings.

Thomas is writing about evaluative research here, and he emphasizes the need to understand the research objectives. In other research, for example, goal-free evaluation or open-ended research, the objectives may be less certain and less the engines of the research. He also recognizes that there can be more than one valid interpretation of the data and that interpretations are influenced by each researcher's own biography, experiences, values and assumptions; hence there may be more than one set of findings and conclusions, which may or may not be similar to each other.

Preparing and organizing the data: transcription and summary

Preparing the data means putting them into a format that lends itself to analysis. For example, it may be a matter of creating: (a) word files/text files of observational data, interview data, questionnaire data, memos, field notes and suchlike; (b) visual data files (e.g. of pictures, graphics, images, videos); (c) audio files; and (d) files of graphs and numerical data. All of these are prepared with ease of access, overall organization and data analysis in mind. This might mean putting files into a common format (layout, font size, organizational sequence, chronology, key features etc.), maybe with

computer analysis in mind so that they can be read into particular computer software. Many computer packages enable multiple kinds of files and data to be imported, and we discuss this below.

In preparing data files, researchers should consider whether to transcribe interview data for analysis. On the one hand, transcriptions can provide important detail and an accurate verbatim record of the interview. On the other hand they omit non-verbal aspects, what may take place before or after the interview and contextual features of the interview.

On a practical level, it may be difficult to catch exactly what was said if people do not speak clearly or sufficiently loudly, or they may speak in broken sentences or with different accents, and these features, whilst difficult for the researcher, may not appear in the final transcript (Denscombe, 2014, p. 279). Transcripts are also very time-consuming to prepare (e.g. one hour of interview may take up to five or six hours to transcribe, even with a transcription machine which can be paused whilst the transcriber writes the words or enters data into computer software). The researcher should consider the costs and benefits of transcription, judging whether close transcription is really necessary.

An alternative to transcription is to write the summary of data or their analysis directly from the video or audio recording, selecting out the important materials directly from the original source, thereby avoiding becoming so caught up in detail that sight of the bigger picture is lost. Such selectivity might also include verbatim quotations and short extracts, accompanied by the researcher's own annotations (e.g. informal observations and comments) (cf. Denscombe, 2014, p. 278). Nonetheless this is data interpretation and selection, and, as such, can reflect on the researcher as much as on the data.

If transcription is used, then the researcher must make clear the transcription conventions being followed (see also Chapter 35), for example:

- give each speaker a name or pseudonym (and keep a list separately of which speaker has which pseudonym);
- record hesitations, small to long pauses, and silences (e.g. through dots (…) in the text;
- record inflections and tone of voice (rising to falling), for example, write down the mood of the speaker or the speech at the time: anger, anxiety, sadness, excitement, questioning, hesitance etc.;
- note: the volume of the speaker (quiet, loud, whispering, shouting); the speed of the speech (slow, fast, hurried, calm); pitch (high, low); tone (calm, angry, excited, nervous etc.); breaks in speech (sudden, considered); stresses and phases in the speech; audible breathing out or breathing in;
- record non-verbal activity (e.g. standing up, leaning back) if transcribing from video recording;
- record uninterpretable noise (e.g. by using the words 'noise' or 'unclear noise' in brackets);
- record several speakers who are all speaking at the same time (e.g. with the word 'together' after each speaker's name or a uniting large bracket);
- be consistent in spelling (so that search and retrieval can be facilitated, particularly if software for this is used, discussed later);
- ensure that each line or section/paragraph is numbered (in Word this can be done through the 'Page Layout' menu);
- ensure that wide margins and double spacing are used for annotating text in hard copy form.

For a fuller description of these see Atkinson and Heritage (1999), Flick (2009, pp. 300–2) and Woods (2010). The transcriber must check the accuracy of the transcription, as it is not uncommon for speech to be heard incorrectly or for words to be confused Gibbs (2007, p. 19 gives many examples of such confusions).

Voice recognition software is available that recognizes and transcribes speech, and this can save time, though the reliability of the transcription is influenced by the accuracy of the speech recognition and the clarity of the speaker.

Managing data files and types

Data management and organization are important, maybe creating an index, for easy categorization and retrieval. Data can be of various types, for example, text, images, videos, graphics, audio, numbers, Internet sites and so on. Within each of these there are several sub-groups, for example, within text-based data there are field notes, interviews, observations, memos, documentary records, working notes and so on. The management of data is essential for ease of access, chronology, data types, linkages and retrieval etc.

The researcher should create a clear and easily accessible system for data location, storage, organizing, filing and handling, be it in terms of hard copy or soft copy. In effect, the researcher creates a mini-reference-library system, with different subjects in different library and shelf locations, different kinds of materials in different locations and indexing, all with secure storage and protected access. Or, put it another way, imagine a textbook, which has a table of contents, parts/sections, chapters, sections within chapters, and an index; the researcher has to create an analogical data storage, organization and retrieval system.

Software is useful here. For example, NVivo enables different kinds of *data* to be organized and stored by category (folders, sources), for example, interviews, observations, documents, videos, pictures, memos, images, audio, graphics etc., and, within each folder, there are specific data files. The software can also retrieve and store *searches* made of the data (e.g. by queries, by code, by node, by reports) and it can save files into different locations which contain *analysis* (e.g. text-based, graphics based); see Figure 32.1 for an example of this.

32.2 Data analysis, thick description and reflexivity

In abiding by the principle of *fitness for purpose*, the researcher must be clear what she/he wants the data analysis to do as this will determine the kind of analysis that is undertaken. The researcher can set out, for example:

- to describe;
- to portray;
- to identify;
- to summarize;
- to interpret;
- to discover patterns;
- to generate themes;
- to understand individuals and idiographic features;
- to understand groups and nomothetic features (e.g. frequencies, norms, patterns, 'laws');
- to raise issues;
- to prove or demonstrate;
- to explain;
- to seek causality;
- to explore;
- to test;
- to discover commonalities, differences and similarities;
- to examine the application and operation of the same issues in different contexts.

The significance of deciding the purpose is that it determines the kind of analysis performed on the data. This, in turn, influences how the analysis is written up. The data analysis is also influenced by the kind of qualitative study being undertaken. For example, a biography and a case study may be written as descriptive narrative, often chronologically, with issues raised throughout (e.g. Hamilton and Corbett-Whittier, 2013). An ethnography may be written as a narrative or stories, with issues raised, but not necessarily conforming to a chronology of events, and including description, analysis, interpretation and explanation of the key features of a group or culture (e.g. Mills and Morton, 2013). A grounded theory and content analysis can proceed through a systematic series of analyses, including coding and categorization, until theory emerges that explains the phenomena being studied or which can be used for predictive purposes (Glaser and Strauss, 1967).

The analysis will also be influenced by the number of data sets and people from whom data have been collected. Qualitative data often focus on smaller numbers of people than quantitative data, yet the data tend to be detailed and rich: thick descriptions (Geertz, 1973). Researchers will need to decide, for example, whether to present data individual by individual and then, if desired, to amalgamate key issues emerging across the individuals, or whether to proceed by working within a largely predetermined analytical frame of issues that crosses the individuals concerned. Some qualitative studies deliberately focus on individuals and the responses of significant players in a particular scenario, often quoting verbatim responses in the final account; other studies are content to summarize issues without necessarily identifying exactly from whom the specific data were derived. Chapter 33 discusses methods to be used with respect to people and issues.

Some studies include a lot of verbatim conversations; others use fewer verbatim data. Some researchers feel that it is important to keep the flavour of the original data, so they report direct phrases and sentences, as they are often more illuminative (diamonds!) and direct than the researchers' own words, and because researchers feel that they should be faithful to the exact words used. Indeed direct conversations can be immensely rich in data and detail. Ball (1990, 1994a) and Bowe *et al*. (1992) use a lot of verbatim data, not least because they interviewed powerful people and justice was done to the exact words that they used. By contrast, Walford (2001, p. 92), commenting on the 'fetish of transcription', admits that he 'rarely fully transcribed more than a few interviews for any of [his] research studies', not least because of the time that it took for transcription (he suggested a ratio of 5:1 – five hours to transcribe one hour of interviews – though it can take much longer than this).

At a theoretical level, a major feature of qualitative research is that analysis often begins early on in the data-collection process so that theory generation can be undertaken (LeCompte and Preissle, 1993, p. 238). Here researchers painstakingly take apart their field notes, matching, contrasting, aggregating, comparing and ordering notes made, then they set out the main outlines of the phenomena under investigation (pp. 237–53), then they assemble blocks or groups of data, putting them together to make a coherent whole (e.g. through writing summaries of what has been

found). The intention is to move from description to explanation to theory generation.

At a practical level, qualitative research rapidly amasses huge amounts of data, and early analysis can reduce the problem of data overload by selecting out significant features for future focus. Miles and Huberman (1984) advise researchers to start writing and analysing early and frequently (i.e. as soon as the first data have been collected, even in a longitudinal study), rather than leaving all the writing and analysis until the data collection or the study is over, as this enables 'progressive focusing', with selection of the key issues identified for further investigation. As Gibbs (2007, p. 25) remarks, 'writing is thinking'. Such analysis should, itself, be given a date and time, and can be included in a diary of field notes which record, for example, what the researcher was doing, where the researcher was, what was happening at the time, who was present, what the data were, particular or notable features of the event, context or situation, reflections and observation (Miles and Huberman, 1994, pp. 50–4).

'Progressive focussing' (Parlett and Hamilton, 1976) starts with the researcher taking a wide-angle lens to gather data. Then, by sifting, sorting, reviewing and reflecting on the data, the salient features of the situation emerge. These are then used as the agenda for subsequent focusing. The process is akin to funnelling from the wide to the narrow. Miles and Huberman (1984) suggest that careful data display (e.g. in graphics and diagrams) is an important element of data reduction and selection.

On the other hand Gibbs (2007, p. 4) argues that qualitative data analysis, far from reducing data, actually increases its 'bulk, density and complexity' as it creates more texts such as notes, reflections, memos, summaries, reflexive insights and further notes in its attempt to generate thick descriptions, i.e. data which describe events in context plus participants' intentions, strategies and agency.

Geertz (1973, pp. 10–21) argues that thick descriptions include reflections on meanings attributed to situations and phenomena, turning a witnessed, momentary event into a written discourse which can be perused repeatedly and 'read' in different ways.

Qualitative data present several challenges. First, data are so rich that analysis involves selecting and ordering on the part of the researcher. As a result, this might involve some personal bias to which the researcher needs to be alert. Second, since the data obtained are all couched in 'social events', reporting involves a double *hermeneutic process* (Giddens, 1976) by which the researcher *interprets* the data from participants who have already interpreted their world, and then relates them to the audience in his/her own words. Further, the researcher is part of the world that he or she is researching. Hence the reporting and analysis should strive to catch the different definitions of the situation from the different participants, and to combine *etic* and *emic* analysis. *Emic* analysis focuses on the participants' own subjective interpretations and perceptions of the situation, whilst *etic* analysis focuses on objective analysis or external frameworks. The researcher's own analysis might be subject to criticism of lack of objectivity, though this can be attenuated by the researchers' reflexivity. Qualitative data analysis is often written in the first person, and with colloquial language rather than the conventional third person, passive voice and past tense used in much research.

In selecting, organizing, analysing, interpreting and reporting data and findings the researcher is faced with several decisions and issues. For example, there is a risk that, since data and interpretation are unavoidably combined, the subjective views of the researcher might lead to him or her being over-selective, unrepresentative and unfair to the situation in hand in the choice of data and the interpretation placed on them. Fact and interpretation are inseparable. As the post-positivists remind us, there is no theory-free observation, and the selection of which events and data to include are under the control of the researcher. Indeed as participants (including the researcher) act on the basis of their interpretations, those interpretations may, themselves, become facts in the situation, i.e. an interpretation can constitute a fact or data, and, in that constructed sense, the written accounts of them are themselves created interpretations (cf. Geertz, 1973, p. 14).

Ensuring validity and reliability in qualitative data analysis is challenging, as there may be few external points of appeal other than respondent validation. The researcher's choice of which data and events to include is almost inevitably personal, but this choice has to be fair to the phenomena under investigation and to the participants, and reflexivity is important here. This is echoed in the later edition of Whyte's (1993) Appendix A to his celebrated study of *Street Corner Society*, where he writes that:

> it seemed as if the academic world had imposed a conspiracy of silence regarding the personal experiences of field workers. … It was impossible to find realistic accounts that revealed the errors and confusions and the personal involvements that a field worker must experience. I decided to do my bit to fill this gap. In undertaking this task it seemed to me important to be as honest about myself as I could possibly be.
>
> (Whyte, 1993, pp. 358–9)

Further, he reports commentaries that the researcher:

> abandons any hope of establishing scientific conclusions, and speaks rather of 'rendering your account credible through rendering your person so'. … Ethnography takes … a rather introspective turn. To be a customary 'I-witness' one must, so it seems, first become a convincing 'I'. Ethnological writing thus comes to depend on persuasion of the reader. … I have come to recognize that the objective-subjective distinction is not as clear as I once thought. … We seek to observe behavior that is significant to our research purposes. Selection therefore depends upon some implicit or explicit theory – a process which is in large part subjective. But the choice is not random. If we specify our theoretical assumptions and the research methods we use, others can utilize the same assumptions and methods to either verify or challenge our conclusions.
>
> (Whyte, 1993, pp. 366–7)

Further, Whyte (p. 362) questions the practicality of, or necessity for, respondent validation, particularly if the researcher discovers something that might contradict or upset the values and practices of the group. There is 'the right of the researcher to publish conclusions and interpretations as he or she sees them' (p. 362). Respondent validation may be problematic as, for example, respondents:

- may change their minds as to what they wished to say, or meant, or meant to say but did not say, or wished to have included or made public;
- may have faulty memories and may have recalled events over-selectively, or incorrectly, or not at all;
- may disagree with the interpretations made by the researcher;
- may wish to withdraw comments made in light of subsequent events in their lives;
- may have said what they said in the heat of the moment or because of peer pressure or authority pressure;
- may feel embarrassed by, or nervous about, what they said.

If respondents are asked to validate the data, the data analysis and interpretation, then, as Gibbs (2007, p. 95) remarks, their responses become data. Respondents may wish to withdraw their comments, and they may be entitled to do this if informed consent was given for *all stages* of the research, but they may not be entitled to do this if the informed consent was given to participate in the research but not to alter the reporting, i.e. the researcher owns the data, once given. Respondents may wish to change them, or prevent their public disclosure. In these situations the researcher might wish to explore the reasons for this, which, in turn, can become part of the research.

Whilst many qualitative data derive from field notes, given the exigencies of the moment (the 'personal convenience' of the researcher (Hammersley and Atkinson, 1983, p. 173)) and the press for time, some of these may also use the researcher's own memory, and this might be fallible, selective and over-interpreting a situation (p. 172), i.e. 'there is no single correct way of retrieving the data for analysis' (p. 173).

Hence it is important not only to examine a situation and events through the eyes of the researcher, but also to use a range of data and to ensure that these data include the views of other participants in a situation, in order to give some 'externality' to the situation and to focus on actual things that happened which can be corroborated by other participants. The process is inductive and reflexive, yet true to the indicators and constructs of the interpretation made.

Hammersley and Atkinson (1983) indicate the importance of reflexivity in addressing validity and reliability in the analysis and writing-up of qualitative data (p. 173). They suggest that the qualitative data analysis itself becomes a text, i.e. a constructed interpretation, and that its organization, ordering, chronology chosen, selection of themes, and narrative style are subject to reflexivity (pp. 212–17). Hence, the validity of the selection, analysis and interpretation of events and the data included in analysis, whilst being inductively and reflexively chosen, and whilst being unavoidably personal and partly impressionistic, are not only that; they are also subject to the validity checks of having other participants' views included and a faithful record made of actual events which involve more than the single researcher.

Qualitative data can be analysed for their nomothetic properties (patterns and themes – both emergent and pre-ordinate – trends, commonalities, generalizations, similarities, laws of behaviour) and their idiographic properties (individual, unique events, people, behaviours, contexts, actions, intentions). Nomothetic approaches to data analysis are well represented in the work of Miles and Huberman (1994), whilst idiographic approaches are well represented in life histories, case studies, individual biographies, phenomenological research and narratives.

32.3 Ethics in qualitative data analysis

Qualitative data analysis frequently concerns individual cases and unique instances, and may involve personal and sensitive matters. This raises questions of identifiability, anonymity, confidentiality and privacy of individuals. Whilst numerical data can be aggregated so that individuals are not traceable, this may not be the case in qualitative data analysis, even if individuals are not named or are given pseudonyms. The researcher has an ethical obligation to address non-maleficence, loyalties (and to whom) and beneficence (see Chapter 7), and to ensure that the principle of *primum non nocere* is addressed: do no harm to participants. This may call for respondent validation and respondent clearance for what is included, which, in turn, places the researcher in a dilemma of whether to include material that has not been cleared or which participants indicate they do not wish to have included or with which they disagree (e.g. in the case of an interpretation).

Given that some qualitative data may be sensitive or personal, the researcher will need to consider not only who will perform any transcription, but also the ethical conditions (e.g. confidentiality) to which the transcriber must be subject. This extends to ensuring that data are kept securely, with appropriately restricted access, and researchers may need to check with software providers on the security of data and who has access.

Ethics here also engages issues of research integrity, consideration of the consequences of the research and its publication, ownership of the data and how it may be used, informed consent and disclosure.

We refer the reader to Chapters 7 and 8 of the present volume, in which ethical matters are discussed in detail.

32.4 Computer assisted qualitative data analysis (CAQDAS)

Software does not analyse material; humans do. Software, as Kelle (2004, p. 277), Gibbs *et al*. (2005) and Gibbs (2012) remark, organizes and structures data for subsequent analysis. Software processes material. There are many ways in which software can be utilized in supporting qualitative research: Computer Assisted Qualitative Data Analysis Software (CAQDAS) (Tesch, 1990; LeCompte and Preissle, 1993; Gibbs *et al*., 2005; Gibbs, 2007, 2012; Creswell, 2012; Denscombe, 2014; Marshall and Rossman, 2016; Paulus *et al*., 2017). As can be seen from the list below, its uses are diverse.

Bazeley and Jackson (2013) note that CAQDAS software (they refer to NVivo) is useful for managing data and ideas, querying and searching data, visualizing data and reporting from the data (p. 3). Data must be organized, managed, processed and stored, with easy access, and software is very useful for this. There are several CAQDAS packages for data processing (Flick, 2009, pp. 360–1; Lewins and Silver, 2009; Creswell, 2012; Gibbs, 2012; Marshall and Rossman, 2016; Paulus *et al*., 2017). From the early days of simple search and retrieval software, CAQDAS has developed into more powerful, flexible tools to help the researcher-as-analyst with all kinds of data, not only text-based. Software has several uses, for example:

- to organize data and files systematically, and to manage data files for a project/research, managing, storing and indexing data in an ordered and organized way, for example, by ascribing data to specific addresses and indexes (see Figure 32.1);
- to store data, notes and searches;
- to search and interrogate data and text;
- to make notes and edit, extend or revise them;
- to transcribe and annotate field notes and audio and visual data;
- to search and retrieve data from individual files or across data files, codes, notes, memos;
- to display data in different ways and to create visual data modelling and graphics;
- to display relationships of categories (e.g. hierarchical, temporal, relational, subsumptive, superordinate);
- to establish linkages between coding categories and to cross-check to see if data can be coded into more than one category, enabling linkages between categories and data to be discovered;
- to code data (i.e. words or very short phrases which describe the data in question, for later ordering, combining or retrieval) and to arrange codes into hierarchies (trees) and nodes (key codes), to enable preliminary coding of data to be undertaken, and to attach identification labels to units of text (e.g. questionnaire responses), so that subsequent sorting can be undertaken;
- to facilitate content analysis (e.g. frequencies of words, meanings, issues, themes, concepts, sequences, locations, people, etc.);
- to check data (e.g. proofread);
- to collate and segment data and make numerous copies of data;
- to enable memoing to take place, together with details of the circumstances in which the memos were written;

- to conduct a search for words or phrases in the data and to retrieve text;
- to annotate and append text to written, audio, graphic, image-based and visual data;
- to partition data into units which have been determined either by the researcher or in response to the natural language itself;
- to sort, re-sort, collate, classify and reclassify pieces of data to facilitate constant comparison and to refine schemas of classification;
- to code memos and bring them into the same schema of classification as that used for other data in the study;
- to assemble, re-assemble and recall data into categories;
- to undertake frequency counts (e.g. of words, phrases, codes);
- to establish the incidence of data that are contained in more than one category;
- to retrieve coded and noded data segments from subsets in order to compare and contrast data;
- to search for pieces of data which appear in a certain (e.g. chronological) sequence;
- to filter, assemble and relate data according to preferred criteria (e.g. words, codes, themes, issues, nodes);
- to link to external sources of data (e.g. Internet sites) at a single keystroke;
- to draw conclusions and to verify conclusions and hypotheses;
- to quote data in the final report;
- to generate and test theory;
- to export data into other formats/software;
- to communicate with other researchers or participants.

CAQDAS can import data files which contain text, graphics, audio, pictures, video (no sound), sound-and-video, numbers (e.g. Excel files) and which link to external sources such as Internet sites and other software (e.g. online survey websites) (see Figure 32.1); they can present data graphically in clusters, 'trees'

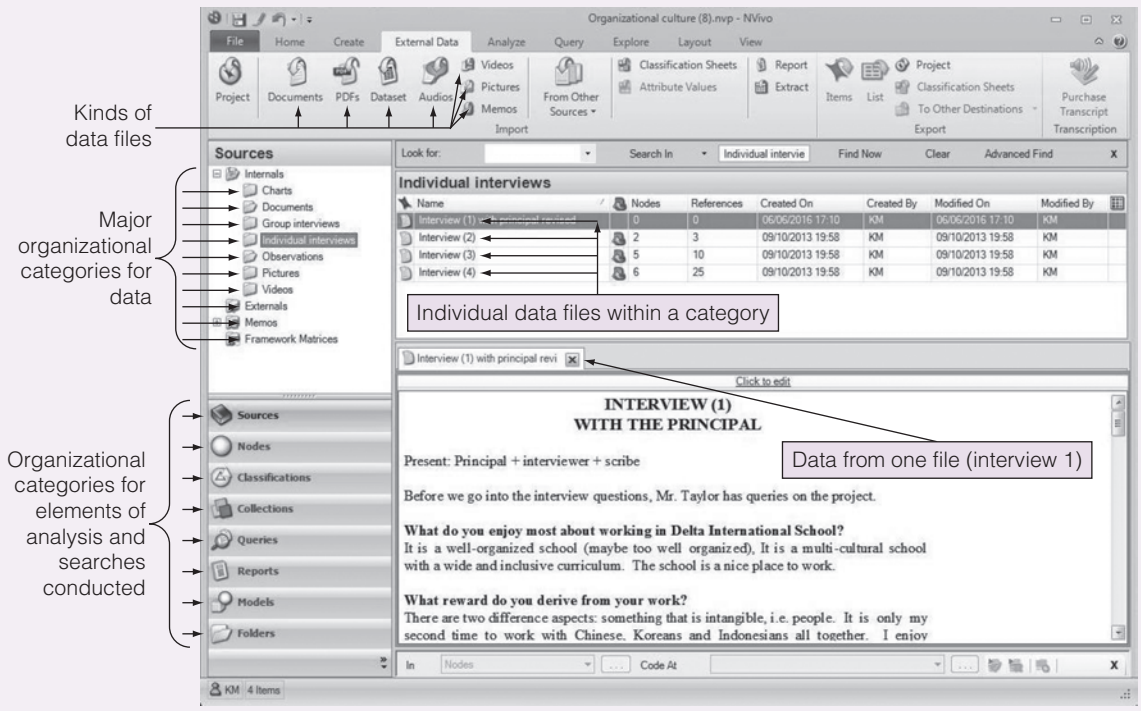

FIGURE 32.1 Organizing data in NVivo (Version 10)

Note

(hierarchies) and linkages, and they can assemble data from different sources.

Software for qualitative data analysis is useful for organizing data files. For example, in Figure 32.1, using NVivo, the data sources (see 'major organizational categories for data') have been set up by the researcher for a project on organizational culture, and are grouped as follows:

Internals: data files organized into categories and stored on the software for the project in question. The categories here are 'charts', 'documents', 'group interviews', 'individual interviews', 'observations', 'pictures', 'videos'. The top left of the screen in Figure 32.1 indicates the kinds of data files (documents, pdf files, data sets, audio, video, pictures and memos);
Externals: external website links that can be accessed for the project;
Memos: memos written by the researcher (Figure 32.2 lists these);
Framework Matrices: graphics of data presentation, with data alongside.

The lower left section of Figure 32.1 indicates where searches, queries, nodes, reports, models etc. prepared by the researcher are stored for ease of access and retrieval.

Figure 32.2 indicates the listing of memos in NVivo, and shows the text data for one of those memos (the memo entitled 'Observations on the pictures'), which is a memo on an observation of teachers' and senior managers' rooms in a secondary school. Figure 32.2 shows the actual contents of the memo (the text in the main central box of the screen shot), which can be stored along with the data file.

Many software programs enable the researcher to work with visual data, both still and moving images, and Figure 32.3 provides an example of annotating a photographic image of a teachers' working room in a secondary school. As with a text file, the image file here has the researcher's annotations stored along with the file. In Figure 32.3, working with NVivo, the researcher can see which part of the image is being referred to, as clicking onto the relevant row of annotated text also highlights that part of the image to

which reference is being made (this is not indicated in the figure).

CAQDAS software, then, can organize and store data in easily accessible and easily understood folders and files, and it can perform many other operations, for example:

- acting as a word processor (e.g. entering, editing and searching text);
- coding and retrieving many kinds of data (searching, summarizing, listing sequences of words, which enable data and texts to be split into smaller units and segments by relevant code and which list and organize and order codes and nodes). Coding data is part of a six-step sequence of data analysis (Kelle, 2000, p. 295): entering and formatting the text data; coding the data; memoing (with reference to specific segments of data); comparison of textual segments which have the same codes, to check for consistency; integrating the codes that have been generated, and memoing the codes; and developing the core category – a feature of grounded theory (see Chapter 37);
- managing data (e.g. searching, sorting and organizing);
- creating and presenting visual graphics such an networks of relationships;
- enabling theory building (e.g. through coding and the categorization and classification of codes and taxonomies to enable relations and superordinate and subordinate categories to be constructed);
- enabling conceptual networks to be plotted and visualized (graphic functions).

Which software one uses depends on the questions one wishes to ask of the data, the kinds of data one has, what one wishes to do with the data, the processes of analysis one wishes to conduct, the technical requirements of the software, the competence level of the researcher/user of the software, costs and the level of detailed required in the analysis.

Software is particularly effective at coping with the often-encountered problem of data overload and retrieval in qualitative research. Software enables the researcher to use codes, memos, hypertext systems, selective retrieval and co-occurring codes, and to perform quantitative counts of qualitative data types. In turn this enables linkages of elements to be created and networks to be built, and, ultimately, theory generation to be under-

taken. Software can assist in the generation of grounded theory through coding, constant comparison, linkages, memoing, annotations and appending, use of diagrams, verification and, ultimately, theory building. For a full discussion of coding and grounded theory we refer the reader to Chapters 34 and 37 respectively.

Kelle and Laurie (1995, p. 27) suggest that computer-aided methods can enhance: (a) validity (by the management of samples and data), and (b) reliability (by retrieving all the data on a given topic, thereby ensuring trustworthiness of the data) without losing contextual factors (cf. Gibbs, 2007, p. 106). An important feature here is the speed of organized and systematic data collation and retrieval; though data entry is time consuming, software can subsequently process and retrieve data rapidly.

There are several computer packages for processing qualitative data, for example: Anvil; AQUAD; ATLAS.ti; C-I-SAID; Dedoose; Diction; ELAN; ETHNOGRAPH; HyperRESEARCH; Kwaliton; Linguistic Inquiry; MAXQDA; NVivo; Qualrus; Quirkos; Transana. Widely used software is NVivo, ATLAS.ti and MAXQDA, though fitness for purpose is the key decision in deciding which software to use. We provide the websites of software packages and their evaluation in the companion website to this chapter, and Lewins and Silver (2009) also provide a guide on selecting software.

Gibbs (2007, 2012) focuses on three widely used packages: NVivo, MAXQDA and ATLAS.ti; Paulus *et al*. (2017) focus on NVivo and ATLAS.ti. These, like other software packages, share common features such as the ability to: (a) import, work with and display rich texts and multi-media material; (b) code text into key codes (nodes) and arrange codes and nodes into hierarchies and clusters; (c) sort, combine and retrieve text and data using different combinations and search strings/terms; (d) work with original documents/files using codes or combine selected extracts from documents/files using codes; (e) annotate, add memos, comments or additional documents to existing data files and documents; (f) sort material using codes; and (g) work with different kinds of data (textual, audio, images, videos, numbers, graphs, etc.). Additionally these programs can cope with large quantities of data rapidly and without any risk of human error in computation and retrieval, and they also release researchers from many mechanical tasks. With respect to words, phrases, codes, nodes and categories they can:

- search for and return data, text, terms, codes, nodes and categories, singly or in combination;
- filter text and data;
- return counts;
- present grouped data according to the selection criterion desired, both within and across data files;
- perform the qualitative equivalent of statistical analyses, such as:
  - Boolean searches (intersections of text which have been coded by more than one code or node, using ‘and’, ‘not’ and ‘or’, looking for overlaps and co-occurrences)
  - proximity searches (looking at clustering of data and related contextual data either side of, or near to, or preceding, or following, a node or code);
  - restrictions, trees, crosstabs (including and excluding documents for searching, looking for codes subsumed by a particular node, and looking for nodes which subsume others);
- construct dendrograms (tree structures) of related nodes and codes;
- present data in sequences and locate the text in surrounding material in order to provide the necessary context;
- locate and return similar passages of text or material (e.g. audio-visual);
- look for negative cases;
- look for terms in context (lexical searching);
- select text on combined criteria (e.g. joint occurrences, collocations);
- enable analyses of similarities, differences and relationships between texts and passages of text;
- annotate text and enable memos to be written about text.

Additionally, dictionaries and concordances of terms can be employed to facilitate coding, searching, retrieval and presentation.

Computer software can be particularly useful for searching, retrieving and grouping text, both in terms of specific words and in terms of words with similar meanings. Single words and word counts can overlook the importance of context, hence computer software packages have been developed that present Key-Words-In-Context. Most software packages have advanced functions for memoing, i.e. writing commentaries to accompany text that are not part of the original text but which may or may not be marked as material incorporated into the textual analysis. Software packages for qualitative data analysis typically include an annotation function, so that the researcher can annotate and append text, and the annotation is kept in the text but marked as an annotation.

CAQDAS does not do away with ‘the human touch’, as humans need to decide and generate the codes and categories, to verify and interpret the data; the software does

not generate the codes automatically. Similarly 'there are strict limits to algorithmic interpretations of texts' (Kelle, 2004, p. 277), as texts contain more than that which can be examined mechanistically and the software does not always suit the range and richness of analytic techniques associated with qualitative research (p. 283).

Woods *et al*. (2016) note that reflexivity remains a key feature of qualitative data analysis with software, and that this extends to consideration of the impact and influence of the software on the action, judgements and analysis conducted by researchers. Researchers cannot be unthinking software operatives, dredging for any information simply because software processes data, nor are they slaves to the software. On the one hand, CAQDAS can undermine reflexivity because: (a) the software does not compel researchers to adopt a particular philosophical position; (b) researchers can use the software relatively unthinkingly, without due reflection and without considering the acceptability of the values implicit in the software approach; (c) researchers can be forced in to a coding approach; and (d) CAQDAS can over-simplify complex issues (p. 393).

On the other hand, Woods *et al*. (2016) write that CAQDAS can encourage reflexivity if researchers think carefully about how the software might steer or influence their data preparation and analytical approaches, how it can improve and clarify their data analysis through otherwise difficult approaches (e.g. modelling and matrix construction). They also note that it can prompt analysis of data with which the researcher may be unfamiliar (e.g. visual data), i.e. it can develop new analytical skills in researchers, prompt them to see how to make appropriate use of these skills, and promote confidence in their analyses. Researchers using CAQDAS, just as those who do not, must be reflexive, and CAQDAS, like other approaches, can stimulate or inhibit reflexivity, depending on the user and his/her conscious decision making (p. 398).

Richards (2002) remarks on the tendency of some software packages to focus on 'code and retrieve' techniques (p. 266), with the risk that software encourages researchers to opt for coding and patterning to the neglect of more complex interrogation of texts (p. 269). Indeed, many researchers do not wish to use coding techniques with their qualitative data but are more concerned to review their texts iteratively (p. 270). Kelle (2004), Flick (2009) and Gibbs (2012) argue that software may be more closely aligned to the technique of grounded theory than to other techniques (e.g. hermeneutics, discourse analysis), that it may drive the analysis rather than *vice versa* (cf. Crowley *et al.*, 2002), and that it has a preoccupation with coding categories. Bazeley and Jackson (2013) note that CAQDAS: raises fears (some unfounded) that software use: 'can distance researchers from their data' (p. 7); privileges code and retrieve methods over other analytic strategies; renders analysis mechanistic and more positivist; and supports grounded theory approaches over other equally valid approaches (p. 7).

Gibbs (2012) and Gläser and Laudel (2013) raise the concern that if too great an emphasis is placed on coding and its applications then some important context may be stripped out of the data when they are assembled by codes alone. Gibbs (2007, 2012) reminds researchers that the use of software is only as good as the codes that have been used and the care taken with coding data, i.e. if poor codes or poor coding have been used and undertaken respectively (e.g. inconsistent coding, or coding that overlooks some text, or miscoding, or using a different code for the same kind or meaning of data) then poor results are likely to ensue (i.e. a problem of reliability). This applies similarly to searching codes, terms or combinations that have been undertaken.

Further, Flick (2009, p. 370) worries that the practicalities of data entry, coding and retrieval with software might distract researchers from the 'real' task of hermeneutically understanding, thinking about and explaining the meanings of the research and the texts. Indeed Taylor and Gibbs (2010) note that coding may be unsuitable for discourse analysis and narrative analysis (see also Chapter 35 here).

However, Bazeley and Jackson (2013) aver that these common criticisms misrepresent recent CAQDAS, as software is much more flexible than such criticisms suggest; it can remove the drudgery of some elements of qualitative data analysis without removing the creativity involved in it (p. 9) and, indeed, software does much more than simply code and retrieve. Indeed, Kelle (1997, para. 3.2) notes that ETHNOGRAPH is rooted in ethnographic and phenomenological research, that MAXQDA has its roots in Weberian 'ideal types' and AQUAD has its roots in Popperian methodology. Similarly Woods *et al*. (2016) note that ATLAS.ti was originally developed to support a grounded theory approach to data analysis.

Despite these answers to criticisms, software for qualitative data analysis does not give the same added value as that which one finds in quantitative data-analysis software (which automatically yields statistics), and textual or data input is a laborious process (Flick, 2009, p. 359). The 'added value' of CAQDAS software packages may not be as great as their statistical counterparts, for they require a significant amount of time and effort in preparing and entering transcribed and other word data and other kinds of data, which the software helps to search, organize, store, retrieve, link and collate. For statistical packages (e.g. SPSS) the

return on effort is much greater, as the software gives test results that do not have their simple equivalent in qualitative data-analysis software.

García-Horta and Guerra-Ramos (2009, p. 152) argue that qualitative software is no substitute for the requirement and capability of the researcher to 'assign meaning, identify similarities and differences, establish relations' between data. Indeed they suggest that, whilst software for qualitative data analysis might be useful for working with structure, software packages cannot currently handle the making of meaning, interpreting data, working out categories, making decisions on coding and interpreting the outcomes of analysis and processing (p. 153). However, advances have been on some fronts, for example in software for natural language processing (Crowston *et al*., 2012), and Paulus and Lester (2016) indicate how ATLAS.ti can be used for conversational and discourse analysis.

Paulus *et al*. (2017) suggest that, in reporting qualitative data analysis, researchers should move beyond conventional statements such as 'data were processed with NVivo' or 'coding and thematic analysis were undertaken with ATLAS.i' to include more information on how, exactly, the software was used and the steps that were taken in conducting the analysis with the software. This could include, for example, providing concrete details on:

- creating and storing text and other data;
- the sequence of the analysis using the software, and the key features of each step taken;
- annotating text;
- coding text and data;
- memo writing;
- linking data;
- creating themes;
- creating 'families' of data and data types, files, memos;
- merging data files;
- linking data to coding, memos, annotations etc.;
- creating visual graphics, hierarchies, networks, models, matrices, clustering, Boolean searches;
- exploring relationships;
- searching and retrieving material, for example, by quotations, words, texts, codes in single files and across files;
- conducting 'query' searches of data, for example, text searches, word frequency counts, coding, matrix coding;
- organizing and managing data;
- categorizing data;
- handling large-scale data (e.g. data reduction and display);
- indicating how the analysis was conducted with the software (e.g. narrative analysis, grounded theory approaches; searching for conceptual similarities and differences; locating quotes; word frequency counts);
- advantages and dangers of using the software (i.e. reflexivity);
- ensuring comprehensive and exhaustive data inclusion and usage;
- reflexivity and transparency;
- addressing reliability, validity, dependability, transferability and confirmability of the findings.

Paulus and Lester (2016) and Paulus *et al*. (2017) report how researchers using ATLAS.ti were able to document their decision making with regard to data analysis, demonstrating transparency, reflexivity, systematization and rigour. They also argue that it is preferable to use the active rather than the passive voice in writing up the analysis and findings, in order to avoid giving the impression that it was the software driving the analysis, rather than the researcher.

There are many websites that contain useful materials on qualitative data analysis and we identify these in the companion website for this chapter. Many of these provide links to a host of other websites providing guidance and resources for qualitative data analysis.

CAQDAS has moved great distances from simply searching and retrieving, and, as Paulus and Lester (2016) note, many of the criticisms of CAQDAS are based on outdated or incomplete understanding of what it can do and what is its potential for qualitative data analysis in a variety of traditions and approaches.

Companion Website

The companion website to the book provides data files and PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections and a full set of word-based data files specifically prepared for NVivo, concerning a single project on assessment and testing (these have also been saved into Word documents). This resource can be found online at: **www.routledge.com/cw/cohen**.

Organizing and presenting qualitative data

CHAPTER 33

There are several ways in which qualitative data can be organized and presented. In this chapter we introduce some important, useful and widely used ways. These address several issues, including:

- tabulating data
- ten ways of organizing and presenting data analysis
- narrative and biographical approaches to data analysis
- systematic approaches to data analysis
- methodological tools for analysing qualitative data

We provide several worked examples here, for clarification. It is important for the researcher to index and provide a record of the provenance of the data, i.e. to record the dates, context, time, participants, researcher, location and so on, so that the setting for the data, and indeed their chronology, can be determined – the latter being useful in charting how situations emerge, evolve, change, lead to other situations, how networks emerge and how causality might be established. We outline several examples of data analysis and presentation in this chapter and the next.

33.1 Tabulating data

Tables are useful for data reduction and data display – key elements of qualitative data analysis as mentioned in Chapter 32 (Miles and Huberman, 1984, 1994). The following example illustrates simple summary and clear, tabulated data presentation and commentary. It derives from a doctoral thesis.

Example: Chinese children learning English – an example of analysing and presenting interview data

Here interview data are presented question by question. In what follows, where the data for respondents in each age phase are similar, they are grouped into a single set of responses by row; where there are dissimilar responses they are kept separate (Tables 33.1 to 33.4). The left-hand column in each table indicates the number of each participant in the research (1–12) and the level which the participant taught (e.g. P1, F3 etc.), so, for example, '1–3: P1' means the responses of participants 1–3, who taught Primary 1 classes; the right-hand column indicates the responses. In many cases, as can be seen, participants *all* gave similar responses in terms of the actual items mentioned and the coverage of items specified. A brief summary comment is provided after each table.

The data concern problems that school children experience in learning English in China. The data set reproduced is incomplete and has been selected for illustrative purposes only. Note that the data are not *verbatim*, but have already been summarized by the researcher, i.e. what is presented here is not the first stage of the data analysis, as the first stage was transcription.

The coding is as follows:

P1–P6 = Primary forms (1–6): P1 = year 1, P2 = year 2, etc.

F = Secondary forms (1–5): F1 = Form 1 (first year of secondary school), F2 = Form 2 (second year of secondary school, etc.)

The numbers preceding each letter in the left-hand column of these tables refers to the number ascribed to the teacher. There were twelve teachers in all, six from primary schools and six from secondary schools.

Table 33.1 indicates that English teaching and learning at school have not really achieved their intended purposes. Students: (a) are poor at understanding written or spoken English, speaking, reading, listening and writing; (b) have limited abilities in English, regardless of the number of years of learning it; (c) use low-level memorization which leads to superficial learning; (d) experience poor teaching and learning; (e) can enter university, even though their standard is poor, as there are many universities taking students; (f) do not require English to gain employment.

Comment: The Primary English teachers had a wider range of views than the Secondary teachers; there was greater unanimity between the Primary teachers in

TABLE 33.1 THE EFFECTIVENESS OF ENGLISH TEACHING

Q6: The effectiveness of English teaching

1–3: P1	■ Students neither understood written or spoken English nor were able to speak or write very well. ■ Though students started learning English at a very young age, their standard was still very low as they could not really understand or use English.
4–6: P6	■ Students could not speak, read or write English well. ■ Students had a low standard as they could not read, write or speak English. ■ They used memorization to learn and thus the English knowledge was very superficial and confined to limited vocabulary.
7–9: F3	■ On the whole, students' standard was low. English teaching and learning was not very successful. ■ Even with a poor knowledge of English students still managed to get jobs. ■ This was not an international city; English was not really that important even if students did not learn well.
10: F5	English teaching and learning were not very effective as students were not working hard and they resorted to memorization to learn English. However, students managed to get into universities.
11: F5	Students had learned at least some basic knowledge about English.
12: F5	It was effective to some extent as some students became English teachers themselves, having finished their university education.

comparison to the Secondary teachers; all the Form 3 Secondary teachers were unanimous in their comments; and all the Form 5 secondary teachers had different views.

Table 33.2 indicates that the strengths of English teaching were that: (a) students start to learn English very young; (b) schools had autonomy over the design of syllabuses. The weaknesses in English teaching were that: (a) insufficient emphasis was placed on understanding; (b) students were too young to learn English; (c) syllabuses were unrealistic in their demands, being too rich, leading teachers to a 'spoon-feeding' mentality in their teaching; (d) undue pressure was put on teachers and students because of the demands of the syllabus; (e) English had to compete with other languages for curriculum space. Hence students did not learn well, despite years of English lessons.

Comment: Apart from one Primary teacher, the other eleven teachers, drawn from both primary and secondary schools, were unanimous in the comments they gave.

Table 33.3 indicates that high class size (between thirty and fifty students, rising to sixty) and tight syllabuses exerted a significant impact on teaching methods and restrictions of class activities, because of class management issues. The nature of this influence was to adopt largely didactic and grammar-translation methods, with little extended recourse to using or 'thinking in' English. Teaching utilized some group activity, but this was very limited. Teachers used Chinese to explain English.

TABLE 33.2 THE STRENGTHS AND WEAKNESSES OF ENGLISH LANGUAGE TEACHING

Q7: Strengths and weaknesses of English language teaching

1: P1	Students started learning English at a very young age and they should be good at it. However, this could also be a disadvantage as students were too young to learn English and to understand what they were taught
2–6: P6 7–9: F3 10–12: F5	These respondents all commented that individual schools had great autonomy over syllabus design. Consequently, some syllabus contents were too rich to be covered within the limited time span. Therefore, it was hard to make adjustments, though students could not cope with the learning requirements. This put pressure on both teachers and students. Worse still, some schools made students learn other foreign languages apart from English, and that made the learning of English more difficult.

TABLE 33.3 TEACHING METHODS

Q9: Teaching methods

1–3: P1 4–6: P6 7–9: F3 10–12: F5	■ All respondents replied that teaching was mostly conducted on a didactic approach though they utilized visual aids and group activities to arouse students' interest, as they had a very tight syllabus to cover within the fixed number of periods. This method also gave them more control over the class, which was necessary as classes were usually big, between 30–50 and could rise to 60. ■ Whenever these teachers taught grammar, they relied heavily on the grammar-translation method. They used mostly Chinese (could be as much as 80%) to explain grammar, as that would make it easier for students to understand the explanation.

Comment: All the teachers here were unanimous in their comments, which fell mainly into two sets of points.

Table 33.4 indicates that students contributed significantly to their own success or failure in learning English. They: (a) were shy, afraid of making mistakes and of losing face; (b) had little interest in learning at all, let alone English; (c) were overloaded with other subjects, a situation exacerbated by their poor time management; (d) held negative attitudes towards the bookish nature of learning English and its unrelatedness to other curriculum subjects; (e) had too many other distractions; (f) had limited abilities in English; (g) had little incentive to learn fast, as they could repeat courses; (h) gave little priority to English; (i) had poor foundations for learning English; (j) had limited motivation or positive attitudes to learning English; (k) were given limited direction in their learning; (l) had limited incentive to learn English well, as universities required only a low standard of English.

Comment: There was a great variety of comments here. There were degrees of agreement: the teachers of the younger Primary children agreed with each other; the teachers of the older Primary children agreed, as did the teachers of the older Secondary children. The teachers of the younger Secondary children raised different points from each other. The four groups of teachers (younger Primary, older Primary, younger Secondary and older Secondary) raised different points from each other.

TABLE 33.4 STUDENT-RELATED FACTORS

Q11: Student-related factors

1–3: P1 4–6: P6	■ Students were shy and were afraid of 'losing face' when they made mistakes in front of the class. ■ Students basically had no interest in learning anything, especially a foreign language. ■ Students had too many subjects to learn, and learning English was too bookish. ■ There were too many other distractions such as surfing the Internet or going out with friends.
7: F3	■ Students could not relate learning English to other things they learned at school, so they had no interest. ■ Students' language learning ability was poor and they feared learning English. ■ Students were allowed to repeat programs, so they could become lazy and indifferent.
8: F3	■ Students spent too much time surfing the Net. ■ Students put more time into science rather than language subjects.
9: F3	■ Students' foundation was weak.
10–12: F5	■ Students lacked enthusiasm and 'proper' learning attitudes. ■ Students had poor time management. ■ Students were afraid of 'losing face' when they made mistakes in front of the class. They were shy as well. ■ Students had no direction in their learning and they had no plan for their future. Therefore, they did not learn well, especially a foreign language. ■ Students had many opportunities to enter universities, despite having a low standard of English.

For an example of the layout of tabulated word-based data and supporting analysis see the accompanying website.

Summary of the interview data

The issues that emerge from the interview data are striking in several ways. What characterizes the data is the widespread agreement of the respondents on the issues, for example:

1. There was absolute unanimity in the responses to questions 7 and 9.
2. There was very considerable, though not absolute, unanimity on question 11.
3. In addition to the unanimity observed in point (1), there was additional unanimity amongst the primary teachers in respect of question 11.
4. In addition to the considerable, though not absolute, unanimity observed in point (2), there was much unanimity amongst the primary teachers concerning question 6.

Such a degree of unanimity gives considerable power to the results, even though, because of the sampling used, they cannot be said to be representative of the wider population. However, the sample of experienced teachers was deliberately selected to provide an informed overview of key issues to be faced. It must be remembered that, though the unanimity is useful, the main purpose of the interview data was to identify key issues, regardless of unanimity, convergence or frequency of mention. The respondents articulated similar issues, however, and this signals that these may be important elements.

Further, the issues themselves are seen to lie in a huge diversity of fields, such that there is no single or simplistic set of problems or solutions. Hence, to complement the considerable unanimity of voice is a similar consensus in identifying the scope of the problem, yet the range of problems is vast. Both singly and together, the issues of English-language teaching, learning and achievement are complex. The messages are clear in respect of Form 5 students and their English teaching and learning:

i. English performance is weak in all its aspects – reading, writing, speaking, and listening – but it is particularly weak in speaking and writing.
ii. Local cultural factors exert an influence on learning English:
    - students do not wish to lose face in public (and the Chinese emphasis on gaining and maintaining face is powerful);
    - students are shy and afraid of making mistakes;
    - the pressure of examination success is universal and severe;
    - the local culture is not English; it is Chinese and there is little need for people to speak or use English.
iii. In some quarters, knowledge of English culture is seen to be an important element in learning English; this was refuted by the teachers in this sample.
iv. English is seen instrumentally, but this message has to be qualified, as many students gain employment and university entrance even though their English is weak. The fact that English is an international language has limited effect on student motivation or achievement.
v. Poor teaching and learning are significant contributors to poor performance, in several areas:
    - the emphasis on drill, rote learning and memorization;
    - the predominance of passive rather than active learning, with teaching as the delivery of facts rather than the promotion of learning and understanding;
    - the use of traditional didactic methods;
    - the reliance on a very limited range of teaching and learning styles;
    - the limited subject and pedagogical knowledge of English teachers, compounded by the lack of adequate initial and post-initial teacher education;
    - frequently the careful laying of foundations of English teaching and learning is absent;
    - students use so much Chinese during English lessons that they have little chance to think in English – they translate rather than think in English.

From the interview data it can be seen that the size of the problems and issues to be faced in English language teaching and learning is vast.

In this example, tables are carefully laid out to draw together similar sets of responses. The tables enable the researcher to see, at a glance, where similarities and differences lie between the two groups of respondents. Note also that after each table there is a summary of the main points to which the researcher draws attention, and that these comprise both substantive and overall comments (e.g. on the topic in hand and on the similarities and differences between the groups of respondents respectively). Finally, note that an overall summary of 'key messages' is provided at the end of all the tables and their commentaries. This is a very

abridged and selective example, and justice has not been done to the whole of the data that the original researcher used. Nevertheless the point clearly illustrates here that summarizing and presenting data in tabular form can address twin issues of qualitative research: data reduction through careful data display and commentary.

33.2 Ten ways of organizing and presenting data analysis

Organizing and presenting data (e.g. data display) are key issues in qualitative data analysis. Here we present ten ways of organizing and presenting analysis: the first two methods are by *people*, the next two are by *issue* or *theme*, the fifth is by *instrument*, the sixth is by *case studies*, the seventh is by *narrative account(s)*, the eighth is by *events*, whilst the ninth keeps these events and puts them in a chronology, by *time sequence* and *time frame*. The final method is by *theoretical perspectives*, enabling the researcher to gain some theoretical purchase on the phenomena under investigation.

In analysing qualitative data, a major tension may arise from using contrasting holistic and fragmentary/atomistic modes of analysis. The example above, of teaching English in China, is clearly atomistic, breaking down the analysis into smaller sections and units. It could be argued that this violates the wholeness of the respondents' evidence, and there is some truth to this, though one has to ask whether this is a problem or not. Sectionalizing and fragmenting the analysis can make for easy reading. On the other hand, holistic approaches to qualitative data presentation can catch the wholeness of individuals and groups, and this can lead to a more narrative, almost case study or story style of reporting, with issues emerging as they arise during the narrative. Neither approach is better than the other; researchers need to decide how to present data with respect to their aims and intended readership. The approaches outlined below address both holistic and atomistic approaches to qualitative data analysis.

In presenting the qualitative data analysis, researchers can utilize graphics, tables, matrices and clustering (e.g. Marshall and Rossman, 2016). However, these are presentational devices rather than analytical devices. The methods set out below deliberately indicate alternatives to coding; there is a risk that qualitative data analysts almost automatically turn to coding, but, as we indicate in Chapters 34 to 37, coding is only useful when it is fit for purpose, and there are many instances where it is an encumbrance and not fit for purpose in qualitative data analysis.

1 Organizing, analysing and presenting data by groups of people

In the example of teaching English above, the data were organized and presented by respondents, in response to particular issues. Where the respondents said the same, they were organized by groups of respondents in relation to a given issue. The groups of respondents were also organized by their membership of different strata in a stratified sample – teachers of: younger primary children, older primary children, younger secondary children and older secondary children. This is *one* way of organizing a qualitative data analysis: by *groups*. The advantage of this method is that it groups the data and enables themes, patterns and similar to be seen at a glance. Whilst this is a useful method for summarizing similar responses, the collective responses of an individual participant are dispersed across many categories and groups of people, and the integrity and coherence of the individual respondent risks being lost to a collective summary. Further, this method is often used in relation to a single-instrument approach, otherwise it becomes unwieldy (e.g. trying to put together the data derived from qualitative questionnaires, interviews and observations could be very cumbersome in this approach). So, researchers may find it helpful to use this approach instrument by instrument.

2 Organizing, analysing and presenting data by individual people

Here the total responses of a single participant are presented, and then the analysis moves on to the next individual. This preserves the coherence and integrity of the individual's response and enables a whole picture of that person to be presented, which may be important for the researcher. On the other hand, unless researchers are only interested in individual responses, it often requires them then to put together the issues arising *across* the individuals (a second level of analysis) in order to look for themes, shared responses, patterns of response, agreement and disagreement, to compare individuals and issues that each of them has raised, i.e. to summarize the data.

Different participants in a situation may have different perspectives on that situation. This method preserves the integrity of each person's perspective on that situation, and this can enable the researcher to find similarities and differences between them. For example, in a piece of curriculum innovation the school principal may support it, the subject head may support it, but the front-line teacher may disagree with it (too much work for little benefit), and the parent representative may be worried about it (e.g. will the students'

performance suffer?). This method enables these different views to be kept intact and attached to key players in the situation.

Whilst approaches that are concerned with people strive to be faithful to those involved, in terms of the completeness of the picture of them *qua* people, unless case study approaches are deemed to be driving the research, they are usually accompanied by a second round of analysis, which is of the issues that arise from the people, and it is to the matter of issues that we turn now.

3 Organizing, analysing and presenting data by issues or themes

Whilst this method is economical in making comparisons across respondents (the issue of data reduction through careful data display, mentioned earlier), again the wholeness, coherence and integrity of each individual respondent is lost.

The derivation of the issue/theme for which data are gathered needs to be clarified. For example, it could be that the issue has been decided *pre-ordinately*, in advance of the data collection. Then all the relevant data for that issue are simply collected together into that single basket: the issue in question. Whilst this is an economical approach to handling, summarizing and presenting data, it raises three main concerns:

- the integrity and wholeness of each individual can be lost, such that comparisons across the whole picture from each individual is almost impossible;
- the data can become decontextualized. This may occur in two ways: first in terms of their place in the emerging sequence and content of the research, the interview or the questionnaire (e.g. some data may require an understanding of what preceded a particular comment or set of comments); and second in terms of the overall picture of the relatedness of the issues, as this approach can fragment the data into relatively discrete chunks, thereby losing their interconnectedness and internal coherence;
- having had its framework and areas of interest decided pre-ordinately, the analysis may be unresponsive to additional relevant factors that could emerge *responsively* in the data. It is akin to lowering a magnet onto data: the magnet picks up relevant data for the issue in question but it also leaves behind data not deemed relevant, and these data risk being lost. The researcher, therefore, has to trawl the residual data to see if there are other important issues that have emerged which have not been caught in the pre-ordinate selection of categories and issues for attention.

The researcher, therefore, has to be mindful of the strengths and weaknesses not only of pre-ordinate categorization (and, by implication, include responsive categorization), but must also decide whether it is or is not important to consider the whole set of responses of an individual, i.e. to decide whether the data analysis is driven by people/respondents or by issues.

4 Organizing, analysing and presenting data by research question

This is a very useful way of organizing data, as it draws together all the relevant data for the exact issue of concern to the researcher, and preserves the coherence of the material. It returns the reader to the driving concerns of the research, thereby 'closing the loop' on the research questions that, in many kinds of research, drive the inquiry. In this approach all the relevant data from various data streams (interviews, observations, questionnaires etc.) are collated to provide a collective answer to a research question. There is usually a degree of systematization here, in that, for example, the numerical data for a particular research question will be presented, followed by the qualitative data, or *vice versa*. This enables patterns, relationships, comparisons and qualifications across data types to be explored conveniently and clearly.

This approach is self-evidently limited to those kinds of research which have clear research questions. Some kinds of qualitative research, for example, ethnography and phenomenography, may not have such precise research questions, in which case this approach may be unsuitable.

5 Organizing, analysing and presenting data by data-collection instrument

This approach is often used in conjunction with another approach, for example, by issue or by people. Here the data from each instrument are presented, for example, all the interview data are presented and organized, then all the questionnaire data are presented, followed by all the documentary data and field notes, and so on. Whilst this approach retains fidelity to the coherence and integrity of the instrument and enables the reader to see clearly which data derive from which instrument, the instrument is often only a means to an end and further analysis will be required to analyse the *content* of the responses, for example, by issue and by people. Hence if it is important to know from which instrument the data are derived then this is a useful method; however, if that is not important then this could be adding an unnecessary level of analysis to the data. Further, connections between data could be lost if the data are presented instrument by instrument rather than across instruments.

6 Organizing, analysing and presenting data by case study or studies

Here organizing and writing up qualitative data is by one or more (e.g. a series of) case studies, or by combining case studies into an overall study that sets out common and singular features and properties of the cases (see also Miles and Huberman (1994) on within site and cross-site analysis). A series of individual case studies can be followed by an analysis that draws together common findings from the different case studies and also indicates the exclusive features of each. The researcher can also identify common themes in and across the case studies. Alternatively, if a theme has been decided in advance (pre-ordinately) or indeed responsively when reading through all the case studies (see content analysis and coding, discussed in Chapters 34 to 37), then materials from case studies can be used selectively to illustrate specific themes, whilst adhering to the principle of fidelity to the case in question. Whilst this approach keeps the richness of the data, it may not solve the common problem of data and detail overload, as each case study inevitably requires detailed reporting in order to be faithful to the detail of the context, person, causality etc.

The six methods above suggest a degree of systematization and coherence in analysing and presenting data. However, such coherence may not always obtain; life is messy and full of internal contradictions. Further, each situation can sustain multiple interpretations and perspectives, and participants in social situations may have differing views that are not susceptible to easy organization or singular, reductionist analysis. Methods 7 and 8 below can be used when such coherence and reductionism neither obtains nor is important, or, if it is important, in the interests of being faithful to the phenomenon and participants, to retain rich detail.

7 Organizing, analysing and presenting data by narrative(s)

This way of organizing the analysis is by constructing a narrative that may be in the form of a chronology, a logical analysis, a thematic analysis and a story or series of 'stories' from the research findings.

The celebrated work of Goffman (1963, 1968, 1969) provides outstanding examples of this approach. For example, his work *Asylums* (1968) provides narrative accounts of perspectives and lived experiences of patients and staff at a psychiatric hospital. The narratives of these two groups are markedly different, very rich in detail and succeed in catching the different perspectives of the participants. There are no coding, categorization, theoretical saturation, core category or other commonly advocated tools for qualitative data analysis (see Chapters 34 to 37), but the narrative accounts that he provides give readers insights into the lives and minds of participants that may not be yielded by more contrived approaches to qualitative data analysis. They catch multiple meanings and multiple stories that other approaches may not. We return to the work of Goffman in Chapter 35.

8 Organizing, analysing and presenting data by event

Here the *events* may or may not be in a time series. It goes almost without saying that the researcher must decide and disclose the criteria used to make the selection of the events. For example this may be in terms of critical incidents (Tripp, 1993, 1994), for example, those incidents which constitute a turning point in the lives of teachers, students, teaching, schooling etc. The event may be something as routine as a staff meeting, a parents' evening or an educational visit. Alternatively it might be something less common such as the decision to bring in a major curriculum reform or to change the assessment system.

The event in question may be a planned or an unplanned event, a typical or atypical incident, something which interrupts or reproduces the existing situation, a problem or a solution, a positive or negative event, a particularly meaningful or significant event for particular people, an event that expands our horizons or diminishes them, opens our minds or closes them and so on. The event may only become significant in retrospect, and this requires the researcher to be reflective and/or to catch the reflections of participants. Different people have different views of an event, and it may be useful to report such differing views.

9 Organizing, analysing and presenting data by time sequence and time frame

Here the researcher decides and justifies the appropriate overall time frame and the duration of each segment of time. This may lead to reporting an emerging narrative. The researcher may decide to have a standard unit of analysis, for example, a week, a month, half a term, a semester, a school year, or a flexible, mutable unit of analysis, changing to suit the events, which may link to the previous method – organizing, analysing and presenting the data by event. By having a fixed unit of analysis, for example, a week, a month, half a term, a semester, a school year, the researcher can see, for example, time when events were happening swiftly or slowly, whether much was happening or little was happening, whether there were periods of development, consolidation or stagnation. Importantly, organizing,

analysing and presenting data by time sequence and time frame can enable the researcher to address causality: cause and consequence.

10 Organizing, analysing and presenting data by theoretical perspectives

In this approach the researcher uses different theoretical lenses to examine and report on phenomena and emerging situations. For example, changes in the management of schools may be examined through the lenses of neo-liberalist market reforms, rational choice theory, new managerialist perspectives, economic theories, theories of change, leadership theories, complexity theory, sociological perspectives and so on. The researcher has to decide and defend the perspectives chosen (e.g. Goldthorpe, 2007), for example on the grounds of fitness for purpose, fidelity to the phenomena and explanatory potential. Chapter 6 presents a worked example of this, from Goldthorpe (2007), in which the author, in examining the 'persistent differentials in educational attainment' (p. 21) had to decide between Marxist theory, liberal theory, cultural theory and rational choice theory.

In looking at phenomena through the chosen theoretical lenses, the researcher must be aware that this may be selective, including, excluding and even distorting data. Imagine looking at a coloured picture wearing spectacles that block out the colour red; what we see is affected by this screening out.

This approach does not mean that the researcher has to decide on a single theoretical perspective. Indeed different participants may have different theoretical perspectives, and the researcher may feel it important to report these.

These ten ways are not all mutually exclusive, and they may be used in combination, so as to better answer the research purposes and questions.

33.3 Narrative and biographical approaches to data analysis

Narrative and biographical approaches are powerful ways of analysing and presenting qualitative data. Bruner (1986) remarks that humans make meaning in terms of 'storied text' which catch the human condition, human intentionality and the vividness of human experience very fully (pp. 14, 19) and the multiple perspectives and lived realities ('subjective landscapes') of participants (p. 29). They model the world (p. 7), starting with metaphors and metamorphosing into empirical statements by verifiable data. They make the familiar strange, 'rescue it from obviousness' (p. 24) and require the reader to fill in the gaps, i.e. they are an interactive medium (p. 24).

Stories personalize generalizations (Gibbs, 2007, p. 57) and are evidence-based. Further, they catch the chronology of events as they unfold over time, and this can enable the researcher to infer causality, coupled with the dramatic and dramaturgical power of carefully chosen words. Narratives can not only convey information but bring information to life. As the poet Pasternak remarks, events 'catch fire' on their way, through the reporting of personal experiences, dramatic events and even the simple unfolding of a sequence of activities, behaviours or people over time. Gibbs (2007, p. 60) comments that narratives not only pass on information but meet people's psychological needs in coping with life; they help a group to crystallize or define an issue, view, stance or perspective; they can persuade or create a positive image; they can help researchers and readers to understand the experiences of participants and cultures; and they can contribute to the structuring of identity (as indeed is the case with life histories and biographies). Narratives are a wonderful foil to the supremacy of coding and coding-derived analysis.

Biographies, too, tend to follow a chronology, to report critical or key events and moments, to report key decisions and people, and to establish causality. Indeed, for their authors, they may even be restorative of broken identities or shattered futures (Gibbs, 2007, p. 67).

Narratives and biographies may have a chronology (but this is not a requirement, as some narratives are structured by logical relations or psychological coherence rather than chronology). They may have a beginning, a middle and an end, they may include critical moments and decisions, complicating factors, evaluation and outcomes (see Labov's (1972) characteristics of a narrative as having: (a) an abstract; (b) an orientation (context); (c) complicating actions (sequences of events that decide the course of the narrative); (d) evaluation (indicating the significance of the narrative and its main points); (e) resolution (outcomes); and (f) a coda (a rounding off of the narrative)).

Narratives and biographies cannot record all the events; rather a selective focus is adopted, based on the criteria that the researcher wishes to use. These may include: key decision points in the story or narrative; key, critical events, themes, behaviours, actions, decisions, people, points in the chronology; meaningful events to the participants; reconstruction of the case history (Flick, 2009, p. 347); key places; and key experiences. Once the researcher has identified the textual units in the biography or narrative, based on the criteria that are fit for the researcher's purpose, the researcher can then analyse and interpret the text for the meanings contained in it, develop working hypotheses to explain

what is taking place, check these hypotheses against the data and the remainder of the text, see the text as a whole rather than as discrete units, ensure that different interpretations of the text have been considered and that the interpretation(s) chosen are the most secure in terms of fidelity to the text.

Following these stages of text selection, analysis, interpretation and checking is the construction of the final narrative. This can be undertaken in several ways, for example:

- by temporal sequence (a chronology);
- by a sequence of causal relations;
- by key participants;
- by key actions;
- by emergent or key themes;
- by key issues and clusters of issues;
- by biographies of the participants;
- by critical or key events;
- by turning points in a life history or biography;
- by different perspectives;
- by key decision points;
- by key behaviours;
- by individual case studies or a collective analysis of the unfolding of events for many cases/participants over time.

In constructing a narrative analysis (as indeed in other forms of qualitative data analysis), the researcher can introduce verbatim quotations from participants where relevant and illuminative; these can add life to the narrative and often convey the point very expressively – without it being mediated or softened by the academic language of the researcher. It is important to keep quotations short enough to convey the main point without distortion or exclusion of relevant details and context, but not so long that the reader does not know what is the point of the quotation, i.e. having to perform an analysis of the data for herself/himself (Gibbs, 2007, p. 97). When using verbatim quotations from participants, it is often useful to accompany them with the researcher's interpretive commentary. Quotations are often chosen for their ability to crystallize or exemplify an issue really well, or typically, or extremely, and the researcher must decide whether to identify the person who said it (see the discussion of ethics in Chapters 7 and 32).

Narrative analysis, together with biographical data, can give the added dimension of realism, authenticity, humanity, personality, emotions, views and values in a situation, and the researcher must ensure that these are featured in the narratives constructed. By 'telling a story', a narrative account, case study or biography breaks with the strictures of coding and the risk of disembodied text that can too easily result from coding and retrieval exercises; it keeps text and context together, retains the integrity of people rather than fragmenting bits of them into common themes or codes, and enables evolving situations, causes and consequences to be charted. A narrative account enables events to 'catch fire' as they unfold. Narratives are powerful, human and integrated; truly qualitative.

33.4 Systematic approaches to data analysis

Qualitative data analysis can be very systematic. Becker and Geer (1960) indicate how this might proceed:

1. comparing different groups simultaneously and over time;
2. matching the responses given in interviews to observed behaviour;
3. analysing deviant and negative cases;
4. calculating frequencies of occurrences and responses;
5. assembling and providing sufficient data but keeping the separate raw data from analysis.

Qualitative data analysis here is inevitably interpretive, hence is less a completely accurate representation and more of a reflexive, reactive interaction between the researcher and the decontextualized data that are already interpretations of a social encounter. As mentioned earlier, the analysis is a construction of meaning rather than a complete reflection of reality and, in this, reflexivity is an important feature. The issue here is that the researcher brings to the data her own preconceptions, interests, biases, preferences, biography, background and agenda. As Walford (2001, p. 98) writes: 'all research is researching yourself'. In practical terms it means that the researcher may be selective in her focus, or that the research may be influenced by the subjective features of the researcher. Robson (1993, pp. 374–5) and Lincoln and Guba (1985, pp. 354–5) suggest that such subjective features can include and/or be subject to:

- data overload (humans may be unable to handle large amounts of data);
- first impressions (early data analysis may affect later data collection and analysis);
- availability of people (e.g. how representative these are and how to know if missing people and data might be important);
- information availability (easily accessible information may receive greater attention than hard-to-obtain data);

- positive instances (researchers may over-emphasize confirming data and under-emphasize disconfirming data);
- internal consistency (the unusual, unexpected or novel may be under-treated);
- uneven reliability (the researcher may overlook the fact that some sources are more reliable/unreliable than others);
- missing data (the issue for which there are incomplete data may be overlooked or neglected);
- revision of hypotheses (researchers may over-react or under-react to new data);
- confidence in judgement (researchers may have greater confidence than is tenable in their final judgements);
- co-occurrence may be mistaken for association;
- inconsistency (subsequent analyses of the same data may yield different results).

The issue here is that great caution and self-awareness must be exercised by the researcher in conducting qualitative data analysis, as the analysis and the findings may say more about the researcher than about the data. For example, it is the researcher who sets the codes and categories for analysis, be they pre-ordinate or responsive (decided in advance of or in response to the data analysis respectively). It is the researcher's agenda that drives the research and she who chooses the methodology.

As the researcher analyses data, she will have ideas, insights, comments and reflections to make on data. These can be noted down in memos, and indeed memos can become data themselves in the process of reflexivity (though they should be kept separate from the primary data themselves). Glaser (1978) and Robson (1993, p. 387) argue that memos are not data in themselves but help the process of data analysis; this is debatable: if reflexivity is part of the data-analysis process then memos may become legitimate (secondary) data in the process or journey of data analysis. Computer software for qualitative data analysis enables researchers to write a memo and attach it to a particular piece of datum. There is no single nature or format of a memo; it can include subjective thoughts about the data, with ideas, theories, reflections, comments, opinions, personal responses, suggestions for future and new lines of research, reminders, observations, evaluations, critiques, judgements, conclusions, explanations, considerations, implications, speculations, predictions, hunches, theories, connections, relationships between codes and categories, insights, and so on. Memos can be reflections on the past, present and the future, thereby beginning to examine the issue of causality. There is no required minimum or maximum length; memos should be dated not only for ease of reference but also for a marking of the development of the researcher as well as of the research. Chapter 37 discusses memos in greater detail.

Memos are an important part of the researcher's self-conscious reflection on the data; they have considerable potential to inform the data-collection, analysis and theorizing processes. They should be written whenever they strike the researcher as important – during and after analysis. They can be written any time; indeed some researchers deliberately carry recording methods with them wherever they go (pen and paper, electronic means, both written and audio) so that ideas that occur can be recorded before they are forgotten. They enable the researcher to comment and theorize on events, situations, behaviours and so on as they are being analysed, and can focus on observations, methodological and theoretical matters, or personal matters (cf. Gibbs, 2007, pp. 30–1).

We have discussed systematic qualitative data analysis in some detail in Chapter 25, including systematic tactics for generating meaning from transcribed data (Miles and Huberman, 1994), systematic content analysis (see also Chapter 34), and systematic procedures for phenomenologically analysing interview data. We advise readers to review the relevant material in that chapter together with the comments on content analysis in Chapter 34.

33.5 Methodological tools for analysing qualitative data

There are several procedural tools for analysing qualitative data. LeCompte and Preissle (1993, p. 253) present analytic induction, constant comparison, typological analysis and enumeration as valuable techniques for the qualitative researcher to use in analysing data and generating theory. Additionally coding is discussed in Chapter 34 and the tools of grounded theory are discussed in Chapter 37.

Analytic induction is a term and process that was introduced by Znaniecki (1934) in deliberate opposition to statistical methods of data analysis. LeCompte and Preissle (1993, p. 254) suggest that the process is akin to the several steps set out above, in that: (a) data are scanned to generate categories of phenomena; (b) relationships between these categories are sought; (c) working typologies and summaries are written on the basis of the data examined; (d) these are then refined by subsequent cases and analysis; (e) negative and discrepant cases are deliberately sought to modify, enlarge or restrict the original explanation/theory. Denzin (1970, p. 192) uses the term 'analytical induction' to describe the broad strategy and sequence of participant observation that is set out below:

1. A rough definition of the phenomenon to be explained is formulated.
2. A hypothetical explanation of that phenomenon is formulated.
3. One case is studied in the light of the hypothesis, with the object of determining whether or not the hypothesis fits the facts in that case.
4. If the hypothesis does not fit the facts, either the hypothesis is reformulated or the phenomenon to be explained is redefined, so that the case is excluded.
5. Practical certainty may be attained after a small number of cases has been examined, but the discovery of negative cases disproves the explanation and requires a reformulation.
6. This procedure of examining cases, redefining the phenomenon, and reformulating the hypothesis is continued until a universal relationship is established, each negative case calling for a redefinition or a reformulation.

A more deliberate seeking of disconfirming (negative) cases is advocated by Bogdan and Biklen (1992, p. 72). Here the researcher searches for cases which do not fit the other data, or cases, or that do not fit expected patterns of findings. They can be used to extend, expand or modify the existing or emerging hypothesis. Bogdan and Biklen also enumerate five main stages in analytic induction:

1. In the early stages of the research a rough definition and explanation of the particular phenomenon is developed.
2. This definition and explanation is examined in the light of the data that are being collected during the research.
3. If the definition and/or explanation that have been generated need modification in the light of new data (e.g. if the data do not fit the explanation or definition) then this is undertaken.
4. A deliberate attempt is made to find cases that may not fit into the explanation or definition.
5. The process of redefinition and reformulation is repeated until the explanation is reached that embraces all the data, and until a generalized relationship has been established, which will also embrace the negative cases.

In *constant comparison* the researcher compares newly acquired data with existing data and categories and theories that have been devised and which are emerging, striving to achieve a perfect fit between these and the data. Hence negative cases or data which challenge these existing categories or theories lead to their modification until they fully accommodate all the data. We discuss this technique more fully in Chapters 34 and 37.

Typological analysis is essentially a classificatory process (LeCompte and Preissle, 1993, p. 257) wherein data are put into groups, subsets or categories on the basis of some clear criterion (e.g. acts, behaviour, meanings, nature of participation, relationships, settings, activities). It is the process of *secondary coding* (Miles and Huberman, 1984, 1994) where descriptive codes are then drawn together and put into subsets. Typologies are a set of phenomena that represent subtypes of a more general set or category (Lofland, 1970). Lazarsfeld and Barton (1951) suggest that a typology can be developed in terms of an underlying dimension or key characteristic. In creating typologies Lofland (1970) insists that the researcher must: (a) deliberately assemble all the data on how a participant addresses a particular issue: what strategies are being employed; (b) disaggregate and separate out the variations between the ranges of instances of strategies; (c) classify these into sets and subsets; and (d) present them in an ordered, named and numbered way for the reader.

The process of *enumeration* is one in which categories and the frequencies of codes, units of analysis, terms, words or ideas are counted. This enables incidences to be recorded and, indeed statistical analysis of the frequencies to be undertaken (e.g. Monge and Contractor, 2003; Johnson and Black, 2012; Lee *et al*., 2015). This is a method used in some forms of content analysis, and we address this topic in the next chapter.

This chapter has suggested several approaches to analysing and presenting qualitative data. It should be read in conjunction with the comments on qualitative data analysis in Chapters 25, 34 and 37, as they complement each other.

Companion Website

The companion website to the book provides data files and additional material and PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Coding and content analysis

CHAPTER 34

A key element of qualitative data analysis is data management. Qualitative data are often extensive, and careful data reduction is key. Too much reduction and the integrity and detail of the data are lost; too little and data overload and loss of clarity ensue. This chapter addresses data reduction with data quality through coding and content analysis. It indicates how coding works, what concerns it raises and how to address such concerns. It indicates different kinds of coding (e.g. open, analytic, axial, selective, theoretical) and how to code data and organize codes. The chapter uses the basis of coding in conjunction with content analysis, indicating what it is and how to conduct and report content analysis. It outlines an eleven-step process of conducting content analysis. Worked examples of coding and content analysis are provided and the chapter notes that both inductive and deductive approaches are important in qualitative data analysis.

This chapter addresses coding and content analysis in qualitative data analysis, both of these widely used, and it introduces key issues in coding and content analysis, including:

- coding
- concerns about coding
- what is content analysis?
- how does content analysis work?
- a worked example of content analysis
- reliability in content analysis

34.1 Introduction

One of the enduring problems of qualitative data analysis is the reduction of copious amounts of data to manageable and comprehensible proportions. Data reduction is a key element of qualitative analysis (Miles and Huberman, 1984, 1994), performed in a way that attempts to respect the *quality* of the qualitative data. One common procedure for achieving this is content analysis, a process by which the 'many words of texts are classified into much fewer categories' (Weber, 1990, p. 15), reducing the material in different ways (Flick, 1998, p. 192). Categories are derived from theoretical constructs or areas of interest devised in advance of the analysis (pre-ordinate categorization) or developed from the material itself (responsive categorization). Before we turn to content analysis, it is important to consider the matter of coding, and we address this below.

34.2 Coding

A major approach to qualitative data analysis is coding, for example, Strauss and Corbin (1990); Kelle (1995, pp. 62–104); Lonkila (1995); Gibbs (2007, pp. 38–55); Flick (2009, pp. 305–32); Creswell (2012); Marshall and Rossman (2016). There are several kinds of codes and we explore these below. Texts may be lightly coded or densely coded (e.g. where a single piece of text has several codes attached to it). A code is simply a name or label that the researcher gives to a piece of text which contains an idea or a piece of information (Miles and Huberman, 1994; Gläser and Laudel, 2013). Gibbs (2007, p. 38) catches the nature of a code neatly when he writes that the same code is given to an item of text that says the same thing or is about the same thing. Seidel and Kelle (1995) suggest that codes can denote a text, passage or fact, and can be used to construct data networks. Coding text means that data from non-textual sources (e.g. audio, visual images, videos, graphs, numerical files, charts and graphics) have had textual material (e.g. annotations, commentaries, notes, memos) added, and the coding works with and on that textual material.

Coding is the ascription of a category label to a piece of data, decided in advance or in response to the data that have been collected. The same piece of text may have more than one code ascribed to it, depending on the richness and contents of that piece of text. Coding is the process of breaking down segments of text data into smaller units (based on whatever criteria are relevant), and then examining, comparing, conceptualizing and categorizing the data. The researcher goes through the text, marking it with codes (labels) that describe that text. The code name might derive from the researcher's own creation, or it may derive from the

words used in the text or spoken by one of the participants in the transcribed data (e.g. if the participant remarks that she is bored with the science lesson, the code may be 'bored': a short term that catches the essence of the text in question).

Codes may be decided in advance, *ex ante*, preordinate from theory and/or from the research question, or, to be faithful to the data, they may be responsive to, and emerge from, the data. Whilst Glaser and Strauss (1967) advocate ignoring literature or theory and going straight into the data, Gläser and Laudel (2013) argue that, echoing the post-positivists, this is 'epistemically naïve' as observations are unavoidably theory-laden and theory orders and classifies how and what we see and look for (p. 72). In reality, the researcher often starts with some codes already decided or in mind and adds to, modifies and adjusts these in response to the data.

Coding enables the researcher to identify similar information. The researcher can search, retrieve and assemble the data in terms of those items that bear the same code. Codes can be regarded as an indexing or categorizing system, like the index in a book, which gives all the references to that index entry in the book, and the data can be stored under the same code, with an indexed entry for that code. A list of codes can be stored (e.g. in software such as NVivo), accompanied by information such as who coded the data, when the coding was undertaken and what the code means (Gibbs, 2007, p. 41). By coding the data the researcher is able to detect frequencies (which codes occur most commonly) and patterns (which codes occur together), and the researcher can retrieve all the data that have the same code, both within and across files.

Coding can be performed on many kinds of textual data (Gibbs, 2007, pp. 47–8), focusing on, for example: specific acts, conversations, reports, behaviours, events, interactions, activities, contexts, settings, conditions, actions, strategies, practices, tactics, meanings, intentions, states, symbols, participation, relationships, constraints, causes, consequences and issues concerning the researcher's reflexivity. In short, nothing is ruled out.

Codes can be at different levels of specificity and generality when defining content and concepts. Some codes may subsume others, thereby creating a hierarchy of subordination and superordination, in effect creating a tree diagram of codes (and software can present this in a graphic). Some codes are very general; others are more specific. Codes are astringent, pulling together a wealth of material into some order and structure. They can maintain context specificity. Codes may be *descriptive* and might include (Bogdan and Biklen, 1992, pp. 167–72): situation codes; perspectives held by subjects; ways of thinking about people and objects; process codes; activity codes; event codes; strategy codes; relationship and social structure codes; methods codes. The researcher goes through the data ascribing codes to each piece of datum. A code is a word or abbreviation sufficiently close to that which it is describing for the researcher to see at a glance what it means (in this respect it is unlike a number). For example, the code 'trust' might refer to a person's trustworthiness; the code 'power' might refer to the status or power of the person in the group. This enables meanings to be seen at a glance, memorized and recalled easily.

Miles and Huberman (1984, 1994) advise researchers to keep codes as discrete as possible and to start coding earlier rather than later as late coding enfeebles the analysis, though there is a risk that early coding might influence too strongly any later codes. It is possible, they suggest, for as many as ninety codes to be held in the working memory whilst going through data, though clearly there is a back-and-forth process whereby some codes that are used in the early stages of coding might be modified subsequently and *vice versa*, necessitating the researcher to go through a data set more than once to ensure consistency, refinement, modification and exhaustiveness of coding (some codes might become redundant whilst others might need to be broken down into finer codes). Data might be recoded on a second or third reading, as codes that were used early on might have to be refined in light of codes that are used later, either to make them more discriminating or to conflate codes that are unnecessarily specific. Codes, they argue, should enable the researcher to catch the complexity and comprehensiveness of the data. They are derived through the dual processes of induction and deduction (1994, p. 111) and should be verifiable by data (p. 108).

Before coding the text, it is important to read and re-read it to obtain a thorough understanding of meanings and key issues, a sense of the entire text and immediate main ideas in it (cf. Creswell, 2012, p. 244). Then, in coding a piece of text, the researcher goes through the data systematically, typically line by line, and writes a descriptive code by the side of each piece of datum, for example:

Text	*Code*
The students will undertake problem solving in science	PROB
I prefer to teach mixed ability classes	MIXABIL

Here the codes are abbreviations, and this is common, enabling the researcher to understand immediately the

issue that they denote because they resemble that issue (problem solving and mixed ability teaching), rather than, for example, ascribing a number as a code for each piece of datum, where the number provides no clue as to what the datum or category concerns. Where they are not abbreviations, Miles and Huberman (1994) suggest that the coding label should bear sufficient resemblance to the original data so that the researcher can know at a glance, by looking at the code, what the original piece of datum concerned. We give a worked example of a coding exercise later in this chapter.

There are several computer packages that can help the researcher here (e.g. MAXQDA, ATLAS.ti, NVivo, ETHNOGRAPH), and they require the original transcript to be entered onto the computer. Software can also enable coded text from across several files to be collated into a single file. Figure 34.1 shows one example of this, where coded text using the code for organizational culture ('orgcult') from three files has been collated into a single file in NVivo, with the names of the original files included and the text which has been selected and coded from each file.

It is important for codes to be applied consistently, so that relevant data are coded consistently, no data are excluded and the same code is used. This enables retrieval, categorization, collation and separation of data (particularly if software is being used).

Often, in the first coding attempt, many new codes are generated; the subtlety of difference of codes may be unclear as the researcher goes further through the text, or the earlier codes may turn out to be unhelpful (e.g. too general), or the later codes may be too strongly influenced (or driven) by the earlier codes, or later coding may make the researcher feel that she or he wishes to alter the earlier coding, or there may be duplication or overlap of codes (e.g. the same kind of meaning but given slightly different codes), or there may be redundant codes (e.g. codes that only appear once or twice and which are more fittingly replaced by other codes in light of the remainder of the text). The point here is that coding is not a 'one-off' exercise; it requires reading and re-reading, assigning and reassigning codes, placing and replacing codes, refining codes and coded data; the process requires the researcher to

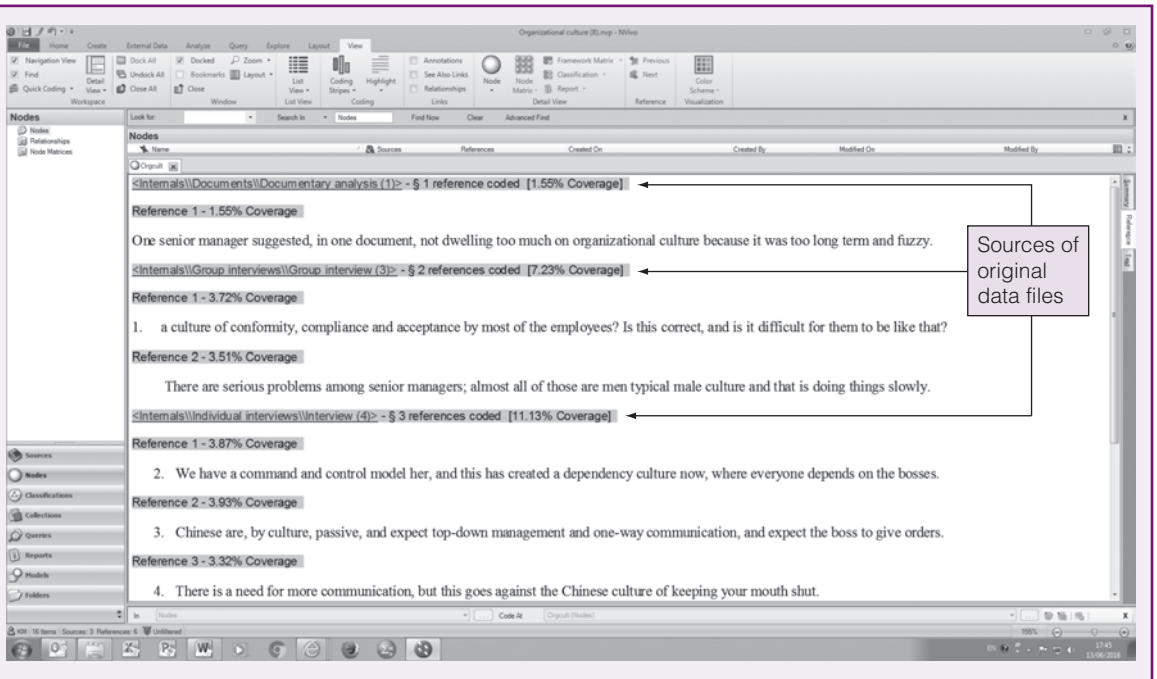

FIGURE 34.1 NVivo (Version 10) coded text for the code on organiztional culture, from several files collated into a single file

go back-and-forth through the data on maybe several occasions, to ensure consistency and coverage of codes and data. Once the initial coding has been undertaken and checked then emergent themes, frequencies of codes, patterns of combinations of codes, key points, similarities and differences, variations and so on can be detected, and we discuss these in this chapter and the next.

Coding, argues Flick (2009, p. 310), can address fundamental questions such as 'who', 'why' 'what', 'where', 'how', 'when', 'how long', 'how much', 'how strong', 'what for' and 'by which'. These, he suggests, are useful questions in steering the coding exercise, particularly for open coding (discussed below).

There are different kinds of code: an open code, an analytic code, an axial code, a selective code and a theoretical code; we discuss these below. Though there is a suggestion in what follows that there is a sequence in coding, and indeed Strauss and Corbin (1990) suggest a sequence of three stages: open coding to axial coding to selective coding, this need not be the case, as different codes operate at different levels, and these are not necessarily driven by a pre-arranged sequence (Flick, 2009, p. 307).

Open coding

An open code is simply a new label that the researcher attaches to a piece of text to describe and categorize that piece of text (Strauss and Corbin, 1990, chapter 5). Open coding generates categories and defines their properties (the characteristics or attributes of a category or phenomenon) and dimensions (the location of a property along a given continuum) (Strauss and Corbin, 1990, p. 69). The authors give an example of the category/code 'colour', which has properties of hue, shade and intensity (p. 70). These properties, in turn, have dimensions: hue can be light to dark; shade can be light to dark; and intensity from high to low. Each category can have several properties, each of which has its own dimensional continuum (p. 70). The authors give an example of properties and dimensions for the category/code/label 'watching' (p. 72), such as: (a) property: 'frequency'; dimension: often to never; (b) property: 'extent'; dimension: more to less; (c) property: 'intensity': dimension: high to low; (d) property: 'duration'; dimension: long to short.

Open coding can be performed on a line-by-line, phrase-by-phrase, sentence-by-sentence, paragraph-by-paragraph, unit-of-text-by-unit-of-text (e.g. section) basis or a semantic unit. Then the codes can be grouped into categories, giving the categories a title or name, based on criteria that the researcher decides (e.g. concerning a specific theme, based on similar words, similar concepts, similar meanings etc.). The title of the category should be more abstract than the specific concepts or contents of the codes that it subsumes (Strauss and Corbin, 1990, p. 69). In undertaking such grouping, it is important that all the data fit into the group consistently, that there are no negative cases.

Open coding is usually the earliest, initial form of coding undertaken by the researcher.

Analytic coding

As its name suggests, an analytic code is more than a descriptive code. It is more interpretive. For example, whereas 'experimenting', 'controlling variables', 'testing' and 'measuring' are descriptive codes (e.g. in describing science activities), an analytic code here could be 'working like a scientist', 'doing science' or 'active science'; it draws together and gives more explanatory and analytic meaning to a group of descriptive codes. An analytic code might derive from the theme or topic of the literature or, responsively, from the data themselves.

Another example is where the descriptive codes given to teacher behaviour might be 'ignores disruption' (when a teacher ignores disruptive behaviour), 'interested students' (when a teacher only concentrates on those students who are interested in the lesson contents) and 'no response' (when a teacher does not respond to students shouting in class). The category might be 'teacher behaviour' and the analytic – more inferential – code might be 'teacher resignation' or 'teacher denial'.

Axial coding

An axial code is a category label ascribed to a group of open codes whose referents (the phenomena being described) are similar in meaning (e.g. concern the same concept). Axial coding is that set of procedures which the researcher follows whereby the data that were originally segmented into small units or fractions of a whole text through open coding are recombined in new ways (Strauss and Corbin, 1990, p. 96). An axial code refers to:

- *causal conditions*: events, activities, behaviours or incidents that lead to the occurrence of a phenomenon (p. 100);
- *a phenomenon*: an event, idea, activity, action, behaviour etc. (p. 100);
- *context*: a specific set of properties or conditions that obtain in a phenomenon, action or interaction (p. 101);
- *intervening conditions*: the broad, general conditions that have a bearing on the action or interaction in question (p. 103);

- *actions and interactions*: purposeful, goal-oriented processes, strategies or behaviours obtaining in an action (p. 104);
- *consequences*: outcomes for people, events, places etc., which may or may not have been predicted and which, in turn, may become the causes or conditions of further actions and interactions (p. 106).

For a worked example of these six areas, we refer readers to Buckley and Waring (2009), in which they diagrammatize the six areas and insert relevant data into them in their study of physical activity in children.

Axial coding connects related codes and sub-categories into a larger category of common meaning that is shared by the group of codes in question (thereby creating a hierarchy in which some codes are subsumed into the large axial category); an axial code, as its name suggests, is a category or axis around which several codes revolve.

Axial coding works within one category; it makes connections between sub-groups of that category and between one category and another. This might be in terms of the phenomena being studied, the causal conditions that lead to the phenomena, the context of the phenomena and their intervening conditions, and the actions and interactions of, and consequences for, the actors in situations.

Selective coding

Selective coding identifies the core categories of text data and integrates them to form a theory. It is the process of identifying the core category in a text, i.e. that central category or phenomenon around which all the other categories identified and created are integrated (Strauss and Corbin, 1990, p. 116), to which other categories are systematically related and by which it is validated. The authors argue that a selective code is very similar to an axial code, except that it is at a greater level of abstraction than an axial code. Creating the selective code requires: (a) a deep understanding of the main 'story line' (p. 117) (the descriptive overview of the main phenomenon being described and analysed, and its salient features); then (b) creating the core category; then (c) relating categories at the level of the dimensions identified; then (d) validating those relations in terms of the data that gave rise to them; and then (e) filling in any gaps in categories (pp. 116–17) to ensure the 'conceptual density' (p. 141) of the category, based on data collected. Though set out in a linear sequence, the authors indicate that, in fact, the process is iterative, and researchers move back and forth between steps (a) to (e).

Once codes have been assigned, ordered and grouped, they can be structured into hierarchies of subsumption, in which lower-order (e.g. descriptive) codes are subsumed under analytic and axial codes, which in turn are subsumed under a selective code. Hierarchies order codes and keep them tidy (Gibbs, 2007, p. 75), and indeed the creation of a hierarchy is itself part of data analysis, as the researcher ascribes meanings to the data. This is a pre-eminent function of CAQDAS software, in the creation of nodes, node trees and hierarchies.

The advice from Gibbs (2007, p. 77) is to keep hierarchies 'shallow' rather than 'deep', i.e. not too many levels. It is important, too, to ensure that the data contained in each code at each level are consistent with each other, hence the researcher has to constantly check and make comparisons across the data (the 'constant comparison' of grounded theory) (Glaser and Strauss, 1967) to ensure that they all fit together, with no exceptions or disconfirming data. Gibbs (2007, pp. 78–83) suggests that this can be done easily with tabulated data, and Chapter 33 provides examples of this, where data in columns can be compared or data in rows can be compared, to look for consistency, patterns, commonalities, relationships, similarities and differences (e.g. Tables 33.1 to 33.4). In such tabulated data (often where individuals are the rows and the issue is the column, it is possible to examine and compare individual cases (the rows) and different interpretations of the issues (the columns), for example, as shown in Table 34.1 (with fictitious data from a primary school, with the codes of 'AttSci' for attitudes to science lessons and 'AttMus' for attitudes to music lessons).

In this example, looking across the rows we can see that the children have positive attitudes but their interest is thwarted by distractions, lack of 'voice' and level of demand in the lessons; they all prefer practical work but this is not always done. One child seems to be more accommodating to the teacher's decisions than the other two, and one seems to be much less accommodating, i.e. there is variation on this dimension. Looking down the columns, we see very different attitudes within and between the two lessons. The table enables comparisons to be made, looking for similarities, differences, consistencies and inconsistencies, variations and homogeneity of responses, and deviant and extreme cases (cf. Gibbs, 2007, p. 96).

Theoretical coding

In theoretical coding, researchers see how codes and categories are integrated and fit together to create a theory or hypothesis. Here theoretical codes are the 'underlying logics' (Thornberg, 2012a, p. 89) that come

TABLE 34.1 TABULATED DATA FOR COMPARATIVE ANALYSIS

Name	*Attitudes to science lessons* *Code: AttSci.*	*Attitudes to music lessons* *Code: AttMus.*
Jane	Finds them difficult, but interesting. Too much homework which is not addressed in the class. Enjoys experiments but is not very good at them.	Enjoys listening to music, but there is too much singing to be done in class, and not enough playing or practical activity. The teacher only concentrates on those who are in the school choir.
John	Cannot concentrate because he finds the work boring and too 'bookish'. Prefers experiments but never has the chance to do them.	We are never allowed to choose the music to listen to, and the teacher's music is boring and old. Why do we have to use babyish instruments?
Stephen	Thoroughly enjoys the practical activities and the idea of exploring what went wrong in the experiments, and why.	I liked it when we were making up our own tunes in groups, but the class was very noisy. I don't like singing. I wish we were taught how to read and write proper music. Lots of children just 'mess around' in the music lesson, and that's horrible.

from pre-existing or emergent theories, together with the core category: that which has the greatest explanatory potential and to which the other categories and sub-categories relate most closely, repeatedly and consistently (discussed below and in Chapter 37). Glaser (1978) identifies 'families' of theoretical codes, including *the six Cs* (causes, contexts, contingencies, consequences, co-variances and conditions); *processes* (phases, progressions, passages, transitions, careers, trajectories, sequences, cycles); *type* (styles, classes, genre); *identity* (self-image, self-concept, self-worth, self-evaluation, identity, transformations of self); *degrees* (range, gradations, levels, limits); *culture* (social values, beliefs and norms). However, these 'families' may not exhaust theoretical possibilities, and the combining of categories may suggest other theoretical codes.

Coding is only an initial stage in qualitative data analysis; from initial coding the research can group codes into categories and then identify themes, trends and patterns (if indeed such trends and patterns exist), relations between themes, clusters of themes and issues, similarities and differences between themes and between data, and on to theory generation. This progression requires data from several texts to be addressed and combined which, in turn, can validate and increase the reliability of the findings and conclusions drawn. This can move towards 'saturation' (discussed below), wherein no additional data add to the key issues and findings.

34.3 Concerns about coding

The use of coding is governed by fitness for purpose; it is not suitable for all kinds of qualitative data analysis. Though coding is a central feature in many forms of qualitative data analysis, researchers need to ensure that it is the most appropriate way to analyse the data, as there is a risk of losing temporality, context and sequence in the coding and retrieval of text. For example, there is a temptation, perhaps to ascribe the same code to an observed behaviour regardless of the setting, the time (e.g. in a longitudinal study or a study that involves observation over several weeks), the prevalent conditions, states of mind, actors involved, intervening events, and so on, when, in fact the meaning and significance of the behaviour is not the same in different contexts or points in time.

Concerns have been raised that coding risks stripping out important contexts from the study and fragmenting holistic data into small segments, thereby losing the whole picture and having only a series of decontextualized codes (St Pierre and Roulston, 2006, p. 677; Blikstad-Balas, 2016, p. 9). In this case, the researcher may wish to write a narrative account rather than to abstract data from the several contexts in which they are set.

Coding can swamp the researcher with too many codes and may not reduce the data very much because the original textual material is still present which may contain irrelevancies (Gläser and Laudel, 2013). Further, St Pierre and Jackson (2014) raise the concern that coding treats words as 'brute data waiting to be

coded, labelled with other brute words (and even counted)' (p. 715), whereas qualitative data analysis is a much more humanistic and holistic activity. They argue against this 'vacuum cleaner approach' (p. 715), wherein all data are swept up and treated as equally important. Qualitative data analysis, they aver, should concern itself with the quality of the data and what is relevant and less relevant (e.g. informed by research questions and theory), with the researcher having to judge which words are and are not relevant for coding and to recognize that data are theory-laden, not theory-free.

St Pierre and Jackson (2014) also warn researchers against the propensity of humans to look for patterns where none exist, and that coding too easily feeds this fallacy. Further they argue that coding risks sacrificing an adequate theoretical or conceptual foundation to superficial presentation of data and codes which are supposed to 'speak for themselves' (p. 716). Rather, they comment that researchers must recognize 'the entanglement of research problems, concepts, emotions, transcripts, memories and images' (p. 717) that make up qualitative data analysis. There are no methodological steps, they argue, that one can simply drop unthinkingly onto data or that one can plan in advance; rather, they claim, qualitative data analysis needs to respond to the data, the research question and purposes, the conceptual and theoretical fields, the participants and so on, i.e. researchers must take a richer decision on data analysis rather than rushing headlong and thoughtlessly into coding.

Adair and Pastori (2011) suggest that qualitative data analysis, including coding, 'necessitates' conversation, debate and sophisticated, thoughtful decision making (p. 32). Texts, they note, are replete with 'subtlety, contradictions, metaphors, redundancy, and emotion', 'deeper meanings' and participants' voices (p. 33) which may not be susceptible to simplistic coding. Rather, coding should catch such subtlety and adopt both an *emic* approach (i.e. in terms that are meaningful to the participants) and an *etic* approach (objective, outsider descriptions), and *a priori* (pre-ordinate) and *a posteriori* (emergent) coding in order to catch such deeper meanings. In this respect, coding is just the start of the deeper process of qualitative data analysis, and not its terminus.

We return to coding in Chapter 37, as it is integral to grounded theory.

34.4 What is content analysis?

Having introduced coding, we are now in a position to consider 'content analysis'. The term is often used sloppily. In effect, it simply defines the process of summarizing and reporting written data – the main contents of data and their messages. 'Qualitative content analysis' (Gläser and Laudel, 2013) defines a strict and systematic set of procedures for the rigorous analysis, examination, replication, inference and verification of the contents of written data (Flick, 1998, p. 192; Krippendorp, 2004, p. 18; Mayring, 2004, p. 266). Texts are defined as any written communicative materials which are intended to be read, interpreted and understood by people other than the analysts (Krippendorp, 2004, p. 30). The intention of qualitative content analysis, argue Gläser and Laudel (2013), is to deliberately move from the original text to analysis of the information extracted from it (p. 13), focusing on the meanings of texts and their constituent parts.

Newby (2010, p. 485) reports three kinds of content analysis: 'conventional content analysis' (from coding); 'directed content analysis' wherein the coding structure derives from pre-existing theory or hypotheses; and 'summative content analysis' wherein keywords are selected based on previous research or the researcher's research interests. This is an entrée into the field, for, in reality, there are many kinds of content analysis, and we address these below.

Originally deriving from analysis of mass media and public speeches, the use of content analysis has spread to examination of any form of communicative material, both structured and unstructured. It may be used for those issues and problems which involve points of contact between culture and the social structure or to study social groups and interaction (Weber, 1990, p. 11). Content analysis can be undertaken with any written material, from documents to interview transcriptions, from media products to personal interviews. It is often used to analyse large quantities of text, facilitated by the systematic, rule-governed nature of content analysis, for example, as enabled by computer assisted analysis. It often uses categorization as an essential feature in reducing large quantities of data (Flick, 2009, p. 323).

Content analysis has several attractions. It is an unobtrusive technique (Krippendorp, 2004, p. 40). It focuses on language and linguistic features, meaning in context; it is systematic and verifiable (e.g. in its use of codes and categories) as the rules for analysis are explicit, transparent and public (Mayring, 2004, pp. 267–9). Further, as the data are in a permanent form (texts), verification through re-analysis and replication is possible.

Many researchers see content analysis as an alternative to numerical analysis of qualitative data. But this is not so, although it is widely used as a device for

extracting numerical data from word-based data. Indeed Anderson and Arsenault (1998, pp. 101–2) suggest that content analysis can describe the relative frequency and importance of certain topics as well as evaluate bias, prejudice or propaganda in print materials. Weber (1990, p. 9) sees the purposes of content analysis as including: (a) coding of open-ended questions in surveys; (b) revelation of the focus of individual, group, institutional and societal matters; (c) description of patterns and trends in communicative content. The latter suggestion indicates the role of statistical techniques in content analysis, indeed Weber (p. 10) suggests that the highest quality content-analytic studies use both quantitative and qualitative analysis of texts (texts defined as any form of written communication).

Content analysis takes texts and analyses, reduces and interrogates them into summary form through the use of both pre-existing categories and emergent themes in order to generate or test a theory. It uses systematic, replicable, observable and rule-governed forms of analysis in a theory-dependent system for the application of those categories. It can utilize coding, 'coding raw data into conceptually congruent categories' (Finfgeld-Connett, 2014, p. 342).

Krippendorp (2004, pp. 22–4) suggests that there are several features of texts that inform content analysis, including the fact that texts have no objective reader-independent qualities; rather they have multiple meanings and can sustain multiple readings and interpretations. There is no unitary meaning waiting to be discovered or described in them. Indeed, the meanings in texts may be personal and are located in specific contexts, discourses and purposes, and, hence, meanings have to be drawn in context. Content analysis, then: (a) describes the manifest characteristics of communication (p. 46) (asking who is saying what to whom, and how); (b) infers the antecedents of the communication (the reasons for, and purposes behind, the communication, and the context of communication) (Mayring, 2004, p. 267); and (c) infers the consequences of the communication (its effects). Krippendorp suggests (pp. 75–7) that content analysis is at its most successful when it can break down 'linguistically constituted facts' into four classes: attributions, social relationships, public behaviours and institutional realities.

34.5 How does content analysis work?

Ezzy (2002, p. 83) suggests that content analysis starts with a sample of texts, defines the units of analysis (e.g. words, sentences) and the categories to be used for analysis, reviews the texts in order to code them and place them into categories, and then counts and logs the occurrences of words, codes and categories. From here statistical analysis and quantitative methods are applied, leading to an interpretation of the results. Put simply, content analysis involves coding, categorizing (creating meaningful categories into which the units of analysis – words, phrases, sentences etc. – can be placed), comparing (categories and making links between them) and concluding – drawing theoretical conclusions from the text.

Anderson and Arsenault (1998, p. 102) indicate the quantitative nature of content analysis when they state that 'at its simplest level, content analysis involves counting concepts, words or occurrences in documents and reporting them in tabular form'. This succinct statement catches essential features of the process of content analysis:

- breaking down text into units of analysis;
- undertaking statistical analysis of the units;
- presenting the analysis in as economical a form as possible.

Denscombe (2014, pp. 283–4), echoing Anderson and Atsenault, sets out a six-stage process of content analysis:

1. Choosing an appropriate sample of data.
2. Breaking down text into smaller component units of analysis.
3. Developing appropriate categories for analysing the data.
4. Coding the units to fit the categories.
5. Conducting frequency counts of the occurrence of the units.
6. Analysing the text from the basis of the unit frequencies and how they relate to other units in the text.

Software can easily provide word frequency counts, and this can be useful. For example, in analysing inaugural speeches of high-profile people, the frequency of the word 'I' in the inaugural speech of 2,095 words by former American president Obama was only two (0.1 per cent), whilst for the word 'we' it was sixty-one (2.9 per cent). By contrast, in the inaugural speech of 1,520 words by former Australian prime minister Julia Gillard, the frequency of the word 'I' was 561 (37 per cent) whilst for the word 'we' it was thirteen (8.6 per cent). That sends signals, and many speech writers are sensitive to this; numbers are revealing. However, such an approach can mask some other important features of content analysis, including, for example, examination of the interconnectedness of units of analysis

(categories), the emergent nature of themes and the testing, development and generation of theory.

Flick (2009, p. 326) summarizes several stages of content analysis:

1. Defining the units of analysis.
2. Paraphrasing the relevant passages of text.
3. Defining the level of abstraction required of the paraphrasing.
4. Data reduction and deletion (e.g. removing paraphrases that duplicate meaning).
5. Data reduction by combining and integrating paraphrases at the level of abstraction required.
6. Putting together the new statements into a category system.
7. Reviewing the new category system against the original data.

More fully, the whole process of content analysis can follow several steps.

Step 1: define the research questions to be addressed by the content analysis

This includes what the researcher wants from the texts to be content-analysed. The research questions will be informed by, indeed may be derived from, the theory to be tested.

Step 2: define the population from which units of text are to be sampled

The population here refers not only to people but also, and mainly, to text – the domains of the analysis. For example, it could be newspapers and newspaper articles, programmes, interview transcripts, textbooks, conversations, public domain documents, journals, examination scripts, e-mails, online conversations etc.

Step 3: define the sample to be included

Here the rules for sampling people can apply equally well to documents. The researcher must decide whether to opt for a probability or non-probability sample of documents, a stratified sample (and, if so, the kind of strata to be used), random sampling, convenience sampling, domain sampling, cluster sampling, purposive sampling, systematic sampling, time sampling, snowball sampling and so on (see Chapter 12). Robson (1993, pp. 275–9) indicates the need for careful delineation of the sampling strategy here, for example, such-and-such a set of documents, or time frame (e.g. of newspapers), or television programmes, or interviews. Key issues in sampling people also apply to the sampling of texts: representativeness, access, size of the sample and generalizability of the results.

Krippendorp (2004, p. 145) indicates that there may be 'nested recording units', where one unit is nested within another, for example, with regard to newspapers that have been sampled: an item is nested in a paragraph, which is nested in an article, which is nested in an issue, which is nested in a particular newspaper (p. 145). This is the equivalent of stage sampling, discussed in Chapter 12.

Step 4: define the context of the generation of the document

This examines, for example: how the material was generated (Flick, 1998, p. 193); who was involved; who was present; where the documents came from; how the material was recorded and/or edited; whether the person was willing to, was able to and did tell the truth; whether the data were accurately reported (Robson 1993, p. 273) and corroborated; the authenticity and credibility of the documents; the context of the generation of the document; the selection and evaluation of the evidence contained in the document.

Step 5: define the units of analysis

This can be at very many levels, for example, a word, phrase, sentence, paragraph, whole text, people and themes. Robson (1993, p. 276) includes here, for newspaper analysis, the number of stories on a topic, column inches, size of headline, number of stories on a page, position of stories within a newspaper, the number and type of pictures. His suggestions indicate the careful thought that needs to go into the selection of the units of analysis. Different levels of analysis will raise different issues of reliability (discussed later). It is assumed that the units of analysis will be classifiable into the same category of text with the same or similar meaning in the context of the text itself (semantic validity) (Krippendorp, 2004, p. 296), though this can be problematic (discussed later). The description of units of analysis will also include the units of measurement and enumeration. The *coding unit* defines the smallest element of material that can be analysed, whilst the *contextual unit* defines the largest textual unit that may appear in a single category.

Krippendorp (2004, pp. 99–101) distinguishes three kinds of units. *Sampling units* are those units which are included in, or excluded from, an analysis; they are units of selection. *Recording/coding units* are units contained within sampling units, i.e. smaller than sampling units, thereby avoiding the complexity that characterizes sampling units; they are units of description. *Context units* are units of text which set boundaries on what is to be noted, i.e. the scope of the information which informs the coding of the material (p. 103).

Krippendorp continues by suggesting a further five kinds of sampling units: *physical* (e.g. time, place, size); *syntactical* (words, grammar, sentences, paragraphs, chapters, series etc.); *categorical* (members of a category have something in common); *propositional* (delineating particular constructions or propositions); and *thematic* (putting texts into themes and combinations of categories). The issue of categories signals the next step.

The criterion here is that each unit of analysis (category: conceptual, actual, classification element, cluster, issue) should be as discrete as possible whilst retaining fidelity to the integrity of the whole, i.e. each unit must be a fair rather than a distorted representation of the context and other data. The creation of units of analysis can be done by ascribing *codes* to the data, akin to the process of 'unitizing' (Lincoln and Guba, 1985, p. 203).

Step 6: decide the codes to be used in the analysis

Hammersley and Atkinson (1983, pp. 177–8) propose that the first activity here is to read and re-read the data to become thoroughly familiar with them, noting also any interesting patterns, any surprising, puzzling or unexpected features, any apparent inconsistencies or contradictions (e.g. between groups, within and between individuals and groups, between what people say and what they do). Then, having become familiar with the text, the process of coding can take place, following the principles and mechanics of coding as set out earlier in this chapter.

Step 7: construct the categories for analysis

Categories are the main groupings of constructs or key features of the text, showing links between units of analysis. For example, a text concerning teacher stress could have groupings such as 'causes of teacher stress', 'the nature of teacher stress', 'ways of coping with stress' and 'the effects of stress'. The researcher will have to decide whether to have mutually exclusive categories (preferable but difficult), how broad or narrow each category will be, the order or level of generality of a category (some categories may be very general and subsume other more specific categories, in which case analysis should only operate at the same level of each category rather than having the same analysis which combines and uses different levels of categories). Categories are inferred by the researcher, whereas specific words or units of analysis are less inferential; the more one moves towards inference, the more reliability may be compromised, and the more the researcher's agenda may impose itself on the data.

Categories must be exhaustive in order to address content validity; indeed Robson (1993, p. 277) argues that a content analysis – a system of categories – can include: subject matter; direction (how a matter is treated, e.g. positively or negatively); values; goals; method used to achieve goals; traits (characteristics used to describe people); actors (who is being discussed); authority (in whose name the statements are being made); location; conflict (sources and levels); and endings (how conflicts are resolved).

This stage of constructing categories is sometimes termed the creation of a 'domain analysis'. This involves grouping the units into domains, clusters, groups, patterns, themes and coherent sets to form domains. A domain is any symbolic category that includes other categories (Spradley, 1979, p. 100). The researcher can recode the data into domain codes, or review the codes used to see how they naturally fall into clusters, perhaps creating overarching codes for each cluster. Hammersley and Atkinson (1983) show how items can be assigned to more than one category, and, indeed, see this as desirable as it maintains the richness of the data. This is akin to the process of 'categorization' (Lincoln and Guba, 1985): putting 'unitized' data into categories of descriptive and inferential information. Unitization is the process of putting data into meaning units for analysis, examining data and identifying what those units are. A meaning unit is simply a piece of datum which the researcher considers to be important; it may be as small as a word or phrase, or as large as a paragraph, groups of paragraphs, or indeed a whole text, provided that it has meaning in itself.

Spradley (1979) suggests that establishing domains can be achieved by four analytic tasks: (a) selecting a sample of verbatim interview and field notes; (b) looking for the names of things; (c) identifying possible terms from the sample; and (d) searching through additional notes for other items to include. He identifies six steps to achieve these tasks: (i) select a single semantic relationship; (ii) prepare a domain analysis sheet; (iii) select a sample of statements from respondents; (iv) search for possible cover terms and include those which fit the semantic relationship identified; (v) formulate structural questions for each domain identified; (vi) list all the hypothesized domains. Domain analysis, then, strives to discover relationships between symbols (p. 157).

Like codes, categories can be at different levels of specificity and generality. Some categories are general and overarching; others are less so. Typically codes are much more specific than categories. This indicates the difference between *nodes* and *codes*. A code is a label for a piece of text; a node is a category into which

different codes fall or are collected. A node can be a concept, idea, process, group of people, place, or indeed any other grouping that the researcher wishes it to be; it is an organizing category. Whilst codes describe specific textual moments, nodes draw together codes into a categorical framework, making connections between coded segments and concepts. It is rather like saying that a text can be regarded as a book, with the chapters being the nodes and the paragraphs being the codes, or the contents page indicating the nodes and the index indicating the codes. Nodes can be related in several ways, for example: one concept can define another; they can be logically related; and they can be empirically related (found to accompany each other) (Krippendorp, 2004, p. 296).

The construction of codes and categories might steer too much the research and its findings, i.e. the researcher may enter too far into the research process. For example, a researcher examining the extra-curricular activities of a school might conclude that the benefits of these are to be found in non-cognitive and non-academic spheres rather than in academic spheres, but this may be fallacious. It could be that it was the codes and categories themselves rather than the data in the minds of the respondents that caused this separation of cognitive/academic spheres from the non-cognitive/non-academic, and that if the researcher had specifically asked about or established codes and categories which established the connection between the academic and non-academic, then he would have found more than he did. This is the danger of using codes and categories to predefine the data analysis.

Step 8: conduct the coding and categorizing of the data

Once the codes and categories have been decided, the analysis can be undertaken. This concerns the actual ascription of codes and categories to the text, as described earlier in this chapter. Mayring (2004, pp. 268–9) suggests that *summarizing content analysis* reduces the material to manageable proportions whilst maintaining fidelity to essential contents, and that *inductive category formation* proceeds through summarizing content analysis by inductively generating categories from the text material. This is in contrast to *explicit content analysis*, the opposite of summarizing content analysis, which seeks to add in further information in the search for intelligible text analysis and category location. The former reduces contextual detail, the latter retains it. *Structuring content analysis* filters out parts of the text in order to construct a cross-section of the material using specified pre-ordinate criteria.

It is important to decide whether to code simply for the existence or the incidence of the concept. This is important, as it would mean that, in the case of the former – existence – the frequency of a concept would be lost, and frequency may give an indication of the significance of a concept in the text. Further, the coding will need to decide whether it should code only the exact words or those with a similar meaning. The former will probably result in significant data loss, as words are not often repeated in comparison to the concepts that they signify; the latter may risk losing the nuanced sensitivity of particular words and phrases. Indeed some speechmakers may deliberately use ambiguous words or those with more than one meaning.

Having performed the first round of coding, the researcher is able to detect patterns and themes and begin to make generalizations (e.g. by counting the frequencies of codes). The researcher can also group codes into more general clusters, each with a code, i.e. begin the move towards factoring the data.

Perhaps the biggest problem concerns coding and scoring of open-ended questions. Two solutions are possible here. Even though a response is open-ended, an interviewer, for example, may pre-code her interview schedule so that while an interviewee is responding freely, the interviewer is assigning the content of her responses, or parts of it, to predetermined coding categories. Classifications of this kind may be developed during pilot studies. Gläser and Laudel (2013) are strong advocates of this pre-coded (*ex ante*) approach, with the codes deriving 'from a theoretically derived set of categories' (p. 14) and the categories deriving from the 'same theoretical framework that already has guided data collection' (p. 15) and which, nevertheless are open to modification. The categories, they aver, should include the material dimensions of the matters in hand, the time dimension and the causal dimension.

Alternatively, data may be post-coded. For example, having recorded the interviewee's response, either by summarizing it during or after the interview itself, or verbatim by recording, the researcher can conduct content analysis of it and apply one of the available scoring procedures – scaling, scoring, rank scoring, response counting, etc.

Extraction of meaning in qualitative data analysis requires identifying 'the category to which the information belongs' (p. 17), in which the unit of analysis is often a paragraph, and the same paragraph may fit more than one category. Gläser and Laudel (2013) are clear to distinguish their process from coding, in that the former extracts meaning rather than text, and is more strongly theory-driven (*ex ante*) and research-question-driven than coding, without 'forcing' data into categories.

Step 9: conduct the data analysis

Once the data have been coded and categorized, the researcher can count the frequency of each code or word in the text, and the number of words in each category. This is the process of retrieval, which may be in multiple modes, for example words, codes, nodes and categories. Some words may be in more than one category, for example where one category is an overarching category and another is a sub-category. To ensure reliability, Weber (1990, pp. 21–4) suggests that it is advisable at first to work on small samples of text rather than the whole text, to test out the coding and categorization, and make amendments where necessary. The complete texts should be analysed, as this preserves their semantic coherence.

Words and single codes on their own have limited power, and so it is important to move to associations between words and codes, i.e. to look at categories and relationships between categories. Establishing relationships and linkages between domains ensures that the richness and 'context-groundedness' of data are retained. Linkages can be found by identifying confirming cases, by seeking 'underlying associations' (LeCompte and Preissle, 1993, p. 246) and connections between data subsets.

Weber (1990, p. 54) suggests that it is preferable to retrieve text by categories rather than single words, as categories tend to retrieve more than single words, drawing on synonyms and conceptually close meanings. One can make category counts as well as word counts and specify at what level the counting can be conducted, for example, words, phrases, codes, categories and themes.

The implication here is that the frequency of words, codes, nodes and categories provides an indication of their significance. This may or may not be true, since subsequent mentions of a word or category may be difficult in certain texts (e.g. speeches). Frequency does not equal importance, and not saying something (withholding comment) may be as important as saying something. Content analysis only analyses what is present rather than what is missing or unsaid (Anderson and Arsenault, 1998, p. 104). Further, as the researcher moves through a piece of text, he or she: may replace nouns with pronouns; must be careful to avoid continuously raising the same issue as such redundancy can lead to unhelpful repetition; must be aware that some issues or topics may be more difficult than others to identify; and must be aware that if the text is short then this might 'inhibit reference to the theme' (Weber, 1990, p. 73).

The researcher can summarize the inferences from the text, look for patterns, regularities and relationships between segments of the text, and test hypotheses. The summarizing of categories and data is an explicit aim of statistical techniques, for these enable trends, frequencies, priorities and relationships to be calculated. There are several approaches and methods for data analysis, for example (Krippendorp, 2004, pp. 48–53):

- extrapolations (trends, patterns and differences);
- standards (evaluations and judgements);
- indices (e.g. of relationships, frequencies of occurrence and co-occurrence, number of favourable and unfavourable items);
- linguistic re-presentations.

Once frequencies have been calculated, statistical analysis can proceed, using, for example:

- factor analysis (to group the kinds of response);
- tabulation (of frequencies and percentages);
- crosstabulation (presenting a matrix where the words or codes are the column headings and the nominal variables, e.g. the newspaper, the year, the gender, are the row headings);
- correlation (to identify the strength and direction of association between words, between codes and between categories);
- graphical representation (e.g, to report the incidence of particular words, concepts, categories over time or over texts);
- regression (to determine the value of one variable/word/code/category in relationship to another): a form of association that gives exact values and the gradient or slope of the goodness-of-fit line of relationship – the regression line;
- multiple regression (to calculate the weighting of independent variables on a dependent variable);
- structural equation modelling (to determine the multiple directions of inferred causality and the weightings of different associations in a pathway analysis of causal relations);
- dendrograms (tree diagrams to show the relationship and connection between categories and codes, codes and nodes).

The calculation and presentation of statistics are discussed in Chapters 38 to 44. At this stage we note that what starts as qualitative data – words – can be converted into numerical data for analysis (though St Pierre and Jackson (2014) argue against frequency counts, suggesting that this betrays the qualitative nature of qualitative data).

If a less quantitative form of analysis is required then, for example, one can establish linkages and

relationships between concepts and categories, examining their strength and direction (how strongly they are associated and whether the association is positive or negative respectively). Robson (1993, p. 401) suggests that drawing conclusions from qualitative data can be undertaken by counting, patterning (noting recurrent themes or patterns), clustering (of people, issues, events etc. which have similar features), relating variables, building causal networks and relating findings to theoretical frameworks.

It is also useful to try to identify core categories (see the later discussion of grounded theory). A core category is that which has the greatest explanatory potential and to which the other categories and sub-categories seem to be repeatedly and closely related (Strauss, 1987, p. 11).

Whilst conducting qualitative data analysis using numerical approaches or paradigms might be criticized for being positivistic, one should note that one of the founders of grounded theory – Glaser – is on record (1996) as saying that not only did grounded theory develop out of a desire to apply a quantitative paradigm to qualitative data, but that paradigmal purity was unacceptable in the real world of qualitative data analysis, in which *fitness for purpose* should be the guide.

The process of analysis continues until 'saturation' is reached, i.e. when additional data do not add anything more to understanding and making meaning of the data (Finfgeld-Connett, 2014, p. 348).

Step 10: summarizing

By this stage the investigator will be in a position to write a summary of the main features of the situation researched so far. The summary will identify key factors, key issues, key concepts and key areas for subsequent investigation. It is a watershed stage during the data collection, as it pinpoints major themes, issues and problems that have arisen, so far, from the data (responsively) and suggests avenues for further investigation. The concepts used will be a combination of those derived from the data themselves and those inferred by the researcher (Hammersley and Atkinson, 1983, p. 178).

At this point, the researcher will have gone through a preliminary sequence of theory generation for qualitative data (Patton, 1980):

1. finding a focus for the research and analysis;
2. organizing, processing, ordering and checking data;
3. writing a qualitative description or analysis;
4. inductively developing categories, typologies, and labels;
5. analysing the categories to identify where further clarification and cross-clarification are needed;
6. expressing and typifying these categories through metaphors;
7. making inferences and speculations about relationships, causes and effects.

Bogdan and Biklen (1992, pp. 154–63) identify several important factors that researchers need to address at this stage, including: forcing oneself to take decisions that will focus and narrow the study and decide what kind of study it will be; developing analytical questions; using previous observational data to inform subsequent data collection; writing reflexive notes and memos about observations, ideas, what is being learned; trying out ideas with subjects; analysing relevant literature whilst conducting the field research; generating concepts, metaphors and analogies and visual devices to clarify the research (Miles and Huberman (1984, 1994) strongly advocate the graphic display of data as an economical means of reducing qualitative data. Such graphics might serve both to indicate causal relationships as well as simply to summarize data).

Step 11: making speculative inferences

This is an important stage, for it moves the research from description to inference. Here the researcher, on the basis of the evidence, posits some explanations for the situation, some key elements and possibly even their causes. It is the process of hypothesis generation or the setting of working hypotheses that feeds into theory generation.

The stage of theory generation is linked to grounded theory, and we turn to this in Chapter 37. Here we provide an example of content analysis that does not use statistical analysis but which nevertheless demonstrates the systematic approach to analysing data that is at the heart of content analysis.

34.6 A worked example of content analysis

In this example the researcher has already transcribed data concerning stress in the workplace from, let us say, a limited number of accounts and interviews with some teachers, and these have already been summarized into key points. Imagine that each account/interview has been written up onto a separate file (e.g. computer file), and now they are all being put together into a single data set for analysis. What we have are already-interpreted, rather than verbatim, data.

Stage 1: extract the interpretive comments that have been written on the data

By the side of each, a code/category/descriptor word has been inserted (in capital letters), i.e. the summary data have already been collected together into thirty-three summary sentences.

1 Stress is caused by deflated expectation, i.e. stress is caused by annoyance with other people not pulling their weight or not behaving as desired, or teachers letting themselves down. **CAUSE**
2 Stress is caused by having to make greater demands on personal time to meet professional concerns. No personal time/space as a cause of stress. Stress is caused by having to compromise one's plans/desires. **CAUSE**
3 Stress comes from having to manage several demands simultaneously, **CAUSE** but the very fact that they are simultaneous means that they can't be managed at once, so stress is built into the problem of coping – it's an insoluble situation. **NATURE**
4 Stress from one source brings additional stress which leads to loss of sleep – a sign that things are reaching a breaking point. **OUTCOME**
5 Stress is a function of the importance attached to activities/issues by the person involved. **NATURE** Stress is caused when one's own integrity/values are not only challenged but called into question. **CAUSE**
6 Stress comes from 'frustration' – frustration leads to stress leads to frustration leads to stress etc. – a vicious circle. **NATURE**
7 When the best-laid plans go wrong this can be stressful. **CAUSE**
8 The vicious circle of stress, inducing sleep irregularity, which in turn induces stress. **NATURE**
9 Reducing stress often works on symptoms rather than causes – it may be the only thing possible **CAUSE** given that the stressors will not go away, but it allows the stress to fester. **CAUSE**
10 The effects of stress are physical which, in turn, causes more stress – another vicious circle. **OUTCOMES**
11 Stress from lowering enthusiasm/commitment/aspiration/expectation. **CAUSE**
12 Pressure of work lowers aspiration which lowers stress. **CAUSE**
13 Stress reduction through companionship. **HANDLING**
14 Stress because of things out of one's control. **CAUSE**
15 Stress through handling troublesome students. **CAUSE**
16 Stress because of a failure of management/leadership. **CAUSE**
17 Stress through absence of fulfilment. **CAUSE**
18 Stress rarely happens on its own; it is usually in combination – like a rolling snowball, it is cumulative. **NATURE**
19 Stress through worsening professional conditions that are out of the control of the participant. **CAUSE** Stress through loss of control and autonomy. **CAUSE**
20 Stress through worsening professional conditions is exponential in its effects. **NATURE**
21 Stress is caused when professional standards are felt to be compromised. **CAUSE**
22 Stress because matters are not resolved. **CAUSE**
23 Stress through professional compromise which is out of an individual's control. **CAUSE**
24 The rate of stress is a function of its size – a big bomb causes instant damage. **NATURE**
25 Stress is caused by having no escape valve; it's bottled up and causes more stress, like a kettle with no escape valve, it will stress the metal and then blow up. **CAUSE**
26 Stress through overload and frustration – a loss of control. Stress occurs when people cannot control the circumstances with which they have to work. **CAUSE**
27 Stress through overload. **CAUSE**
28 Stress through seeing one's former work being undone by others' incompetence. **CAUSE**
29 Stress because nothing has been possible to reduce the level of stress. So, if the boil of stress is not lanced, it grows and grows. **CAUSE NATURE**
30 Handling stress through relaxation and exercise. **HANDLING**
31 Trying to relieve stress through self-damaging behaviour – taking alcohol and smoking. **HANDLING NATURE**
32 Stress is a function of the importance attached to activities by the participants involved. **NATURE**
33 The closer the relationship to people who cause stress, the greater the stress. **NATURE**

The data have been coded very coarsely into four main categories. It might have been possible to have coded the data far more specifically, for example, each specific cause has its code, and indeed one school of thought would argue that it is important to generate the specific codes first. One can code for words (and, thereafter, the frequency of words) or meanings – it is sometimes dangerous to go for words rather than meanings, as people say the same things in different ways

Stage 2: sort data into key headings/areas

The codes that have been used fall into four main areas:

a causes of stress
b nature of stress
c outcomes of stress
d handling stress

Stage 3: list the topics within each key area/heading and put frequencies in which items are mentioned

For each main area the relevant data are presented together, and a tally mark (/) is placed against the number of times that the issue has been mentioned by the teachers.

a Causes of stress
- Deflated expectation/aspiration /
- Annoyance /
- Others not pulling weight /
- Others letting themselves down /
- Professional demands, for example, troublesome students /
- Demands on personal time from professional tasks /
- Difficulties of the job /
- Loss of personal time and space /
- Compromising oneself /one's professional standards and integrity ///
- Plans go wrong /
- Stress itself causes more stress /
- Inability to reduce causes of stress /
- Lowering enthusiasm/commitment/aspiration /
- Pressure of work /
- Things out of one's control //
- Failure of management/leadership /
- Absence of fulfilment /
- Worsening professional conditions /
- Loss of control and autonomy //
- Inability to resolve situation /
- Having no escape valve /
- Overload at work /
- Seeing one's work undone by others /

b Nature of stress
- Stress is a function of the importance attached to activities/issues by the participants /
- Stress is inbuilt when too many simultaneous demands are made, i.e. it is insoluble /
- It is cumulative (like a snowball) until it reaches a breaking point /
- Stress is a vicious circle //
- The effects of stress are exponential /
- The rate of stress is a function of its size /
- If stress has no escape valve then that causes more stress //
- Handling stress can lead to self-damaging behaviour (smoking/alcohol) /
- The closer the relationship to people who cause stress, the greater the stress /

c Outcomes of stress
- Loss of sleep/physical reaction //
- Effects of stress themselves cause more stress /
- Self-damaging behaviour /

d Handling stress
- Physical action/exercise /
- Companionship /
- Alcohol and smoking /

Stage 4: go through the list generated in Stage 3 and put the issues into groups (avoiding category overlap)

Here the grouped data are re-analysed and re-presented according to possible groupings of issues under the four main headings (causes, nature, outcomes and handling of stress: (a)–(d) below).

a *Causes of stress*:

i Personal factors
- Deflated expectation/aspiration /
- Annoyance /
- Demands on personal time from professional tasks /
- Loss of personal time and space /
- Stress itself causes more stress /
- Inability to reduce causes of stress /
- Lowering enthusiasm/commitment/aspiration /
- Things out of one's control //
- Absence of fulfilment /
- Loss of control and autonomy //
- Inability to resolve situation /
- Having no escape valve /

ii Interpersonal factors
- Annoyance /
- Others not pulling weight /
- Others letting themselves down /
- Compromising oneself/one's professional standards and integrity ///
- Seeing one's work undone by others /

iii Management
- Pressure of work /
- Things out of one's control //
- Failure of management/leadership /
- Worsening professional conditions /
- Seeing one's work undone by others /

- **iv** Professional matters
  - Others not pulling weight /
  - Professional demands, for example, troublesome students /
  - Demands on personal time from professional tasks /
  - Difficulties of the job /
  - Compromising oneself/one's professional standards and integrity ///
  - Plans go wrong /
  - Pressure of work /
  - Worsening professional conditions /
  - Loss of control and autonomy //
  - Overload at work /
- **b** *Nature of stress*
  - **i** Objective
    - It is a function of the importance attached to activities issues by the participants /
    - Stress is inbuilt when too many simultaneous demands are made, i.e. it is insoluble /
    - It is cumulative (like a snowball) until it reaches a breaking point /
    - Stress is a vicious circle //
    - The effects of stress are exponential /
    - The rate of stress is a function of its size /
    - If stress has no escape valve then that causes more stress //
    - Handling stress can lead to self-damaging behaviour (smoking/alcohol) /
  - **ii** Subjective
    - Stress is a function of the importance attached to activities issues by the participants /
    - The closer the relationship to people who cause stress, the greater the stress /
- **c** *Outcomes of stress:*
  - **i** Physiological
    - Loss of sleep /
  - **ii** Physical
    - Physical reactions //
    - Increased smoking /
    - Increased alcohol /
  - **iii** Psychological
    - Annoyance /
- **d** *Handling stress*
  - **i** Physical
    - Physical action/exercise /
  - **ii** Social
    - Social solidarity, particularly with close people ///
    - Companionship /

Stage 5: comment on the groups or results in Stage 4 and review their messages

Once this stage has been completed, the researcher is then in a position to draw attention to general and specific points, for example:

1. There are very many causes of stress (give numbers).
2. There are very few outlets for stress, so it is inevitable, perhaps that stress will accumulate.
3. Causes of stress are more rooted in personal factors than any others – management, professional etc. (give frequencies here).
4. The demands of the job tend to cause less stress than other factors (e.g. management), i.e. people go into the job knowing what to expect, but the problem lies elsewhere, with management (give frequencies).
5. Loss of control is a significant factor (give frequencies).
6. Challenges to people and personal integrity/self-esteem are very stressful (give frequencies).
7. The nature of stress is complex, with several interacting components (give frequencies).
8. Stress is omnipresent.
9. Not dealing with stress compounds the problem; dealing with stress compounds the problem.
10. The subjective aspects of the nature of stress are as important as its objective nature (give frequencies).
11. The outcomes of stress tend to be personal rather than outside the person (e.g. systemic, or system-disturbing) (give frequencies).
12. The outcomes of stress are almost exclusively negative rather than positive (give frequencies).
13. The outcomes of stress tend to be felt non-cognitively, for example, emotionally and psychologically, rather than cognitively (give frequencies).
14. There are few ways of handling stress (frequencies), i.e. opportunities for stress reduction are limited.

The stages in this example illustrate several of the issues raised in the preceding discussion of content analysis, though the example here does not undertake word counts or statistical analysis, and, being fair to content analysis, this could – some would argue even 'should' – be a further kind of analysis. This analysis raises several issues:

- the researcher has looked *within* and *across* categories and groupings for patterns, themes and generalizations, as well as exceptions, unusual observations etc.;

- the researcher has had to decide whether frequencies are important, or whether an issue is important even if it is only mentioned once or a few times;
- the researcher has looked for, and reported, disconfirming as well as confirming evidence for statements;
- the final stage of the analysis is theory generation, to account for what is being explained about stress. It might also be important, in further analysis, to try to find causal relationships here: what causes what and the directions of causality; it may also be useful to construct diagrams (with arrows) to show the directions, strength and positive/negative nature of stress.

34.7 Reliability in content analysis

There are several issues to be addressed in considering the reliability of texts and their content analysis, indeed in analysing qualitative data using a variety of means, for example:

- Witting and unwitting evidence (Robson, 1993, p. 273): witting evidence is that which was intended to be imparted; unwitting evidence is that which can be inferred from the text, and which may not be intended by the imparter.
- The text may not have been written with the researcher in mind and may have been written for a very different purpose from that of the research (a common matter in documentary research); hence the researcher will need to know or be able to infer the intentions of the text.
- The documents may be limited, selective, partial, biased, non-neutral and incomplete because they were intended for a different purpose other than that of research (an issue of validity as well as of reliability).
- It may be difficult to infer the direction of causality in the documents – they may have been the cause or the consequence of a particular situation.
- Classification of text may be inconsistent (a problem sometimes mitigated by computer analysis), because of human error, coder variability (within and between coders) and ambiguity in the coding rules (Weber, 1990, p. 17).
- Texts may not be corroborated or be able to be corroborated.
- Words are inherently ambiguous and polyvalent (the problem of homographs), for example, what does the word 'school' mean? A building; a group of people; a particular movement of artists (e.g. the impressionist school); a department (a medical school); a noun; a verb (to drill, to induct, to educate, to train, to control, to attend an institution); a period of instructional time ('he stayed after school to play sports'); a modifier (e.g. a school day); a sphere of activity (e.g. 'the school of hard knocks'); a collection of people adhering to a particular set of principles (e.g. the utilitarian school); a style of life (e.g. 'a gentleman from the old school'); a group assembled for a particular purpose (e.g. a gambling school), and so on. This is a particular problem for computer programs which may analyse words devoid of their meaning.
- Coding and categorizing may lose the nuanced richness of specific words and their connotations.
- Category definitions and themes may be ambiguous, as they are inferential.
- Some words may be included in the same overall category but they may have more or less significance in that category (and a system of weighting the words may be unreliable).
- Words that are grouped together into a similar category may have different connotations and their usage may be more nuanced than the categories recognize.
- Categories may reflect the researcher's agenda and imposition of meaning more than the text may sustain or the producers of the text (e.g. interviewees) may have intended.
- Aggregation may compromise reliability. Whereas sentences, phrases and words and whole documents may have the highest reliability in analysis, paragraphs and larger but incomplete portions of text have lower reliability (Weber, 1990, p. 39).
- A document may deliberately exclude something for mention, overstate an issue or understate an issue.

At a wider level, the limits of content analysis are suggested by Ezzy (2002, p. 84), where he argues that, due to the pre-ordinate nature of some forms of coding and categorizing, content analysis is useful for testing or confirming a pre-existing theory rather than for building a new one, though this perhaps understates the ways in which content analysis can be used to generate new theory, not least through a grounded theory approach (see Chapter 37). In many cases content analysts know in advance what they are looking for in text, and perhaps what the categories for analysis will be. Ezzy (p. 85) suggests that this restricts the extent to which the analytical categories can be responsive to the data, thereby confining the data analysis to the agenda of the researcher rather than the 'other'. Indeed Finfgeld-Connett (2014) draws attention to the risk of 'verifying the obvious' (p. 342) by a deductive rather than an inductive approach to content analysis, and

Mayring (2004, p. 269) argues that if the research question is very open or if the study is exploratory, then more open procedures than content analysis may be preferable, for example, grounded theory.

Though inductive approaches may be ruled out of the early stages of content analysis, they may feature in the later stages, as themes and interpretations may emerge inductively from the data and the researcher, rather than only or necessarily from the categories or pre-existing theories themselves. Hence to suggest that content analysis denies induction or is confined to the testing of pre-existing theory (Ezzy, 2002, p. 85) is to misrepresent the flexibility of content analysis. Indeed Flick (1998) suggests that pre-existing categories may need to be modified if they do not fit the data. Both inductive and deductive approaches are important in qualitative data analysis.

Companion Website

The companion website to the book provides data files and PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Discourses

CHAPTER 35

Conversations, narratives and autobiographies as texts

Whilst coding represents one major approach to analysing qualitative data (discussed in the previous chapters), nevertheless it is only one way. In this chapter we provide very different methods of analysing qualitative data, founded in part on discourse analysis, and we address:

- discourse analysis and critical discourse analysis
- conversational analysis
- narrative discourse
- autobiography

These approaches do not use coding and they keep together the text rather than fragmenting it as in coding. In each instance we provide a worked example, so that readers can understand the issues more clearly.

35.1 Discourse analysis and critical discourse analysis

Words carry many meanings; they are nuanced and highly context-sensitive. Meanings are always contextual; what we say, hear, write and read are always connected to their contexts (Andrelchik, 2016, p. 137), for example, physical, temporal, interpersonal (shared understandings and evaluations), cultural, societal, valuative, ideological etc., and to the hidden assumptions in which they are embedded. As Denscombe (2014) suggests, we can never take qualitative data, in this case texts, at face value; they have to be deconstructed to expose their hidden messages (p. 288).

In qualitative data analysis, interpretation and analysis are often fused and, indeed, concurrent or simultaneous. It is naive to suppose that the qualitative data analyst can separate analysis from interpretation, because words themselves are interpretations and open to interpretation. In this chapter we show how qualitative researchers can analyse discourses, be they in written texts or transcriptions of spoken conversations.

'Discourse' is a slippery term. It designates how language represents meanings, conventions, codes in specific socio-cultural, temporal and historical contexts, how linguistic practices are both located in, and create, their own contexts (Hammersley, 2013). Discourses shape and are shaped by different meanings, and people are members of different discourse communities – those communities which hold similar values, views, ideas and ways of looking at the world. Discourses are 'social texts … particular signifying practices of a given group [that] are both constituted by and constitutive of the discursive field in which members of the group live and function' (Elbaz, 1990, p. 15).

Discourse analysis is an umbrella term with many different meanings and types, and we address some of these here.

Discourse analysis can include linguistic matters in their cultural, ideological, political (micro and macro), historical and societal contexts, and in the assumptions in which they are embedded. Denscombe (2014, p. 290) suggests several issues which discourse analysts can address, for example:

- the discourse in context (variously defined as above), be it in the form of text, conversation, narrative, biography etc., and in terms of which groups and conditions they represent;
- how power, interests and influence operate through language;
- whose perspective/version is being portrayed in the discourse, and what alternatives are possible;
- what is absent, silenced, neglected or suppressed in the discourse;
- what linguistic devices are present in the discourse.

We distinguish between discourse analysis and critical discourse analysis.

Discourse analysis

At one level discourse analysis investigates language and the meanings that are given to texts which create and shape knowledge and behaviour (cf. Sinclair and Coulthard, 1975; Lemke, 1989; Gee, 2005). It examines language in use, linguistic features and forms, language patterns and units, and how meanings are constructed through texts beyond the single sentence level (cf. Wetherell *et al*., 2001; Souto-Manning, 2014).

Any text can be the bearer of several discourses, and a single text can be deconstructed into several meanings. Texts are set in social contexts (Gee, 1996, 2005) and reality is a social construction, so discourse analysis has to take account of the social contexts in which the texts are set. Hence, at another level, discourse analysis looks beyond linguistic features to the links between language and society, language and the social context in which they are set. We give examples of these below, in conversational analysis, narrative analysis and autobiographical analysis. We also introduce critical discourse analysis.

To constitute a discourse, Renkema (2004) suggests that a text – spoken or written – must fulfil seven main criteria:

1. *Cohesion*: there must be a grammatical relationship between the different parts of the text or conversation.
2. *Coherence*: the sequence and structure of the text must make sense and 'hang together'.
3. *Intentionality*: the text or conversation must be written or spoken intentionally.
4. *Acceptability*: it has to be accepted or acceptable to its intended audience.
5. *Informativeness*: it must include new information.
6. *Situationality*: the context, conditions and circumstances in which it is embedded must be known and made explicit.
7. *Intertextuality*: the text or conversation must go beyond simply the text to an outer world of the reader, interpreter, researcher and other agents.

Discourse analysis regards talk and texts as social practices (Potter and Wetherell, 1994, p. 48), agentic, interactive and socially constructivist (Clifton, 2006). Discourse analysis is influenced by speech act theory (Austin, 1962; Searle, 1969) of locutions (what is uttered), illocutions (doing something whilst saying something) and perlocutions (achieving something by saying something), and by textual analysis, ideological analysis and ideology critique (Potter and Wetherell, 1994, p. 47). Here language is not simply a 'representation of an inner mental state or a conduit for one's thoughts' (Paulus and Lester, 2016, p. 408); rather it is used to do something, to achieve something; it is oriented to action (p. 408). A discourse is language in use as a social practice (Fairclough, 1992).

The researcher analysing discourses in their linguistic form can examine, for example: meanings, form, style genre, register, order, cohesion, episodes, metaphors, categories, aporias, metonyms, key issues, repetitions, mimesis, shibboleths and networks (e.g. Lemke, 1989; Tunnicliffe and Reiss, 1999; Andrelchik, 2016).

Wetherell *et al*. (2001) add to this the broader social context, identifying four methods of discourse analysis, analysing:

1. words in context (e.g. cultural, social, group) as ways in which people express themselves and in which context influences the language used, i.e. how context affects meaning and language;
2. interactions conducted through language;
3. patterns of language use (e.g. language used to express wishes, emotions, reactions, to create scenarios, to give information);
4. links between language and the constitution, structure and nature of society, often focusing on differentials of power and their reproduction.

Texts themselves carry many levels of meaning, and the qualitative researcher must strive to catch these different levels or layers. Further, researchers are often part of the world that they are actually writing about, and, even if they are not, they bring their own culture, norms and values to bear in conducting, analysing, interpreting and reporting the research. Issues of projection and countertransference are important: the researcher's analysis may say as much about the researcher as about the text being analysed, both in the selection of the levels of analysis, the actual analysis, and the inference of intention and function of discourses in the text, with their corollary in the key issue of reflexivity.

Critical discourse analysis

Critical discourse analysis moves beyond the purely linguistic level set out above, and examines the exercise of power through discourses, texts, conversations and narratives (e.g. Fairclough, 1995; Gee, 1996), i.e. how power operates through all types of discourses. Here language is not neutral and 'there are no "neutral" words and forms' (Bakhtin, 1981, p. 293). Hence critical discourse analysis links language and society, and is a way of thinking, perhaps culturally or institutionally conditioned, which, like a paradigm, is legitimated by communities, often those with power. Critical discourse analysis reveals how power operates and is constituted, shaped, legitimated, maintained, regulated and challenged in and through language and discourses (e.g. Fairclough, 1992, 1995; Fraser, 2004). As Foucault (1998, p. 101) remarks, 'discourse can be both an instrument and an effect of power'; it is the 'tactical dimension' of the operation of power in individuals, groups and organizations.

Power is immanent in discourse; it is one of its defining features, and power relations are intrinsically discursive. Indeed the three examples in this chapter all

concern power, its possession, denial, operations, fluidity, negotiation, relations, absence, and so on. In critical discourse analysis, researchers examine how language 'colonized everyday life through institutional discourses' (Souto-Manning, 2014, p. 160), i.e. how power, operating through language, reproduces power differentials in society and the lifeworlds of its members (the 'taken-for-granted universe of daily social activity' which 'always remains in the background') (Habermas, 1987b, p. 131).

Critical discourse analysis, stemming in large part from the Frankfurt School of critical theory (see Chapter 3), is linked to ideology critique of power and power relations, interests and their operations, and has an explicit agenda of critiquing inequalities, discrimination and ideological domination; it seeks to transform and emancipate society and its members, and redress illegitimate imbalances of power and influence within relationships. It interrogates ideological, political, social and economic power and how this is created, achieved, perpetuated and reproduced through discourses.

Critical discourse analysis works with, for example, the voices of marginalized, disempowered and oppressed groups, and it critiques the illegitimate power of dominant groups and the role of language in this. We discuss critical theory much more fully in Chapter 3, and we advise readers to review that chapter. Critical discourse analysis looks at a social problem, not just a research question (Fairclough, 2003), and uses linguistic analysis to identify and expose ideology and power at work in society. It links micro- and macro-analysis, and this differentiates it from purely linguistic discourse analysis which typically operates much more at the micro-level.

In critical discourse analysis, texts are interrogated not only for what they include but what they exclude: structured silences and how these embody differentials of power and influence in society. They also concern what is implied, though not overtly spoken. In other words, the researcher must read along, between and beyond the lines.

Below we take three examples of ways in which researchers can conduct discourse analysis: a conversation, a narrative and an autobiographical text. A conversation involves more than one person; a narrative is written by a single person; and an autobiography is a narrative that is written by, and in, the first person.

35.2 A conversational analysis

Conversation analysis is one type of discourse analysis, looking at a conversation between two or more people in a specific context, examining what they say, how they say it, for what reasons or purposes, and using what kinds of interaction, sequences, contexts and structures in the conversation. It is the 'formal analysis of everyday situations' (Flick, 2009, p. 334), how participants create meanings of their conversational situations and achieve their intended actions and outcomes, and how they get things done through conversations (e.g. speech acts). Though some forms of conversational analysis have been criticized for their focus on the trivial (Hammersley, 2013), there is a much richer story to be told, as we indicate below.

Conversation analysis can examine turn-taking, sequences and the evolution of a conversation, interaction in conversation, cohesion, purposes of conversations and the expectations of participants, language rights and roles in conversations, strategizing in and through language. Further, it can focus on issues of power, domination and the constructions and reproduction of power in texts and conversations, and language in social contexts and interactions.

Conversational analysis is a rigorous investigation of features of a conversation, how it is generated and constructed, how it operates, what its distinguishing features are, how participants construct their own meanings in the conversational situation (Clifton, 2006, p. 203), and how conversations are located within their several contexts (Vaughan, 2012). The following example of a conversational analysis exposes the multi-leveled interpretations that can be made of conversations as discourses.

The example is of a transcript of a short conversation in an infant classroom (Cummings, 1985) which contains the potential for several levels of analysis; several meanings can be deconstructed from this conversation, and some of them concern power. The analysis also raises the issue of reflexivity in the researcher. The example is in the tradition of Sinclair's and Coulthard's (1975) seminal work on 'institutional talk' in classrooms. Here, as in many examples of conversational analysis, a single episode is analysed.

This is a class of twenty-seven 5–6-year-old children, with the children seated on a carpet and the teacher seated on a chair. A new set of class books has arrived for the children's free use. After a few days the teacher feels that the class and the teacher should look at them together.

Let us explore the levels of analysis here. If we ask 'what is being learned here by the children?' there are

BOX 35.1 TRANSCRIPT OF A CONVERSATION IN AN INFANT CLASSROOM

1	T	Right. Let's have a look at this book – 'cause these are – smashing books. Are you enjoying them?
2	CC	Yes // Yes // Yes.
3	T	What's it called this one? Can anyone tell me?
4	CC	Splosh//.
5	C	//Splish//
6	CC	//Splosh//
7	T	Splosh not splish. It's got an 'o' in the middle. Splosh.
8	CC	Splish splosh//
9	C	//Splosh//
10	T	Splosh it says. (Reading) A dog, a pig, a cow, a bear, a monkey, a donkey, all in the –
11	T & CC	Air
12	T	((Showing pictures)) There's the dog and the pig and the cow and the bear and the monkey and the donkey all in the air. What are they in the air in?
13	CC	()//
14	T	//Put up your hand if you know. Vicky. ((Buzz of children trying to get in))
15	C	The cow's popped it
16	Vicky	// A hot air balloon.
17	T	A hot air balloon
18	C (as 15)	The cow's popped it.
19	T	What's the cow popped it with?
20	CC	Horn//horn//ear//horn//his horn.
21	T	His horn – it's not his *ear* is it – his ears//
22	CC	((Laughing))//
23	T	are down here. It's his horn that's sticking up.
24	CC	((Laughing))
25	T	What does this mean then? ((showing stylized drawings of air escaping))
26	C	Air's coming out//
27	C	//Air//
28	T	The air coming out of the balloon isn't it. Can you *really* see the air coming out of a balloon?
29	CC	No. No. No.
30	T	No – very often in cartoons it look like that doesn't it.
31	C	I can see gas coming out of my mouth when I () on the windows.
32	T	*When* can you see it?
33	C	When it's steamed up.
34	T	Yes. And if//

continued

continued

35	C	//When it's cold.
36	T	When it's cold. When you hhh//
37	C	//When your breath – when your breath turns over and it steams on the – steams on the window.
38	T	Yes//
39	C	And it//
40	T	But only when it's –
41	CC	Cold.
42	T	Cold. Only when it's cold.
43	C	I saw a airship.
44	T	Did you. When? Where?
45	C	On the park.
46	T	Really.
47	CC	I have // I saw // Mrs. Cummings
48	T	Shh – Yes, Luke.
49	Luke	When we – when the airship was aft – when it was finished and the Pope was on we took the telly outside – and – we took the telly outside – and – and we saw – we saw the good old airship.
50	T	Did you.
51	Luke	An air balloon as well.
52	T	It's not good *old* airship – it's Goodyear – the Goodyear airship.
53	CC	Good year // Mrs. Cummmings
54	T	Good year. Yes.
55	C	I seed the airship. ((Many children talking at once))
56	T	Just a moment because I can't hear Luke because other people are chattering. You'll have your turn in a minute.
57	Luke	I said Mummy, what's that thing with the 'X' on the back and she didn't answer me but when I () it off () an air balloon.
58	T	Yes. It was an airship. Yes. Actually I think we saw it at school one day last summer, didn't we.
59	CC	Yes.
60	T	We all went outside and had a look at it. It was going through the sky.
61	CC	()//
62	Luke	Mrs Cummings //
63	C	()
64	T	Uuhm – Ben
65	Ben	I remember that time when it came () over the school.
66	T	Did you. Y-//
67	Ben	//() the same one came over my house when I went home.
68	T	Yes. Paul.

69	Paul	I went to a airship where they did //
70	Luke	//It flew over my house ()//
71	T	//Just a moment Paul because Luke is now interrupting. We listened to him very carefully. Now it's his turn to listen to us.
72	Paul	I went to see a airship where they take off and when I – when I got there I saw () going around.
73	T	Oh … What keeps an airship up in the air?
74	CC	Air//air//gas//
75	Luke	Mrs Cummings.
76	T	Air or gas. Yes. If it's air, it's got to be *hot* air to keep it up – or gas. Now put your hands down for a minute and we'll have a look at the rest of the book. ((Reading)) Help said Pig. There he is saying help. ((There is a cartoon-like 'bubble' from his mouth with 'help' written in)) Help said –
77	CC	Monkey
78	T	Help said donkey. It's gone wonky.
79	CC	h-h-h ((untranscribable talk from several children))
80	T	Look as though it had gone wonky once before. What makes me say that?
81	C	Because – because there's – something on the balloon.
82	T	Mmm. There's already a patch on it isn't there to cover a hole ((reading)) A bear, a cow, a pig, a dog, a donkey and a monkey *all – in – a* – and this is the word you got wrong before – all in a –
83	C	Bog
84	T	Bog – Who said it said dog at the end and it shouldn't?
85	James	Me.
86	T	*James*! James, what does it start with?
87	James	'b' for 'bog.
88	T	'b'. It only goes to show how important it is to get them the right way round//
89	C	//Toilet//
90	T	No. I don't think it means toilet.
91	CC	((Laughter))
92	T	I don't think they're in a toilet.
93	CC	((Laughter))
94	T	What's a bog when it isn't a toilet?
95	Gavin	My brother call it the bog.
96	T	Yes. Lots of people do – call a toilet a bog but I don't think that's what this means.
97	Paul	(fall in) something when – when it sticks to you.
98	T	Yes, you're quite right Paul. It's somewhere that's very sticky. If you fall in its very sticky //
99	C	()
100	T	It's not glue

continued

continued

101	C	It's called a swamp.
102	T	Swamp is another word for it, good boy – but it's not glue, it's usually mud or somewhere. It's usually somewhere – somewhere in the countryside that's very wet. ((Many children talking))
103	C	Mrs. Cummings what ()
104	T	Just a moment you are forgetting to listen. You *are* remembering to think and to talk but you're forgetting to listen and take your turn. Now Olga.
105	Olga	Once my daddy –

Source: Cummings (1985)

several kinds of response. At a formal level, first, there is a *curricular* response: the children are learning a little bit of language (reading, speaking, listening, vocabulary, spelling, letter orientation (e.g. 'bog' and 'dog')), science (condensation, hot and cold, hot air rising, hot air and gas-filled balloons) and soil (a muddy swamp). That concerns the academic curriculum, as it were.

At a second level the children are learning other aspects of development, not just academic but personal, social, emotional and interpersonal, for example turn-taking and organization, exchanging, asking questions, giving responses, cooperation, shared enjoyment, listening to each other, contributing to a collective activity, taking risks with language (the risqué joke about the word 'bog' with its *double entendre* of a swamp and an impolite term for a toilet), and action formation (doing and achieving things through language).

At a third level one can see language rights, nature and uses in the classroom (cf. Edwards, 1980; Walsh, 2006; Vaughan, 2012). Here the text usefully provides numbered lines to assist analysis and to preserve the chronology of events, an essential feature of conversational analysis. One can observe the following, using a closer textual analysis:

- A great deal of the conversation follows the sequence of teacher → student → teacher → student and so on (e.g. lines 28–48); here the analysis of the sequence of the conversation is important. Here it is rare for the sequence to be broken, for instance teacher → student → student (e.g. lines 3–7 and 14–16), and where the sequence is broken, it is at the teacher's behest, and with individual children only (lines 48–52, 64–9, 84–8, 94–8). Where the conventional sequence is broken without the teacher's blessing the teacher intervenes to restore the sequence or to control the proceedings (lines 54–6, 70–1, 103–4).
- It appears that many of the twenty-seven children are not joining in very much – the teacher only talks directly to, or encourages to talk, a few named children individually: Vicky, Luke, Ben, Paul, James and Olga.
- There are almost no instances of children *initiating* conversations (e.g. lines 43, 65, 101); most of the conversations are in *response* to the teacher's initiation (e.g. lines 3, 11, 20, 25, 28, 32, 34, 36 etc.); again the analysis of the sequence of the conversation is important here.
- The teacher only follows up on a child's initiation when it suits her purposes (lines 43–6).
- The teacher teaches the children about turn-taking (lines 56, 71).
- Nearly everything goes through, or comes from the teacher who mediates everything.
- Where a child says something that the teacher likes or is in the teacher's agenda for the lesson, then that child is praised (e.g. lines 34, 42, 54, 58, 76 and 96, 98 (the word 'yes'), 102) and the teacher repeats the child's correct answer (e.g. lines 16–17, 20–1, 29–30, 35–6, 41–2).
- The teacher feeds the children with clues as to the expected answer (lines 10–11, 40–1, 76–7, 82–3).
- Where the conversation risks being out of the teacher's control the teacher becomes much more explicit in the classroom rules (e.g. lines 56, 71, 104); again the sequence of the conversation is important here.
- When the teacher decides that it is time to move on to get through her agenda she closes off further discussion and moves on (line 76); as before, the analysis of the sequence of the conversation is important here.
- The teacher is prepared to share a joke (lines 90–3) to maintain a good relationship but then moves the conversation on (line 94).

- Most of the conversation, in speech act terms, is perlocutionary (achieving the teacher's intended aim of the lesson) rather than illocutionary (an open-ended and free-range, multi-directional discussion where the outcome is unpredictable).
- The teacher talks a lot more than the children.

At a fourth level, employing speech act theory, we can see how some utterances in the conversation are intended not only to involve the children but, thereby, to control them. Lines 76, 82 and 102 show the teacher taking charge of the conversation by talking a lot, which has the effect of keeping the children quiet and of reining in the children's talk: a perlocutionary speech act that reasserts classroom control through talk, and it is noticeable that this is later in the conversation rather than earlier, as the children may be starting to become restless. Then, in line 104, when that strategy has not worked particularly effectively, the teacher takes a more overt control strategy and tells children to listen and take turns.

At a fifth level, one can begin to theorize from the materials here. It could be argued, for example, that the text discloses the overt and covert operations of power, to suggest, in fact, that what the children are learning very effectively is the hidden curriculum in which power is a major feature, for instance:

- The teacher has the power to decide who will talk, when they will talk, what they will talk about and how well they have talked (cf. Edwards, 1980).
- The teacher has the power to control many children (twenty-seven children sitting on the floor whilst she, the teacher, sits on a chair, i.e. physically above them).
- The teacher controls and disciplines *through* her control of the conversation and its flow, and, when this does not work (e.g. lines 56, 71, 104) then her control and power become more overt and naked. In this sense it is important to note that conversational analysis often addresses the sequence of the conversation, and this is pertinent here: once a gentle control strategy does not work a more overt strategy is brought into play. What we have here is also an example of Bernstein's (1975) 'invisible pedagogy', for example: where the control of the teacher over the child is implicit rather than explicit; where the teacher arranges the *context*; and where there is a reduced emphasis upon the transmission and acquisition of specific skills.
- What we have here is an example of how talk in classrooms is 'institutionalized' (Sinclair and Coulthard, 1975), and of the importance of the children learning the hidden curriculum of classrooms (Jackson, 1968), wherein they have to learn how to cope with power and authority, praise, denial, delay, membership of a crowd, loss of individuality, rules, routines and socially acceptable behaviour. As Jackson says, if children are to do well in school then it is equally, if not more important that they learn and abide by the hidden curriculum rather than the formal curriculum.
- What we have here is also an example of Giddens's (1976, 1984) structuration theory, wherein the conversation in the classroom is the cause, the medium and the outcome of the perpetuation of the *status quo* of power asymmetries and differentials in the classroom, reinforcing the teacher's control, power and authority.
- The teacher has been placed in a difficult position by being the sole adult with twenty-seven children, and so her behaviour, motivated perhaps benevolently, is, in fact a coping or survival strategy to handle and manage the discipline with large numbers of young and demanding children – crowd control.
- The children are learning to be compliant and that their role is to obey, and that if they are obedient to a given agenda then they will be rewarded.
- The 'core variable' (in terms of grounded theory') is 'power': the teacher is acting to promote and sustain her power. When it can be asserted and reinforced through an invisible pedagogy then it is covert; when this does not work it become overt.

Now, one has to ask whether, at the fourth level, the researcher is reading too much into the text, over-interpreting it, driven by her own personal hang-ups or negative experiences of power and authority, and over-concerned with the issue of discipline, projecting too much of herself onto the data interpretation. Maybe the teacher is simply teaching the children socially acceptable behaviour and moving the conversation on productively, exercising her professional task sensitively and skilfully, building in the children's contributions, and her behaviour has actually nothing to do with power. Further, one can observe at level four that several theories are being promulgated to try to explain the messages in the text, and one has to observe the fertility of a simple piece of transcription to support several grounded or pre-ordinate/pre-existing theories. The difficult question here is, 'which interpretation is correct?' Here there is no single answer; perhaps they are all correct.

The classroom transcription only records what is said. People will deliberately withhold information; some children will give way to more vocal children, and others may be off task. What we have here is only one medium that has been recorded. Even though the transcription tries to note a few other features (e.g. children talking simultaneously), it does not catch all the events in the classroom. How do we know, for example, whether most children are bored, or if some are asleep, or some are fighting, or some are reading another book and so on? All we have here is a selection from what is taking place, and the selection is made on what is transcribable.

One can see in this example that the text is multilayered. At issue here are the levels of analysis that are required, or legitimate, and how analysis is intermingled with interpretation. In qualitative research, analysis and interpretation frequently merge. This raises the issues of validity and reliability. What we have here is the 'double hermeneutic': as researchers we are members of the world that we are researching, so we cannot be neutral; we live in an already-interpreted world. Look at the example above:

- The teacher and the children act on the basis of their interpretations of the situation (their 'definitions of the situation').
- The lived actions are converted from one medium (observations, actions and live events) to another (written) by choosing to opt only for transcription: an interpretation of their interpretation.
- The researcher then interprets the written data (a third hermeneutic) and writes an unavoidably selective account (a fourth – quadruple – hermeneutic – an interpretation of an interpretation of an interpretation of an interpretation!).
- The reader then brings his/her own biography and background to interpret the researcher's written interpretation (a fifth – quintuple – hermeneutic).

Given the successive interpretations, it is difficult not to suggest that reliability and validity can easily be compromised in qualitative research. Reflexivity, as the disclosure of one's possible biased interpretations, does little to reduce them; I can state my possible biases and interpretations but that does not necessarily stop me or them from being selective and biased. This suggests, perhaps, the limits of reflexivity. In connection with increasing reliability and validity, reflexivity is not enough.

35.3 Narrative analysis

Narrative analysis, as with discourse analysis, encompasses different approaches which adopt differing ontological and epistemological positions on the social world and how it is construed and constructed (Gee, 2005; Kennedy-Lewis *et al*., 2016). A narrative is a story with an individual perspective, written in the teller's own voice, in which the teller controls what is released, when and in what sequence. A narrative can also process and condense large amounts of data, to provide a 'more complex and complete picture of social life' (Hendry, 2007, p. 489); it has a purpose, a plot and a human element (Denscombe, 2014, p. 291). Narrative analysis creates a unity out of disparate elements; it creates a story. Narratives often include and evoke emotional and aesthetic elements and responses respectively (Rogan and de Kock, 2005; Barone, 2007; Hendry, 2007; Rosiek and Atkinson, 2007). As Rosiek and Atkinson write: 'humans generally live a storied existence' (p. 503). Indeed Hendry (2007) suggests that narratives are 'highly seductive' (p. 488) and a form of democratic research (p. 490).

We distinguish here between: (a) 'narrative analysis' (Polkinghorne, 1995, p. 12), where the researcher produces a narrative from data, events, happenings and information from various sources to create a plot, a thematic line a temporal sequence or structure; and (b) 'analysis of narratives' (p. 12), where the researcher analyses the narratives produced by other parties. In the former, the narrative is the *consequence* of the research whilst in the latter it is the *source* of the researcher's knowledge (Smeyers and Verhesschen, 2001, p. 76). The example below is of the latter. However, the comments we make here apply to both (a) and (b).

Polkinghorne (1995) describes a narrative as 'a type of discourse composition that draws together diverse elements, happenings, and actions of human lives into thematically unified goal-directed processes' (p. 5). Connelly and Clandinin (1999) broaden Polkinghorne's definition to move beyond simply stories and to include the research process and the researchers' interpretation of the story of the research itself, though Smeyers and Verhesschen (2001) caution against adopting too wide a definition, as it would mean that anything could count as a narrative (p. 78).

A narrative analysis reports personal experiences or observations and brings fresh insights to often familiar situations; narrative text has an 'omniscient, authorial voice' (Bruner, 2004, p. 702). It is strongly interpretivist, the author's construction rather than an objective truth (Smeyers and Verhesschen, 2001), with meanings constructed through observations and

language. Indeed it is sometimes difficult to separate facts from observations, as many narratives can use data selectively and report them in non-neutral terms (as in the example that follows). As with other forms of discourse analysis, narrative analysis is rooted in a social constructivist paradigm in which behaviours and their meanings are socially situated and socially interpreted.

Riessman (2008) suggests that narrative analysis can use *thematic analysis* (identifying categories and themes), *structural analysis* (how the narrative is structured and what the language does at textual and cultural levels), *performance analysis* (how narratives are co-constructed/done/performed and the difficulties encountered in such structuring) and *visual analysis* (of narratives constructed using visual media).

The example that follows is taken from Goffman's (1968) *Asylums* (a study of a psychiatric hospital). Here the 'asylums' – hospitals – bear many similarities to schools, particularly boarding schools, in being 'total institutions'. By taking a non-school example here, it is intended to 'make the familiar strange' (Blumer, 1969): to make the familiar world of schools 'strange' to the researcher (i.e. to see schools with a new eye) by comparing them to another similar but also different institution.

Goffman (1968, pp. 17–19) writes that a total institution (e.g. a hospital, an army, a boarding school, a prison), is characterized by several features:

- The institution is convened for a specific purpose.
- All aspects of life take place in the same place and under the same single authority.
- Every part of the member's normal daily activities takes place in the company of many others.
- All members are treated the same and are required to do the same things together.
- The daily activities are precisely and tightly scheduled by a controlling authority and officials, and through formal rules that are tightly enforced.
- The several activities are part of a single, overall plan that is intended to fulfil the aims of the organization.
- There is a division between the managers and the managed (e.g. the inmates and the hospital staff; the teachers and the students).
- The inmates have limited or no contact with the outside world but the officials do have contact with the outside world.
- Access to the outside world for inmates may be physically or institutionally restricted, controlled or forbidden.
- There is some antagonism between the two groups, who hold hostile stereotypes of each other and act on the basis of those stereotypes, often based on inequalities of power.
- Officials tend to feel superior and powerful whilst inmates tend to feel inferior and powerless.
- The cultures and cultural worlds of the officials and the inmates are separate.
- The two worlds – of officials and inmates – have limited penetration of each other.
- There is a considerable social distance between the two groups.
- Inmates tend to be excluded from knowledge of decisions made about them.
- Incentives (for work, behaviour) and privileges have greater significance within the institution than they would in the outside world.
- There are limited and formal channels of communication between the members of the two worlds.
- Release from the institution is often part of the privilege system.

These features can apply to several different total institutions, of which schools are an example.

Goffman (1968, pp. 220–5) presents a narrative account of his field notes on the psychiatric hospital, synthesized into a single text.

> In everyday life, legitimate possessions employed in primary adjustments are typically stored, when not in use, in special places of safekeeping which can be gotten to at will, such as foot-lockers, cabinets, bureau drawers, and safe-deposit boxes. These storage places protect the object from damage, misuse, and misappropriation, and allow the user to conceal what he possesses from others …
>
> When patients entered Central Hospital, especially if they were excited or depressed on admission, they were denied a private, accessible place to store things. Their personal clothing, for example, might be stored in a room that was beyond their discretionary use. Their money was kept in the administration building, unobtainable without medical and/or their legal agents' permission. Valuables or breakables, such as false teeth, eyeglasses, wrist watches, often an integral part of body image, might be locked up safely out of their owners' reach. Official papers of self-identification might also be retained by the institution. Cosmetics, needed to present oneself properly to others, were collectivized, being made accessible to patients only at certain times. On convalescent wards, bed boxes were available, but since they were unlocked they were subject to theft from other patients and from staff, and in any case were often located in rooms locked to patients during the day.

If people were selfless, or were required to be selfless, there would of course be a logic to having no private storage places, as a British ex-mental patient suggests:

> I looked for a locker, but without success. There appeared to be none in this hospital; the reason soon [became] abundantly clear; they were quite unnecessary – we had nothing to keep in them – everything being shared, even the solitary face cloth which was used for a number of other purposes, a subject on which my feelings became very strong.

But all have some self. Given the curtailment implied by loss of places of safekeeping, it is understandable that patients in Central Hospital developed places of their own.

It seemed characteristic of hospital life that the most common form of stash was one that could be carried around on one's person wherever one went. One such device for female patients was a large handbag; a parallel technique for a man was a jacket with commodious pockets, worn even in the hottest weather. While these containers are quite usual ones in the wider community, there was a special burden placed upon them in the hospital: books, writing materials, washcloths, fruit, small valuables, scarves, playing cards, soap, shaving equipment (on the part of men), containers of salt, pepper, and sugar, bottles of milk – these were some of the objects sometimes carried in this manner. So common was this practice that one of the most reliable symbols of patient status in the hospital was bulging pockets. Another portable storage device was a shopping bag lined with another shopping bag. (When partly full, this frequently employed stash also served as a cushion and back rest.) Among men, a small stash was sometimes created out of a long sock: by knotting the open end and twisting this end around a belt, the patient could let a kind of moneybag inconspicuously hang down inside his trouser leg. Individual variations of these portable containers were also found. One young engineering graduate fashioned a purse out of discarded oilcloth, the purse being stitched in separate, well-measured compartments for comb, toothbrush, cards, writing paper, pencil, soap, small face cloth, toilet paper – the whole attached by a concealed clip to the underside of his belt. The same patient had also sewn an extra pocket on the inside of his jacket to carry a book. Another male patient, an avid newspaper reader, invariably wore a suit jacket, apparently to conceal his newspapers, which he carried folded over his belt. Still another made effective use of a cleaned-out tobacco pouch for transporting food; whole fruit, unpeeled, could easily be put in one's pocket to be taken back to the ward from the cafeteria, but cooked meat was better being carried in a grease-proof stash.

I would like to repeat that there were some good reasons for these bulky carryings-on. Many of the amenities of life, such as soap, toilet paper, or cards, which are ordinarily available in many depots of comfort in civil society, are thus not available to patients, so that the day's needs had to be partly provided for at the beginning of the day.

Fixed stashes, as well as portable ones, were employed, too; they were most often found in free places and territories. Some patients attempted to keep their valuables under their mattresses but, as previously suggested, the general hospital rule making dormitories off-limits during the day reduced the usefulness of this device. The half-concealed lips of window sills were sometimes used. Patients with private rooms and friendly relations with the attendant used their rooms as stashes. Female patients sometimes hid matches and cigarettes in the compacts they left in their rooms. And a favourite exemplary tale in the hospital was of an old man who was claimed to have hidden his money, $1,200 in a cigar box in a tree on the hospital grounds.

It would be plain that some assignments also provided stashes. Some of the patients who worked in the laundry availed themselves of the individual lockers officially allocated only to non-patient workers. The patients who worked in the kitchen of the recreation building used the cupboards and the refrigerator as places in which to lock up the food and drink they saved from the various socials, and other indulgences they had managed to acquire.

(Goffman, 1968, pp. 220–5)

The narrative account tells a gripping, disturbing story in much more graphic detail than would be possible through the often decontextualized world of extracted, codified and reassembled data; the narrative makes the most of the virtues of a story: an account that 'catches fire' through the language used, that persuades, that is human, that is rich in detail and that tells a story. What is that story?

At first sight the patients' behaviour may seem very odd, they seem fixated on minute matters, they dress bizarrely, their clothing bulges with a range of objects that 'normal' people would not carry around, they are

obsessive about hoarding, they trust nobody, and what they take so many pains to carry around is almost worthless. They might be rightly accused of not being in their right mind, and therefore that they are rightly incarcerated in the secure hospital so that they are no danger to themselves and to others. That is one version, one discourse.

However, an alternative explanation can be offered, an alternative discourse is at work. Here one can see why their behaviour is as it is. For example, if we look at the descriptions of what the patients were experiencing we can observe:

- their personal clothing was available only at the discretion of the staff;
- valuables were kept locked away from the patients;
- self-identification papers were held by the institution;
- cosmetics were made available only at certain times;
- everyday amenities of life in civil society were not available to the patients;
- bed boxes were kept unlocked, i.e. nothing was secure;
- everything was shared;
- there were no free places;
- private spaces (dormitories) were off-limits during the day;
- individual lockers were for non-patients.

What we see in both an actual and metaphorical sense is the stripping away of identity, personality, individuality, privacy, security, power, freedom, autonomy, humanity and decision making, and all by those with power over the inmates. Goffman (1968) terms this the processes of *depersonalization* and *mortification*. Nothing personal is left to the patients; nothing is private, nothing is safe.

If we look at the vocabulary that Goffman uses in connection with the patients, we see very many terms about these same points: 'stash', 'possessions', 'protect', 'conceal', 'stored', 'storage', 'safekeeping', 'valuables', 'hidden', 'hid', 'half-concealed', 'lock up', 'containers', 'saved'. They have actual and metaphorical meaning: at both an actual and metaphorical level the patients are trying to retain their lost personalities, identities, rights, autonomy and freedoms, even their sanity. It is little wonder, then, that metaphors of storage, protection, privacy, keeping things safe and containment are realized in practice. Indeed it could be argued that, far from being disturbed or out of their minds, the patients were behaving very sanely and sensibly in an insane or disturbing situation. How often do we find the same situation in schools, where students behave very sensibly in the face of extreme or unacceptable behaviour by teachers (but often the blame is placed on 'disruptive' students who dare to disrupt the power-and-control oriented, boring and dominatory behaviour of teachers)? Sanity and madness are, to some degree perhaps, a social construct rather than an objective reality.

Descriptive data in this narrative form enable the researcher to understand the situation vividly from the perspective of the participants, their 'definition of the situation'. The hospital staff might have put a very different interpretation on their own behaviour, arguing that they were removing sources of distress and danger from the patients, and caring for them very extensively. That may be true also; reality is multifaceted. Through an analysis of the narrative, the descriptive data help the researcher to explain why situations are the way that they are. In fact one could argue that the patients are behaving very rationally and reasonably in an unreasonable, power-stripping and depersonalizing situation, even though their behaviour at first might seem strange.

The extract is powerfully written; the structured silence on the less antagonistic or depersonalizing behaviour of the staff and the regime is presented selectively, if at all, but the force of the narrative is the stronger for this. The well-chosen examples of the hiding of even everyday objects are given extraordinary semiological, symbolic power in indicating how power reaches right to the heart of commonplace, almost taken-for-granted matters. The narrative is a well-worked example of how the taken-for-granted, everyday world and its artefacts can have extraordinary meaning in certain contexts. When these everyday objects are used to make grotesque shapes in the clothing of the patients, rendering them instantly recognizable as patients by their freakish garb, the contrastive power of this juxtaposition is startling. Whilst this is not the place to go into semiotics, narrative analysis can use semiotic analysis: the interpretation of signs and symbols as signifiers of meaning.

In examining the narrative, the researcher can look for what is happening, what are the main features being reported, why the behaviours were as they were (and on what basis of evidence the researcher is making that judgement), what other inferences and explanations might be made of the data provided, and what other data might be needed to support or refute the inferences and explanations given.

35.4 Autobiography

Bruner (2004) argues that we regard 'lived time' as a narrative (p. 692), a story that has meaning for us and which shapes our lives (as he remarks (p. 694): 'we become the autobiographical narratives by which we "tell about" our lives'); our own stories direct our future lives (p. 708), they instruct, shape, reveal and inform our lives (Eisner, 1997, p. 6). Or, as Sartre (1964, p. 39) notes: we are surrounded by our own and others' stories and we interpret our lives in terms of these and, indeed, try to live our lives as if we are recounting those stories. Indeed Plummer (1995; 2001) argues that an essential feature of being human is our creation of stories to ourselves and others, and that these are essential features of research inquiry.

An autobiography is, as Bruner (2004) writes, 'a privileged but troubled narrative because it is both subjective and objective, reflective and reflexive', in which the narrator is also the central figure (p. 693). Given this, an autobiographical narrative is multilayered and selective, and it can be deconstructed at many levels: personal, cultural, interpersonal, ideological, linguistic and so on. It has facts, themes, actors, a sequence, a plot, agency, coherence, situatedness and a sense of audience, all of which are elements of a true discourse as set out at the start of this chapter. It is not coolly objective but often a vivid, evocative account (Tedder, 2012).

In the example that follows, the fictitious autobiography tells a personal story in a highly selective and authentic way. Imagine that the researcher had asked the teacher to write a brief autobiography of his experiences as a teacher; what we have here is the teacher's own views, and this indicates the significance that the writer gives to the events selected.

> I had always wanted to teach music to secondary school students. I had played in a school band when I was at secondary school, and had taken piano lessons for ten years, and had passed all the grades, and I thought that it would be really good to teach. I thought it would be good for students to be exposed to the great classics, or modern music, and I thought that it would be even better if I could teach them how to read, write and compose music. I thought that this would be particularly interesting for downtown kids who had not had access to such music, so I was keen to work in an inner city school.
>
> I had been working in business for 25 years, ten years with a printing company and then 15 years in a commercial company selling paper products. But I felt dissatisfied with my life, so I decided to do what I had always wanted to do, which was to train to be a secondary school music teacher. So I discussed it with my family and gave up my job to take a teacher training course. I was very keen and worked hard on my studies.
>
> I was very happy when the course began; we were introduced to all sorts of ways in which students could learn to write, read and play music, how they could work in pairs and groups to devise musical compositions, how to read non-standard musical scores, how to use the electronic instruments that had not been around when I was at school, and how to teach students to appreciate all different kinds and genres of music.
>
> I passed my course and went to a downtown school. What a total let down! The students didn't care about music; they saw it as a waste of time and boring. They thought that the music syllabus was old-fashioned, that it did not represent the music that they were interested in. All they wanted to do was to play to the whole class their own latest music releases and albums from the ridiculous groups and so called 'artists' whom they had seen gyrating sexily on the television and the Internet. When I tried to change the activities, so that they were playing musical instruments and composing their own music, they either just made a whole lot of noise with them, and the din was awful, or they thought that the instruments and the activity were just babyish, so they did nothing except fool around in the class. Everything that I had been taught about discipline in my teacher training didn't work. At first I thought that it was that my class control wasn't very good, so I asked my mentor how to improve this, but it did not help – the students just sat and laughed, shouted, or refused to do anything.
>
> So I tried a different approach: I told them that they had to learn several musical 'facts' such as information about the lives of composers and the names of pieces of music of certain composers. In fact this wasn't so much a music lesson as a reading lesson. I told them that I was going to give them a test on this, and that those who didn't score highly enough on the test would be punished. I thought that by making the lesson more like a 'high status' area of the curriculum, and coupled this with a test, it would make the students take this more seriously, but it didn't. All they said was that they didn't care, that music was a waste of time, and that it wouldn't help them to get a job. I felt very frustrated.
>
> It didn't get better and I was worn out, stressed, and felt that I was in a job that was completely unrewarding. So, in the end I looked for a job in a

private secondary all-boys boarding school, thinking that at least the students would be more motivated and well behaved. I was hopeful and felt good. I got a job in a small private secondary school where the students had to learn a music instrument at school, as well as taking class music lessons. I hoped that this would be the answer, and that I would be happy again and able to teach 'real' music.

However, I quickly found out that this wasn't the solution. Whilst some of the students were motivated and very nice indeed, some of them were arrogant and treated me as a hired servant whom they could control by threatening to report me to the Senior Teacher if I raised my voice to them or set them too much work to do. I felt insulted.

I didn't like their attitude to me or to the subject; I had been told to follow a more traditional curriculum, and I was very happy to do this, but I found that the students thought that the music lessons were 'beneath their dignity', trivial, and 'tame' compared to the other subjects on the curriculum. In turn, at first I thought that they were just young, fashionable, upper-class or would-be upper-class students with a superior attitude and self-confident manner, wealthy, privately educated, privileged, brash, indulgent, with an expensive lifestyle and high living, a love of country sports, and even a shared way of speaking, and I humoured them, but, the longer it went on the more it irritated me, as I felt that they were looking down on me and on the music lessons.

In fact they weren't all like that, and some of them were from poor, middle-class and working-class homes, whose parents wanted to give their children the chances that had not been available to them, and some students had been thrown out of other schools and had been put into this school by anxious and overwrought parents or by parents who were at their wits end in trying to cope with their badly behaved child. These students continued to be badly behaved, but I was told to 'put up with it', as they brought in a lot of money to the school.

I couldn't take it. One day I exploded with them. I insulted them very strongly, called them all upper-class idiots, called the others 'layabouts', shouted that they should treat teachers with a shred of decency, and basically 'lost it'. The class laughed loud and long; they had won. I left the class and walked out of the job.

I feel very dispirited and let down. I feel as though I have a lot to offer to teaching, but there's no way I can offer it under the present system, so I'm getting out. I'm going back to find another job in business and maybe I'll do some part-time music tuition and give piano lessons in the evenings, with motivated kids and in a situation that is under my control, and where my students will learn something other than how to behave badly.

The autobiography has several *themes* (and themes or *leitmotivs* are a feature of narratives): optimism turning to resentment turning to disillusionment; positive to negative; empowerment turning to disempowerment; dreams turning to dust; power shifts (from the writer to the students); achievement and loss; aspiration turning to deterministic frustration; ignorance turning to knowledge; power turning to loss of control; false expectations to growing realism; and so on. It has a purpose and a plot – a cumulative progression of events over time – and a human, emotional side, i.e. key elements of discourse.

We can observe that the narrative employs a chronological, linear sequence which is interrupted only very occasionally to break off into reflection or comment. The writer has chosen to focus on critical events and decisive moments, all of which are autonomously chosen and life-changing. This is an existential journey in which agentic choice struggles to realize itself as planned and which, in the end, leads to resignation in several senses.

If we examine the text we can observe the overwhelming preponderance of the active rather than the passive voice; here is a writer who is existentially alert. We can note the absence of metaphor, the emphasis on the 'facts' of the events, and a 'no-nonsense' approach to getting on with life (albeit selectively chosen and interpreted) rather than reflections, indeed it is only towards the end of the extract that we can detect a sense of deeper reflection in the writer, i.e. that the writer has learned from experience and the reflection on that experience, and has gained a truer knowledge of the 'real' rather than the perceived or desired situation.

We can note the presence of many stative verbs, phrases and their accompanying adjectives to indicate feelings: 'I thought it would be good'; 'I thought it would be even better'; 'I felt dissatisfied'; 'I was very keen'; 'I felt very frustrated'; 'I was in a job that was completely unrewarding'; 'I was hopeful and felt good'; 'I didn't like'; 'I felt insulted'; 'I felt that they were looking down on me'; 'I feel very dispirited and let down'. Here is a writer who is seeking authenticity, self-realization, emotional fulfilment, who is concerned with feelings.

One interpretation of the text is that it reveals a writer who seeks control and the realization of a personal agenda for happiness; when this is challenged, he finds it hard to come to terms with the situation, to accept it or to accommodate to it. Points of conflict

chart the movement in the text from 'me' to 'them', from the writer's agenda to the student. The word 'I' is used fifty-four times in the extract, whereas the word 'them' occurs only fifteen times. Indeed one can suggest that using the contrast of 'I' and 'them' can denote a perhaps antagonistic stance of the writer, a significant divide between the teacher and the student, a power struggle for control of the agenda. Indeed the word 'them' occurs more frequently whenever things are going wrong for the writer.

We can see a distinctly sympathetic choice of prose, in which the writer's own situation is presented sympathetically and in which the report on the students is almost entirely negative: they are the ones who 'let down' the writer, who 'didn't care' about music, who only wanted to play 'music from the ridiculous groups and so called "artists" whom they had seen gyrating sexily on the television and the Internet', who 'did nothing except fool around', who 'just made a whole lot of noise' and 'just sat and laughed' or who were 'just young, fashionable, upper-class or would-be upper-class students' (note the use of the word 'just' – a negative term here), who didn't take the lesson seriously, and so on. The pejorative tone of the writer – sympathetic to one party and highly unsympathetic to the others – constitutes a very one-sided text. Indeed, as Riessman (1993) remarks, silence – what is not spoken or included, what is left out – is as important as what is said or included (cf. Denscombe, 2014, p. 290). The question is whether this is a problem, as the text is authentic, strong in reality and reveals the intense emotions at play in the situation; it surely catches the 'quality' of the situation so prized by qualitative research.

There are a few tell-tale verbs: the early part of the text includes positive, hopeful verbs such as 'wanted', 'worked hard', 'passed', whereas by the final paragraph we have the dramatic verbs 'getting out', 'going back' (the use of 'back' is perhaps a sign of defeat and a retrograde step).

Do we have sympathy with the writer? Do we think that the writer is a 'control freak' who deserves to come to the kind of self-knowledge that becomes clear by the end of the extract? Did the writer simply receive his just deserts or were the outcomes undeserved and a pity? Did the writer deserve what happened? Has the writer really taken any account of the students? Do we think that the writer has been treated badly by the students? Is the writer weak, strong, too strong, too controlling a person?

This is one reading of the text. But a discourse permits many interpretations. The interpretation above has operated at the level of the personal perspective of the writer, and has suggested that issues of power, control and self-realization feature strongly in the text. An alternative reading is that this is an accurate and authentic account of a horrible situation in which a decent, hard-working and committed person is treated very badly by two groups of distasteful students. Another reading could focus on the quality and contents of teacher training and false aspirations that the teacher training might have led the writer to hold. Another reading might be of the text as an insight into the problems of teaching, for example, indicating that teachers face huge problems of stress, disruptive behaviour and appalling treatment by students, that these constitute a major reason for the flight out of teaching and problems of teacher recruitment and retention, and that there are insufficient support systems for teachers in school. Another reading might be that of social class in education, and the perpetuation of deep-seated class structures through the provision and uptake of different kinds of schooling, curricula and education. We bring our own agenda to the reading and deconstruction of texts. Texts are multilayered.

And who is the writer? Is the writer male, female, young, old, single, in a relationship, living with parents or living alone, able-bodied or disabled, easy-going, temperamental, easily stressed, tolerant, outgoing, introverted, sociable or antisocial, white, non-white, politically left-wing or right-wing, working class or middle class, and with what views on education and music, and so on? We don't know. Perhaps if we had known some of these details then our reading of the text would have been different.

35.5 Conclusion

This chapter has introduced alternatives to coding and the collation of segmented data in qualitative data analysis. It has suggested that the holism of complete texts can constitute discourses, and that variants of discourse analysis have to recognize that discourses and texts are multilayered and open to a range of interpretations and deconstructions. The chapter has given three different examples of these, selected not only for their content but also for their exemplification of three main kinds of discourse: a conversation, a narrative text and an autobiographical extract. Discourse analysis has many meanings, included in which is the recurrent theme of power and its operations (Foucault, 1998; Fraser, 2004). Whilst discourses have the attraction of *emic* research, authenticity and rich language, the researcher has to be mindful not only of the effects of this on the reader, but of the reader's own effects on the text. As Riessman (1993, p. 70) explains, how a person relates

his or her story 'shapes how we can legitimately interpret it'. The chapter has indicated that analysis of narrative, discourse-based data has to attend to the fine-grained details of texts (Potter and Wetherell, 1994, p. 58; Hammersley, 2013, p. 61), together with situating these in the social context and milieu in which they are set (e.g. Clifton, 2006). In combining different narratives, patterns and themes, the researcher can note similarities, commonalities and differences, not only in content, but in terms of tone, style, register, genre, vocabulary, audience, settings, contexts, metaphors and intentions. Given this, there is no single privileged, definitive way of analysing discourse or the meanings that surface from it.

Companion Website

The companion website to the book provides additional material, data files and PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Analysing visual media

CHAPTER 36

This chapter introduces researchers to key issues in analysing different kinds of visual image, including still and moving images, and artefacts. It uses tools of analysis that have been introduced in previous chapters, such as content analysis and discourse analysis, and it provides an entrée into the next chapter on grounded theory. With reference to analysing visual data, the chapter introduces:

- content analysis
- discourse analysis
- grounded theory
- interpreting images
- interpreting an image: an example
- analysing moving images

We provide an extended worked example of an analysis of a photograph, to clarify key issues in this kind of analysis.

36.1 Introduction

Chapter 35 introduced discourse analysis. Visual media are a form of discourse. Hence the researcher can use some of the analytical tools that are available to quantitative and qualitative data analysts, for example: content analysis (both numerical and qualitative); discourse analysis and grounded theory. We address these below. Computer software (e.g. NVivo, ATLAS.ti) works with visual data as well as textual data and there are several software packages specifically designed for video data, for example, The Observer XT, Orion, Transana and Video Traces. However, as with other software for qualitative data analysis, software 'does not come with an inbuilt methodology' (Mercer, 2010, p. 10).

Analysing visual data is not straightforward, as images (moving or still) concern meaning making and interpretation. Images are polysemous (Johnson and Black, 2012). Consider, for example, Figure 36.1, an apparently objective, factual photograph of a secondary school senior teacher's office, which has been placed into NVivo, with the researcher's commentary.

What is the researcher to make of this commonplace photograph? It is open to multiple, perhaps contradictory interpretations; there is no simple, single, cold observational analysis. The researcher's commentary reads thus:

> Senior teacher's office. It is small: just enough room for a workstation, one other person, limited shelf space, but little else (note: some materials have to be kept above the top shelf in plastic containers). It has functional office furniture, so the only space to personalise it is by pictures on the notice board and the wall. The location of the smaller chair and the lack of space behind the chair suggest a cramped and confined working space (notice the scrape marks on the wall behind the small chair), though the senior teacher has a more comfortable, and larger chair. Not a room to receive the public, e.g. parents or visitors. No window, lighting comes from fluorescent lighting. A room for working in alone rather than sharing.

Then the researcher moves to some more interpretive comments, and many of these remarks project something of the researcher's own self:

> Given the kind of furniture, the lack of space, no room for superfluous materials, furnishings or ornament to personalise the room, cramped conditions, it is more like a monastic cell for private work and functionality alone: concentrate on the work with no distractions or creature comforts. The occupant could be removed at short notice (so little to remove), or, more positively, is it a retreat for the senior teacher for some peace/silence/privacy/sanctuary? Is the school so short of space that it gives the senior teacher such cramped working conditions? Is it disrespectful? Who would sit in such close – almost physical – proximity to the senior teacher?

Note the different possible interpretations here. Is the room about peace, or privacy, or silence, or sanctuary, or comfort, or solitude, or functionality, or disrespect, or impersonality, or retreat, or invasion of personal

space etc.? Is the school trying to sicken the senior teacher by giving her/him a poky little room so that she/he will leave? Do other senior teachers in the school have their own room, and if so, is theirs similar to this? Is the school really so short of space that it is a privilege to have one's own room, regardless of its size and contents?

Maybe the photograph is about all of these, in which case, which interpretation(s) should prevail? The point here is that visual data on their own might be insufficient to draw conclusions, and that it is often wise to use visual data alongside other data in order to support secure conclusions, i.e. to triangulate (see Chapter 31). In analysing visual images, just as with other types of qualitative data analysis, interpretation and analysis run together and it is difficult, if not impossible, to separate them. What starts out as an innocuous image opens floodgates to interpretation. Indeed it is difficult to decide when the process of visual data analysis actually begins (Knoblauch *et al*., 2006), as analysis and interpretation merge into each other.

Before one starts the analytical process, just as with word-based data, it is important for researchers to become very familiar with the data, looking at the images (videos, photographs etc.) several times and immersing themselves in the data, maybe producing some initial narratives about the data. Immersion and its subsequent meaning-making can operate at several levels. For example Kaufmann (2011) suggests four levels of analysis and meaning-making in visual data, in constructing narratives from the images and the 'dynamic interdependence between experience, theory, and power' (p. 8):

- the image itself as interpreted through the technology which produced the image (e.g. video, film, photograph), shutter speed, focus, viewpoint, context of the image;
- the personal, subjective lenses of the researcher;
- the theoretical frameworks used to analyse the image;
- the medium of the message and the meanings that the medium constructs (e.g. video photograph, film etc.).

Denscombe (2014) suggests various strands in analysing visual data:

The image itself: content, genre, styles;
The producer: intentions and context (by whom, when, under what circumstances, why, the intention of the creator);
The viewer: interpretation and context.

(Denscombe, 2014, p. 292)

As he notes, the image can be approached through different lenses: as containing factual information, as a cultural artefact and as a symbolic representation.

With this background in mind we turn to specific ways of analysing visual images.

36.2 Content analysis

We can analyse visual images in a similar way to that of analysing texts, for example, through 'reading' the meanings, through disclosing our own views, perspectives, backgrounds and values (reflexivity). Here content analysis – purportedly an 'objective' form of analysis – can be performed in ways similar to those in qualitative and indeed quantitative data analysis. A possible sequence is set out below:

1. Start with research questions that determine which images (sampling) will be used in the analysis.
2. Retrieve the appropriate images.
3. Decide the unit of analysis. For example, in photographic or still image data it may be the group, the individual, the object; in video data it may be the setting, the time and the events (e.g. Lee *et al*., 2015).
4. Devise a coding system and codes (which must be mutually exclusive, exhaustive and enlightening) (Rose, 2007, p. 65).
5. Code the images according to the codes (cf. Johnson and Black, 2012; Lee *et al*., 2015).
6. Count codes and their frequencies.
7. Reflect on what the coding and the frequencies have indicated.

The researcher can look for patterns in the data, for example over codes, over images, over time, which patterns vary or do not vary, how the patterns are organized etc. (Knoblauch *et al*., 2008).

A celebrated example of this approach is from Lutz and Collins (1993), who examined some 600 visual images in the magazine *National Geographic*. They devised twenty-two predetermined codes to analyse the photographs (e.g. smiling, gender of adults, group size, skin colour, activity, surroundings of people, wealth indicators etc.). From their analysis they concluded that westerners defined non-westerners in terms that made them very different from westerners and 'as everything that the West is not' (Rose, 2007, p. 67) (akin to Edward Said's (1978) notion of the 'other'), as 'natural', less advanced technologically, more attuned to their environment, more spiritual, more exotic and, indeed, naked. The photographs avoided negative imagery (e.g. of poverty, wars, starvation, conflict, illness, physical deformity); in short a sanitized, non-disturbing, non-upsetting and unreal view of non-westerners was portrayed. Issues of power, of dissatisfaction were simply excluded; a structured silence that acted ideologically to reproduce the *status quo* of inequality within and across countries.

Content analysis, as its name suggests, is more concerned with the contents of the image rather than the production or 'audiencing' of the image (Rose, 2007, p. 61); it might not sustain comment on the cultural significance of the images made or caught. In content analysis, the whole is more than the sum of the parts, and this is particularly so in visual data, as the effect of the whole and the combination of parts can be greater than each item of composition. Content analysis must catch both the detail and the bigger picture in order to avoid being over-reductionist (Snell, 2011). As part of content analysis, coding risks losing this wholeness, being atomistic and fragmentizing. Rose (2007, p. 72) argues that content analysis does not discriminate between weaker and stronger instances of the code, and can lose important interconnections between elements of an image. Further, codes miss the mood that an image might be trying to create. Indeed she argues that, fundamentally, they overlook the important point that different people view images in different ways and with different interpretations. Whilst content analysis, conducted through coding, lends itself to the scientifically approved maxim of replicability, this may miss important features of the researcher working with visual data.

In summary, then, content analysis risks overlooking an ideology-critical way of viewing an image; it builds out such an approach, and yet ideology critique is an important element of deconstructing a visual image. Ideology, defined as the views of the ruling, dominant groups who succeed – by force or by consent (hegemony) – in having their views and values 'count' or seen as legitimate, is all-powerfully pervasive, and the views and values of others are relegated or discredited, i.e. ideology serves to reproduce social inequalities in society and to have those social inequalities played out in the everyday lives of participants. Ideology is 'lived experience', legitimating the power of the powerful at the expense of the powerless.

Ideology critique is a powerful way of looking at visual data, exposing illegitimate operations and

functions of power, and how these are produced and reproduced through images, how images legitimize social inequality (e.g. Kaufmann, 2011). This takes place, for example, in the selection, focus, exclusion, inclusion and interpretation of images and their contents. This is evidenced in semiological studies (studies of signs – signifiers – and the meaning given to that which they signify – the signified – for the viewer of the image), how meaning is encoded in the image and decoded by the viewer. In this context it is interesting for researchers to look at school prospectuses and websites; for example look at the images on the front page of school websites (e.g. Eton College and Winchester College, both of them private schools for the privileged) to see the images of the school that are selected, given or received, by the school and the viewer, to see what the images denote or connote.

Content analysis is a useful way of examining images, but its limitations have to be recognized. That is not to say that the outcomes of content analysis cannot be subject to ideology critique (indeed the study by Lutz and Collins (1993) is an example of this).

36.3 Discourse analysis

Visual images can also be read as discourses, and here the discussion of discourse analysis in Chapter 35 can apply, as images can be 'read' for the meanings that they convey to, or elicit from, the viewer. A discourse, as Rose (2007, p. 142) remarks, is a group of statements which structure how we think about things and how we act on the basis of those thoughts. As Chapter 35 makes clear, discourses structure and define what is valuable knowledge, how to know and how to think (cf. Foucault's (1998) view that discourse is an instrument and an effect of power). Discourses, like ideology, are saturated by power; hence in understanding images we have to engage in an analysis and critique of power, how it operates and with what effects (a worked example of this is presented below in an analysis of a photograph).

Discourse, as Rose (2007, p. 146) remarks, operates in several spheres, be they individual (the viewer or the producer of the image) or institutional (the items that galleries, museums etc. hold and display and how they present them). We can 'read' images for their symbolism, their messages and their iconography. This may involve trying to set on one side our own interpretations or views, and endeavouring to see the image as it might have been intended by the producer of the image, to look at the image anew, to review and review again the image iteratively and reiteratively, as Rose (2007, p. 157) remarks, to immerse ourselves in the image.

One can review the image on the basis of the structured approach of content analysis, to discover key themes or features, to identify interesting features or messages, to look for contradictions, discontinuities or complex issues in the image, to look at what the image has omitted (deliberately or not), i.e. to consider silences and absences as well as the items that have been included. In conducting this kind of discourse analysis, as with the conversational analysis in Chapter 35, there is a high level of detail in the focus and the analysis. Writing up a discourse analysis can be done through the construction of a narrative. Further, one can consider the purpose of the image in terms of its effects on the audience – intended audience or unintended audience, intended effects or unintended effects. This engages consideration of the production of the image as well as the audience of the image.

As discourse analysis and the interpretation of images involve a large element of subjectivity as intrinsic to the activity, it is incumbent on the researcher to be reflexive in the account given, indeed to regard his or her interpretation as itself a discourse.

Discourse analysis is conducted at the level of the individual image, but also at the level of the institution which holds the image, for example. the gallery, the museum, the newspaper, the film archive, the school, the broadcasting network. Rose (2007, p. 175) particularly cites this in her examples of photographs, where the home of the image may be giving messages about the institution and its values and, indeed, the intended message behind the institution's selection and use of the image, not least because institutions are sites of the operations of power (a central feature of discourses) in deciding what visual images to display or to give, together with considerations of to whom, how and where to display the images. Were the images commissioned, bought, donated, acquired, and from whom – families, philanthropists, other institutions, and how and why, and so on? How did they change hands? Here we can consider the near-instantaneous transfer of digital images in contrast to the protracted transfer of many valuable oil paintings. Images have their own social lives and biographies. What labels and captions accompany the image (e.g. the painting, the photograph), and what does it say about the priorities that the institution gives to the image? How are images stored, labelled, catalogued, archived and indexed? What are the visitor rules that must be obeyed in the viewing institution (e.g. no touching, no approaching the image too closely, no eating, no talking, no undesirable clothing (if the image is in a place of worship), how and in what order to move around the institution, where to sit etc.)?

In terms of moving images, the researcher can investigate the kinds of films that come out of film companies and studios, the kinds of programmes that television channels put out, for whom and in what format. For example, the easy-going, familiar, polite, superficial and chatty style of television talk shows, which always end on a happy note and take pains not to touch on sensitive or dangerous knowledge, can be contrasted to the gritty documentary about child prostitution or the raw film genre (Cormack, 1992). Here 'audiencing' features large: examining which audiences watch which films or which programmes, or go to see which images and where. In educational research the techniques of discourse analysis can be applied to still and moving images taken by, or provided by, the researcher and/or the participants.

Discourses and discourse analysis can apply to artefacts as well as to images. For example Francis (2010) analysed the discourses of gendered worlds into which young boys and girls are inducted through commercially produced toys and films.

36.4 Grounded theory

Both the tools and the outcomes of grounded theory can be used in analysing images. The tools of grounded theory, discussed in Chapter 37, include induction, open coding, axial coding (relating conceptually similar codes to a code that embraces them all), selective coding (looking at relationships between axial codes), categorizing, theoretical sampling, constant comparison, memoing, generation of core categories, theoretical saturation, and the generation of the theory itself as the end point of the analysis (i.e. derived from the data, not driving the data). We refer the reader to Chapter 37 for a fuller overview of these techniques. The researcher gathers together the visual data, then codes the data, moving to generating categories, themes, key issues and features, all accompanied by the writing of memos about these, thence to formulating general concepts, thence to saturating the category and theoretical sampling and onwards to the generation of the grounded theory itself. For a worked example of this with visual images, we refer the reader to Konecki (2009).

Figueroa (2008) argues that, although there is a large battery of analytical tools available for qualitative data analysis, these tend to focus on interactional studies. She argues for a variant of grounded theory to be used in analysing audio-visual texts, in the context of looking at audio-visual texts and narratives in their own right (as phenomena themselves) rather than solely regarding the audio-visual medium as the means for collecting data on a phenomenon. Texts, she avers, are 'crystallised pieces of this symbolic social net of meanings' (p. 4) and have to be examined in their own right. This entails looking at the actors' behaviours and strategies, and the consequences of these. But who are the actors – the people who have been filmed or the producers of the final image? Regarding audio-visual media simply as the means or instruments for observing a phenomenon will look at actors' behaviours and interactions; however, she suggests that it is not always easy to identify who the actors are. For example, in a piece of television journalism, the actors may be the cameraman, the journalist in the film, the chief editor, the television presenter, eyewitnesses or other people in the film, the film editor or, indeed, others. Hence it is not always easy to see who is 'speaking' in the text.

Given this difficulty, Figueroa (2008) argues that researchers have to look at texts in their own right as a single product, to see the text as a single-perspective narrative. If the researcher regards texts as the medium/means to another end, rather than as the product in itself, then this will lead the researcher to look at individual actors and their different behaviours, interactions, strategies etc. However, if texts are regarded as ends in themselves, then they will be analysed and coded differently, and, not least, interrogated for what they omit as well as what they include. Such texts and their associated readings are recognized to be: (a) already selective (having *created* a world, not only *reflected* one); (b) fictional (because they are constructed narratives); and (c) affected by the manner of their construction (they are dramaturgical and framed in a certain way, e.g. by news editors and news presenters) (p. 6).

Reading audio-visual products as texts, to be analysed through grounded theory, Figueroa suggests (p. 7), risks breaking down elements into smaller 'microscopic' units of coded fragments too soon, usually at the beginning of the analysis. This, she argues, can lose sight of the whole text and the force of the whole text, in which that whole is more than the sum of its parts. She comments that early coding analysis loses the impact of the whole when it is undertaken before any 'deep interpretation' and analysis of the overall structure of the text has been conducted.

Hence Figueroa suggests that, whilst grounded theory of texts (as products rather than as media for studying other phenomena) is useful, it should be undertaken differently from the normal sequence of open coding moving to axial coding and categorizing and, through constant comparison and the generation of core categories, to the generation of the grounded theory. Rather, she suggests that the researcher needs to

turn this approach to grounded theory on its head (p. 8). Here an analysis of audio-visual texts should start by looking at the whole, with the overall 'global impressions' and picture, as these influence the more detailed analysis that can follow. Only after the overall impression has been formed should the researcher move to the more detailed analysis and coding, i.e. with the overall picture in mind, together with an insight into the interconnections and interrelationships between different parts of the text. This echoes our earlier comment that researchers have to immerse themselves in the data and review them many times before commencing a more formal analysis, in order to see the whole picture as well as its constituent elements.

Resonant with Blumer's (1969, p. 41) advocacy of moving from the broad view to a sharper, close-up focus, this recognizes that the text is not simply a collection of independent, coded units but a whole, which has a structure and overall impact. The textual analysis becomes an 'exploration' (Figueroa, 2008, p. 9) to create a comprehensive overall picture and account of what is 'going on' in the audio-visual text, rather than simply being a coding exercise. To accompany such 'exploration', she argues for Blumer's (1969, p. 43) use of 'inspection': 'an intensive focused examination of the empirical content of whatever analytical elements' (p. 43) arise from, and come out in, the text, i.e. smaller units and pieces of the text. Indeed she writes that a more suitable way of interpreting Blumer's 'inspection' is not as examination of analytical units, but as 'exemplification' of analytical elements and emergent constructs and hypotheses.

In moving from the global to the detailed levels, macro to micro, the emergent hypotheses which are a feature of grounded theory take account of the audio-visual texts as a whole and are exemplified in the text, enabling the researcher to come to the close-up focus more slowly, after undertaking an overall view (Figueroa, 2008, p. 10). This, Figueroa avers, does greater justice to the nature of audio-visual texts and the structures of meaning within them. Though her comments are intended to apply to audio-visual texts of moving images, they can apply equally well to still images and visual data.

In advocating grounded theory, then, the researcher can start with the overall, general impression and awareness of the broad-based structures and interlocking elements of the whole, then move to the fine-grained, micro-analysis in coding and then through the several stages of the generation of the grounded theory, informed and influence by the overall impression and messages gained at the early stages of approaching the analysis.

36.5 Interpreting images

Images are 'compressed performances' (Pinney, 2004, p. 8), they take place in a social milieu, at the sites of both production and 'consumption', and the sites of 'consumption' (viewing) may change over time. They are produced for one set of purposes but often used for other purposes. The researcher has to be alert not to over-interpret photographs or to read into them meanings which are barely supportable by the material itself, i.e. he or she needs to be highly reflexive. In this respect, educational researchers should accompany the photograph in question with text, for verification, for contextualizing the photograph and, not least, for third-party validation of interpretations (ensuring that the photograph is not 'read' in entirely different ways from those of the researcher; see the comments about Figure 36.1 at the start of this chapter).

In examining images, several questions can be asked (cf. Rose, 2007, pp. 258–9):

- Why, when, where, by whom, for whom, how is/was the image made?
- Who is/was/are/were the originally intended audiences of the image?
- How is/was the image displayed?
- What do we know about the maker, the owner(s) and the people (if any) on the image?
- What were the relations (if any) between the producer, the subjects and the owner(s) of the image?
- What is the image about, and what/whom does the image show?
- What are the features of the image (e.g. compositional, genre, style, colour, elements, structure, format, arrangement, symmetry etc.)?
- What is the medium of the image?
- What are the striking features of the image?
- Is the image 'stand-alone', is it part of a set or series, is it part of a collection?
- Should the image be seen on its own or in the context of a set or series?
- From where was the image taken?
- What do the different elements of the image signify, and how do we know?
- What interpretations can be made of the image?
- Do the interpretations made of the image accord with the intentions of the producer of the image (do we know the original intentions)?
- What different interpretations of the image are made by different audiences (and from different backgrounds, e.g. related to ethnicity, age group, sex, sexuality, social class, income groups, geographical location, etc.)?

- What and whose knowledge is included in or excluded from the image?
- Who is empowered/disempowered in or by the image?
- What contradictions, if any, exist within the image?
- Where is the image kept/stored/displayed?
- Who has/had access to the image?
- How can/could the image be viewed?
- How is the image described, labelled, indexed, catalogued, archived?
- Is there a written commentary on the image, and, if so, what does it contain?
- What is the intended and actual relation between the image and those who view it?

There is a wealth of literature on examining images in educational research, particularly in the history of education, and we refer readers to O'Donoghue (2010) for comprehensive references here. His paper also suggests that images, including photographs, can be regarded as 'installation art', i.e. those artworks that are produced at an exhibition site. Regarding photographs as 'photographs of installations' (p. 411) invites researchers to imagine not only the three-dimensional nature of the classroom but also how it must feel to be inside that classroom.

36.6 Interpreting an image: a worked example

A worked example of a 'reading' of an image is presented Figure 36.2. This is a still image, a photograph.

This fascinating historical photograph of a UK schoolroom in the north-east of England carries the museum label thus: 'Children possibly at Woodland school, taken during an art class. Note sculptured trees on desks.' It is a typical photograph of its time (early twentieth century), and, indeed it is part of the genre of this type of photograph in which each child's head is turned to the left, the teacher is at the back of the class and the photographer is on one side of the room in order to include all the children in the photograph (and

FIGURE 36.2 An early twentieth century photograph of children in an art lesson

maybe to utilize natural light). In places the photograph is faded and the image is a little fuzzy: the ravages of time and technology. It has also been preserved in digital form by the museum, so that further image quality loss is prevented.

If we examine the picture, what can we notice?

The people

- There are sixty children in the class (there may have been just a few more, out of the camera shot on the right; the presence of light from the right suggests that the last row on the right may be next to a window).
- There are more girls than boys.
- The sexes sit together, and indeed in some places a boy is wedged between two girls.
- All the children are white Caucasians.
- The teacher is female.
- Nearly all of the children are dressed smartly in the style of the day; it is unclear whether there is a uniform, or clothing for the special event of the photograph, but there is a homogeneity or standardization of clothing.
- Some boys are wearing expensive lace collars, others are wearing stiff 'Eton' collars, but the school is probably not for rich children (who would be in much smaller classes and with different uniforms; perhaps here the parents wanted the best for their children).
- Clothing is clearly differentiated by sex.
- The children are wearing warm clothing.
- The only person not looking at the camera is the teacher, and, like a military officer, she is looking imperiously, sternly and unsmilingly at the children, and is the only one standing in the photograph, i.e. physically and metaphorically above the students.
- All the children are facing the camera; no child is looking away.
- The picture is 'posed' and serious, not light-hearted; clearly the children have been told what to do, how to sit (hands behind their backs) and where to look. Some are trying to smile, one or two seem to be smiling more naturally, and yet most are not.
- The situation seems unusual for the children, to have a photographer in the classroom, as many of them have an air of curiosity in their look.

The classroom and the furniture

- Proportional to the number of people, the classroom is quite small and the children are tightly packed.
- The back of the classroom is raised up (by one step, visible on the upper right of the photograph), so that the children at the back can see the teacher at the front, and be seen by that teacher.
- There are no windows out of which children can look (the windows are too high or are blocked out).
- The children are sitting in solid desks, three to a desk.
- The desks are standardized, the same, dark (black iron and dark wood), heavy (too heavy to move easily) and unable to be adjusted.
- The desks are large, taking up all the classroom space, yet the children are small. The desks are bigger than the children.
- The desks are fixed, made of strong wood and cast iron.
- The desks are hard, strong and large, in contrast to the students who are fragile and small.
- There is little room for movement in the desks; the position of the seats is fixed, as they are joined to the desk by the iron bar at the base.
- The seating arrangement suggests that all the interactions go through the teacher.
- The seating arrangements may be designed to control children, not least the boys (mixing the sexes and having some boys sitting between two girls).
- The children sit in rows and columns, each row facing the front. It is very regimented, and oriented to a single focal point – the teacher at the front.
- There appears to be a gap, a distance, between the front row of children and the teacher's desk (out of the image).
- There are some unusual objects in the class: the large thermometer hanging from the light fitting (a science instrument?), the large portraits high up around the room (not all completely contained within the photograph), with dignitaries looking down on the children.
- There is bare, but varnished, brickwork in the classroom.
- Some work that is on the walls is too high for children to read – it is for decoration only.
- The children's pictures are nearly all the same, and are about the same topic – flowers; all are nearly identical.
- The pictures by the children, on the walls, are stylized and almost the same.
- There is an almost exclusive focus on nature in the children's pictures and no other work is on display (indicative, perhaps, of an alternative to the hardness of the real world inside and outside the classroom).
- This is an art lesson, yet there is no evidence of drawing materials. There is evidence of what the children should be looking at in the art lesson (the

jar of flowers on their desk or the sculptured trees). It is unclear whether this is an art/drawing lesson or an art appreciation lesson.
- All the objects on the desks are the same.

The photograph and the photographer

- The photograph is old, and, in parts, the focus is not always sharp or even, the images are slightly unclear in places, the contrast is uneven and, in parts, the image is faded. Hence the researcher has to be careful not to over-interpret those parts of the photograph which are unclear or to read into the analysis any points that are not supportable by the evidence. This is a commonplace problem with old materials, and argues for the value of a third party to examine the photograph.
- The photographer must have been standing some distance from the children (nearly two desks' length from the front row of desks if we calculate the ratios) and higher than floor level. Standing higher than the children makes them look smaller – the symbolism is striking.
- The way in which, taken as a two-dimensional image, the teacher is at the apex and the children are below, constitutes a visual hierarchy reflecting a positional/role hierarchy.
- Why was the picture taken? For whom? For what purpose?
- There is no clear single focal point in the photograph; the conventional 'rule of the thirds' (where the focus is one third or two thirds of the way into the picture) is not there, nor is there a clear centre to the image.
- There are many points of focus, for example:

  a the girls' bright dresses in the first complete right-hand row;
  b the staring eyes of the boy sitting at the front, or the worried look of the little girl in the second row, or the haughty teacher at the back;
  c the children who are more in the image's sharp focus towards the rear of the second row of desks;
  d the bright lace collar of the boy in the centre rear;
  e the near-rhomboid symmetry in terms of the rows and columns of children's heads, which suggests order, regulation and regularity;
  f the use of diagonals here, rather than a front shot (whether simply out of the requirements to include all the children seated in their desks, or for artistic effect, or to make the most of the natural light, or some other reason), which brings a sense of inclusiveness to the picture and which draws the viewer into the picture;
  g the field of vision of the viewer (from a single point outwards), which is matched by the shape of the classroom (Figure 36.3) and the view of the arrangement of the desks and children (almost a rhombus, see Figure 36.3);
  h the match between the direction of the walls of the classroom and the layout of the rows and columns of the desks (the children are triply 'contained': (a) within their desk; (b) within the rows and columns of the desk arrangement; and (c) within the confines of the classroom walls, all of which is supervised by the overriding presence of the teacher). There is a scalability to the picture: each desk is a scaled-down version of the arrangement of all the desks (into rows and columns) and the arrangement of all the desks is a scaled down version of the proportions and layout of the classroom walls;
  i the contrast between the foreground and the background – the foreground shows powerless children whilst the background shows the powerful teacher keeping watch;
  j the dowdy walls and gloomy far reaches of the classroom contrast with the humanity and clothed children and models sitting in the centre of the picture;
  k the contrast between the harsh brick walls and the soft children;
  l the contrast between the staid and very formally dressed teacher and the relatively innocent children's faces and clothing;
  m the emphasis on regularity (rows and columns) and the repeated motifs of the three children sitting at a desk, multiplied eighteen times (eighteen complete desks in the picture);
  n the contrast between the static pose rather than the dynamic potential of the photograph, there being sixty-one potentially dynamic agents (people) in the photograph.

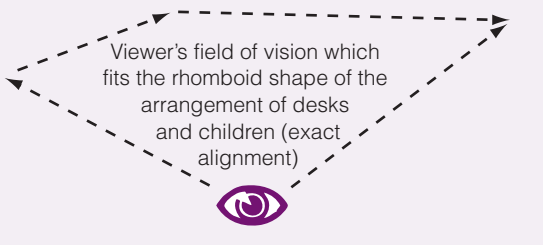

FIGURE 36.3 Matching the viewer's field of vision and the shape of the main part of a photograph

- The way in which the picture's background is cut off at crucial points.
- The old, faded and fuzzy parts of photograph.
- The observation that there are almost no shadows, everything is open to scrutiny and nothing is shaded or hidden.

What we see is often what we look for; this makes us look selectively and construe what we see through the interpretive lenses of our own subjectivity and ideological frameworks and values. Researchers bring their own subjectivities and cultural backgrounds to the photograph (hence the issues of reflexivity and disclosure of possible subjectivity assume a high profile here).

For example, one researcher might 'read' this picture as presenting stark messages and themes:

- lack of freedom and no room for freedom;
- power (the teacher has it all and the children seem to have none): asymmetrical relations of power;
- lack of creativity;
- standardization, sameness and uniformity;
- surveillance, control, domination, authoritarianism and containment;
- the gendered nature of primary school teaching;
- conformity, obedience, passivity and loss of individuality.

Though the formal curriculum here may be art (which, perhaps, concerns individuality and creativity), the hidden curriculum (that which is learnt without being taught; the unspoken messages that children must learn very thoroughly if they are to survive in school, e.g. about being one of a crowd, about differentials of power, about delay, denial and domination) (Jackson, 1968) is the exact opposite.

Of course, this interpretation might say more about the researcher than the researched: the researcher may be attuned to looking for dominatory forms of schooling, to the neglect of its more positive aspects. For example, another researcher may interpret the photograph as showing:

- a clear, undistracted focus on the teacher and children's own work, designed to promote learning and concentration;
- clear understanding by all parties of roles and behaviours, so that learning can take place beneficially, willingly and without disruption.

Here the researcher may feel that the clarity of role specifications and expected behaviours are not at all negative, but are designed to promote the effective learning of children. Indeed the power of this arrangement for learning and its outcomes could be immense, for example, for children to be able to climb the social ladder in the future: education as a great emancipatory force in society.

Further, initially we have the photograph's title attached to it by the museum: 'School Children in Art Class', with the museum's own label reading: 'Children possibly at Woodland school taken during an art class. Note sculptured trees on desks'. Immediately the reader's attention is drawn to the fact that this concerns an art lesson, and that there are some art materials. Why were these features included in the text, and not others? Is that really the purpose or key message of the image, or is the museum, in a positive endeavour to be helpful, drawing attention to points that otherwise might go unnoticed? Is it trying not to be pejorative in its comments, or is it simply that the museum wanted a short label for indexing and referencing purposes? The point here is that labels can frame the researcher's or the viewer's insights, and the researcher needs to be aware of this. It is not only the focus of the text label, but the tone of those words: the label used by the museum may appear to be couched in neutral terms, but it has already decided what to comment on and what to ignore. Guidelines on inclusion and exclusion can be both useful and dangerous.

In considering the photograph, indeed any visual image, we can focus on the subject matter, its form, its genre, its meanings, its composition, its style and technical matters. However, we can go further, to examine the context of the photograph, its audience, its provenance, why it was taken, its usages and, indeed, the ethical issues that are raised by the photograph.

The researcher can speculate on the history of the photograph in question: why it was taken, for whom it was taken and what use was intended to be made of it, or indeed was made of it? Was it designed to impress parents, school governors, inspectors, local officials (and, if so, why was an art lesson chosen)? Was it designed to be simply a document of record of the school's history, and if so, why this scene in particular? Was it designed to be a celebratory record (the children may have been dressed smartly for the occasion, in clothes that they would not normally wear for school)? Who was the intended audience: the children themselves (e.g. in later life), their parents, education officials, researchers, visitors, historians, the families in question?

We can also ask how and why the photograph came to be in the museum in question (an award-winning national museum of social and industrial history).

For example, was it a donation, a purchase, did it arrive by happenstance, or deliberately, or as part of a large collection, or what?

The photograph raises several ethical questions, for example:

- Are the people still alive?
- Was informed consent gained from the people in the photograph to be photographed (or was it simply an accepted part of being at school)?
- What informed consent was gained by the museum, and from whom, to release the document into the public domain, or has the passage of time obviated the need for this?
- Is it acceptable and fair of the researcher to portray the school, the teacher and the students in question in a perhaps negative way, and, if not, then who actually suffers?
- Will the use of the photograph bring harm or good, and to whom?

What we have here encapsulates the problem that often adheres to documentary evidence: that it is prepared (or in this case taken) for one set of purposes and audiences, but it is used for other reasons and intentions.

Photographs, like other visual materials, are multilayered and capable of sustaining several interpretations. Hence the visual researcher, just like the textual researcher, has to disclose his or her own reflexivity and the possible influence that this has on the analysis and interpretation made. Though a picture may be worth a thousand words, photographs on their own may be relatively inert; it is only in the interaction between the producer of the image, the image itself and the audience that it comes alive.

We can read a photograph like a text, and indeed it is often useful to accompany the image with text. Text and photograph run together. A commentary can be useful to accompany, explain, interpret and contextualize the image, and, in research terms, this can tie the image into other evidence – visual or textual – that the researcher is using.

36.7 Analysing moving images

The term 'moving images' here is taken to include video and film material. Denzin (1990, p. 102) remarks that 'films do not faithfully reproduce reality'; rather, they are ideological interpretations and selections from reality; they are a particular version or view of reality. Hence the researcher has to interrogate the moving images in light of the research questions and to undertake a more valuative and ideology-critical reading of their content. This includes selecting, and justifying the selection of, particular parts of the moving images (what to focus on and what to overlook), which may be informed by the research questions and purposes.

Denzin (2004) suggests that films (including videos) should be considered initially at their 'textual realism' level, i.e. the story that the material is telling and how it is telling that story. At a second level, which he terms a 'subversive' level (p. 240), he suggests that a film can be read for its ideological content and effects, i.e. how the film functions to reproduce the (dominant) values and beliefs of everyday life and society. Hence the researcher starts with an overall view of the film as a whole, noting themes, impressions, key points, rather as one would 'read' a text. Having gained an overall view, the researcher can then go into details, for example, scenes, events, sequences and so on, in short, a micro-analysis of the material (Flick, 2009, p. 247). In this, the methods and tools of grounded theory, discourse analysis etc. can be used, working not only with the visual images but also, where relevant, transcriptions of the spoken words. As Flick remarks (p. 249), films can be regarded as visual texts, and so the range of tools for textual analysis can be brought into play here. He argues that researchers can look for patterns in the film (p. 247). Having conducted a first-level and second-level analysis, the researcher can then look for points of resonance, consonance, dissonance and contradiction between the two levels of analysis.

In video analysis, researchers can decide the unit of analysis (e.g. a time interval, a setting, an event, a sequence, an interaction) (Lee *et al*., 2015) and then analyse data using those units of analysis. The researcher can use inductive approaches (without a hypothesis or theory to be tested) and deductive approaches (hypothesis testing), time sampling or event sampling of video footage, both random and purposive, and looking for similarities and differences between coded elements (Lee *et al*. 2015). As in other forms of data analysis, coding can be used (Johnson and Black, 2012), for example, for quantitizing qualitative data or simply as part of conventional coding and analytical practices, indeed Lee *et al*. (2015) report using colour coding to indicate levels of interaction in classrooms, from cold colours for limited interaction to warm colours for greater interaction.

In selecting the time interval for coding the researcher has to balance too fine a level of detail, which might overlook the big picture, with too broad a picture, which might overlook important detail (Snell, 2011; Lee *et al*., 2015). Snell (2011), using the software The Observer XT, comments on its possibilities for generating systematic observation of video data

for statistical analysis, and for micro-ethnographic analysis, using coding and data management of video data. Codes and their related data are time-stamped, logged and saved in dedicated locations, synchronizing the codes and their related video data. Snell makes the point that detailed analysis contributes to nuanced interpretation and prevents over-reduction to which systematic analysis might be prone. Conversely, systematic analysis might overcome the 'cherry picking' of video clips and the overlooking of the bigger picture (p. 257).

As with much qualitative data analysis, exploration and interpretation run together; hence researchers have to be acutely aware of the influence of their own values, cultures, interests and background in the selection and interpretation of the data; in short they have to be reflexive. In this respect the repeatability of moving image material is useful in being able to be viewed by a third party, to check for alternative interpretations of the material.

Analysing moving images is costly in terms of time, as they have to be watched and re-watched many times in order to extract fair and suitable data and interpretations (e.g. for coding, constant comparison and narrative construction). This can be exacting and demanding of the researcher's insight and persistence.

36.8 Conclusion

This chapter has suggested that analysis and interpretation of images are often inextricably linked, raising the need for considerable reflexivity on the part of the researcher. Content analysis (both numerical and qualitative), discourse analysis and grounded theory can be used in the analysis and interpretation of visual images. The chapter provided a worked example of the analysis and interpretation of a single still image: a photograph. It has used this not only to indicate the processes and kinds of observations and interpretations that can be made, but to indicate how interpretations are multiple, sometimes conflicting, and subjective. The interpretation used elements of ideology critique in its exposure and disclosure of power in the image and its explanation. The authority of the researcher to determine the focus, analysis and interpretation of a still or moving image is, itself, subject to ideology critique and interrogation of power within a discourse. Visual images invite researchers to consider alternative forms of representing data, alternative questions to be asked about education systems and new ways of looking at and seeing things (Eisner, 1997, p. 6). That is a powerful challenge.

Companion Website

The companion website to the book provides PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Grounded theory

CHAPTER 37

One intention or outcome of analysing qualitative data is the generation of theory. Here we introduce key issues in grounded theory and the tools of grounded theory. The chapter includes:

- versions of grounded theory
- stages in generating a grounded theory
- the tools of grounded theory
- the strength of the grounded theory
- evaluating grounded theory
- preparing to work in grounded theory
- some concerns about grounded theory

Readers may find it helpful to refer also to Chapter 15 and particularly Chapter 34 on coding, as coding is integral to grounded theory (see below: coding).

37.1 Introduction

Theory generation in qualitative data can be emergent, and grounded theory is an important method of systematic emergent theory generation. Strauss and Corbin (1994, p. 273) remark that grounded theory is a methodology which seeks to develop theory which is rooted in – grounded in – data which have been collected systematically and analysed systematically; it is an orderly, methodical and partially controlled way of moving from data to theory, with 'clearly specified analytical procedures' (Greckhamer and Koro-Ljungberg, 2005, p. 731). It is more inductive than content analysis as, typically though not exclusively, the theory emerges from, rather than exists before, the data. The theory is derived inductively and, in some versions, deductively and abductively, from the analysis and study of, and reflection on, the phenomena under scrutiny (cf. Strauss and Corbin, 1990, p. 23).

Grounded theory, as Moghaddam (2006) avers, is a set of relationships among data and categories that proposes a plausible and reasonable explanation of the phenomenon under study, i.e. it explains by drawing on the data generated. It is a method or set of procedures for the generation of theory or for the production of a certain kind of knowledge (Greckhamer and Koro-Ljungberg, 2005, p. 729; Kolb, 2012). Glaser, one of the key writers in grounded theory, focuses on the methods of grounded theory, and Birks and Mills (2015, p. 5) add to this its philosophical roots in pragmatism and symbolic interactionism.

Grounded theory uses systematized methods (discussed below) of theoretical sampling, coding and categorization, constant comparison, memoing, the identification of a core variable, and saturation, all of which lead to theory generation. Grounded theory is not averse to quantitative methods, indeed it arose out of them (Glaser, 1996) in terms of trying to bring to qualitative data some of the analytic methods applied in statistical techniques (e.g. multivariate analysis). In grounded theory the researcher discovers what is relevant; indeed Glaser's and Strauss's (1967) seminal work is entitled *The Discovery of Grounded Theory*.

However, where it parts company with much quantitative, positivist research is in its view of theory. In positivist research the theory pre-exists its testing and the researcher deduces from the data whether the theory is robust and can be confirmed. Grounded theory, on the other hand, does not force data to fit a predetermined theory (Glaser and Strauss, 1967, p. 3); indeed it eschews such 'forcing', though the difference between inductive and deductive research is less clear than appears at first sight. For example, before one can deduce, one has to generate theory and categories inductively. The intention of grounded theory is to build and generate theory rather than to test an existing theory, providing researchers with tools to generate this theory through data analysis, to weigh up alternative explanations (e.g. through constant comparison) and to relate concepts in the development of theory (Moghaddam, 2006; Birks and Mills, 2015).

Grounded theory starts with data which are then analysed and reviewed to enable the theory to be generated from them; it is rooted in the data and little else. Theory derives from the data; it is grounded in the data and emerges from it. Glaser (1996) writes that 'forcing methodologies were too ascendant', not least in positivist research, and that grounded theory had to reject forcing or constraining the nature of a research

investigation by pre-existing theories. As grounded theory sets aside any preconceived ideas, letting the data themselves give rise to the theory, certain abilities are required of the researcher, for example:

- tolerance and openness to data and what is emerging;
- tolerance of confusion and regression (feeling stupid when the theory does not become immediately obvious);
- resistance to premature formulation of theory;
- ability to pay close attention to data;
- willingness to engage in the process of theory generation rather than theory testing; it is an experiential methodology;
- ability to work with emergent categories rather than preconceived or received categories.

As theory is not predetermined, the role of targeted prereading of literature is not as strong as in other kinds of research which use literature reviews to generate issues for the research. Indeed conducting prior literature reviews may be dangerous as it may prematurely close off or determine what one sees in data; it may cause one to read data through given lenses rather than with fresh eyes. As one does not know what one will find, one cannot be sure what one should read before undertaking grounded theory. One should read widely within and outside the field, or not at all, rather than narrowly and in too focused a direction (Glaser, 1996).

37.2 Versions of grounded theory

There are many versions of grounded theory (Hutchison *et al*., 2010), and indeed Greckhamer and Koro-Ljungberg (2005) comment that what grounded theory actually is has become a contested issue (p. 731). Three widely referenced versions are:

- the original, emergent model by Glaser and Strauss (1967) and Glaser (1978, 1992);
- the revised, systematic model by Strauss and Corbin (1990, 1998) and Corbin and Strauss (2008, 2015);
- the constructivist model by Charmaz (2006).

They differ in their processes, key elements, epistemologies, ontologies, theoretical foundations and frameworks. There are other models (e.g. Clarke's (2007) situational analysis model) which we do not include here.

The original, emergent model

In the original model articulated by Glaser and Strauss (1967), the theory emerges from the data, using various tools to facilitate such emergence and the 'discovery' of the theory that is embedded in the data. In this process there are two main types of coding: substantive and theoretical; substantive coding (with open coding) precedes theoretical coding (with selective coding and theoretical sampling).

This model uses memoing, constant comparison, theoretical sampling, derivation of the core category and theoretical sampling (all discussed below). Here the authors argue against starting with a literature review as this could lead to preconceived ideas which could influence too strongly or bias the researcher's responsiveness to the data, as, in their view, the researcher must be as open to the data as possible (Glaser and Strauss, 1967; Glaser, 1998). Substantive codes deliberately 'fracture' the data whilst theoretical codes deliberately recombine them into an organized whole.

The revised, systematic model

The revised grounded theory model from Strauss and Corbin (1990, 1998) is much more systematic and prescriptive than the original model, so much so that there was a well-documented split between Strauss and Glaser, with Glaser arguing that the revised model of Strauss and Corbin was formulaic and too prescriptive, 'forcing' a theory onto data and forcing data into a theory, whereas the essence of grounded theory was its aversion to forcing. (The third and fourth editions of their book (Corbin and Strauss, 2008, 2015) are more flexible and accommodating than the first edition in terms of processes and procedures.) The revised model gave prominence to axial coding (axial coding was absent from the original model of Glaser and Strauss (1967)), with a prescribed sequence of open coding leading to 'axial coding' and 'axial coding' leading to 'selective coding'. The analytical process was more prescriptive, detailed and predetermined than the original, emergent model, and this new model included a required 'conditional matrix' which was not present in the original model.

This new model also accorded greater value to the literature review early on in the research process (on the grounds that there is no *tabula rasa* in the mind of the researcher), as this can develop theoretical sensitivity and hypothesis generation, whereas the original model deliberately argued against researchers conducting a literature review in advance. Further, the revised model adopts a more prescriptive approach to the types of memos researchers write (e.g. operational, coding-related, theoretical), whereas the original model kept the nature of the memo open and flexible. The original model emphasized an inductive approach to data analysis whereas the revised model by Strauss and Corbin

included deductive approaches and theory verification by the data.

The Strauss and Corbin model differs from the original model as they argue that: (a) sampling proceeds on theoretical grounds (a point which the original model rejects as introducing bias into the research and that the research should commence with data alone); (b) hypotheses can be developed and verified (whereas the original model abjures prior theory generation, testing and verification); (c) induction, deduction and abduction can be used, whereas the original model advocates induction alone and rejects deduction; and (d) attention must be given to broader structural contents and influences (whereas the original model argues that these, if they are present in the research, would be manifested in the data alone and, otherwise, should not be considered).

The constructivist model

In the constructivist model from Charmaz (2006), subjective meanings are attributed to the data by participants and researchers, and there might be multiple interpretations of what these meanings are. This moves beyond 'facts' and descriptions of acts to interpretations and perspectives. Charmaz holds that concepts are not so much revealed or 'discovered' (the title of Glaser's and Strauss's original book (1967)) as 'constructed', for example through interactions and involvements, both past and present, with people, ways of looking, interpretations and meanings, leading to one or more 'constructions of reality' (p. 10).

The theoretical basis of her view, rather than being objectivist as in the two previous models, is interactionist and constructivist (Charmaz, 2002, p. 678). Data are 'reconstructions of experience; they are not the experience itself' (Charmaz, 2000, p. 514) and hence are open to interpretation, and there may be more than one grounded theory that emerges from the data (Greckhamer and Koro-Ljungberg, 2005, p. 744).

Charmaz (2002) sets out six analytical steps in her grounded theory: (i) data collection and analysis, simultaneous and ongoing; (ii) early data analysis to identify emergent themes; (iii) identification of basic social processes from and within the data; (iv) inductive construction and co-construction of abstract explanatory categories for those processes; (v) constant comparison to refine the categories; and (vi) integrating the categories into a theoretical framework that identifies causes, consequences and conditions (cf. Greckhamer and Koro-Ljungberg, 2005, p. 739). In this constructivist model there are three types of coding: open, focused and theoretical. Theoretical coding here means the fusing together of concepts into groups as the analysis proceeds, not as a later stage or end-point of the analysis.

In the constructivist model an initial literature review is entirely acceptable. This model is less objectivist than the other two models, and emphasizes subjective constructions and co-constructions of knowledge, the generation of different meanings by participants and researchers, and the openness to modification of any emergent theory in light of those meanings and interpretations. Objective notions of reality, as discovered by a neutral observer, are replaced by the (social) construction of subjective meanings of reality (Keane, 2015).

Hernandez and Andrews (2012) contend that, whereas the original model of grounded theory gives rise to explanatory theory, the constructivist model gives rise to a descriptive theory. Indeed Charmaz (2002) notes that grounded theorists working in the constructivist perspective admit that it is they who define and *construct* what is taking place in the data, in contrast to objectivist grounded theorists who *discover* what is taking place in the data (p. 684).

The models from Strauss and Corbin (1990, 1998) and Charmaz both reject the idea of holding back from conducting a preliminary literature review. Similarly, Dunne (2011) sees it as simply unworkable for researchers seeking permission to conduct research or to obtain research funding not to demonstrate that they have done their homework and that they are familiar with the field, both of which require a literature review. There is no good reason why a researcher cannot review relevant literature, as this is part of the 'historicity', familiarization and contextualization of the study, just as other familiarization activities might be acceptable, indeed unavoidable. As Thornberg (2012a) argues, researching the literature can support greater sensitivity and creativity, spotting matters that might otherwise be overlooked.

Common features of the three models

Though there are different versions of grounded theory, and variations in its forms and epistemologies (Greckhamer and Koro-Ljungberg, 2005, p. 731; Buckley and Waring, 2009, p. 318; Hutchison *et al*., 2010; Waring, 2012), nevertheless there are several features in common in these definitions:

- theory is *emergent* rather than predefined and tested; it emerges from the data rather than *vice versa*;
- the grounded theory process is recursive;
- sampling is targeted at generating theory;
- the process of analysis involves coding and categorization;

- data collection and analysis proceed simultaneously and are ongoing;
- systematic comparisons are made in the process of analysis ('constant comparison');
- theory generation is a consequence of, and partner to, *systematic* data collection and analysis;
- patterns and theories are implicit in data, waiting to be discovered;
- grounded theory is close to the data that give rise to it.

Glaser (1996) states that 'grounded theory is the systematic generation of a theory from data'; it is an inductive process in which everything is integrated and in which data pattern themselves rather than having the researcher pattern them, as actions are integrated and interrelated with other actions. Glaser's and Strauss's (1967) seminal work rejects simple linear causality and the decontextualization of data, arguing that the world which participants inhabit is multivalent, multivariate and connected. As Glaser (1996) says: 'the world doesn't occur in a vacuum', and the researcher must take account of the interconnectedness of actions. In everyday life, actions are interconnected and people make connections naturally; it is part of everyday living, and hence grounded theory catches the naturalistic element of research and formulates it into a systematic methodology. In seeking to catch the complexity and interconnectedness of everyday actions, grounded theory is faithful to how people act; it takes account of apparent inconsistencies, contradictions, discontinuities and relatedness in actions. As Glaser says: 'grounded theory is appealing because it tends to get at exactly what's going on'. Flick (1998, p. 41) writes that the aim is to recognize complexity by including contextual details, rather than to reduced complexity by atomizing it into variables.

There are several elements of grounded theory that contribute to its systematic nature and it is to these that we now turn.

37.3 Stages in generating a grounded theory

The stages in generating a grounded theory depend, in part, on the model of grounded theory adopted, and they may vary. However, a typical sequence is:

1. Decision on whether a grounded theory approach is most suitable →
2. Theoretical sampling + memoing →
3. Data collection + memoing →
4. Coding: open codes leading to axial codes (clustering open codes into groups by meaning), leading to selective codes (relating axial codes to each other and drawing linkages); theoretical codes + memoing →
5. Categorization (which might involve reducing the number of codes and creating hierarchies of codes) + memoing →
6. Constant comparison + memoing →
7. Identification of the core variable + memoing →
8. Saturation + memoing →
9. Theory generation/verification →
10. Writing the report.

However, this suggests linearity, a sequence. Though Strauss and Corbin (1990, 1998) advocate sequencing (including adding a conditional matrix to the sequence above), in reality the researcher will operate recursively, going back and forth in these stages, or indeed operating several stages in parallel, reviewing, revising and reworking as considered appropriate.

37.4 The tools of grounded theory

There are several common tools that researchers use in grounded theory: theoretical sampling; coding (discussed in Chapter 34); memoing; constant comparison; identification of the core variable(s); 'saturation'; and theoretical sensitivity. We discuss these below.

Theoretical sampling

Theoretical sampling, as Glaser and Strauss (1967) write, is a process for generating theory. In this the researcher collects the data, processes data with coding and analyses the results, and this analysis informs where to go next in collecting data in order to develop the emerging theory (p. 45), i.e. the emerging theory controls the process of data collection and is the criterion – theoretical relevance – for proceeding further with data collection (p. 49) rather than, for example, conventional sampling approaches. Data are collected which are useful to the generation of theory (Creswell, 2012, p. 433), i.e. purposive sampling takes place.

Theoretical sampling is that kind of sampling which is based on the concepts which have shown themselves to be theoretically relevant to the evolving or emerging theory (Strauss and Corbin, 1990, p. 176; Birks and Mills, 2015, pp. 68–71). Here data are collected and analysed on an ongoing basis, with the analysis informing the further collection of data, i.e. a process of continual refining of the categories, ideas, concepts and emergent theory. The researcher keeps on adding cases to the sample until she has enough data to describe what is going on in the context or situation under study and until 'theoretical saturation' is reached (discussed

below) (Glaser and Strauss, 1967; Strauss and Corbin, 2008). As one cannot know in advance when this point will be reached, one cannot determine the sample size, nature or representativeness until one is actually doing the research. Kolb (2012) suggests that, therefore, theoretical sampling might lead to biased sampling.

In theoretical sampling, data collection continues until sufficient data have been gathered to create a theoretical explanation of what is happening and what constitutes its key features. It is not a question of representativeness, but, rather, a question of enabling the theory to emerge. Corbin and Strauss (2008) write that purposeful sampling takes place at the levels of open coding and selective coding, whilst structured, systematic sampling takes place at the level of axial coding.

Coding

Coding is the process of disassembling/fracturing and then reassembling the data. Data are disassembled when they are broken apart into lines, paragraphs or sections, subsequent to which these fragments are rearranged, usually through coding, to produce an organized and structured thematization and theory (cf. Ezzy, 2002, p. 94).

In grounded theory there are three main types of coding: *open*, *axial* and *selective*, the intention of which is to disassemble the data into manageable chunks in order to facilitate an understanding of the phenomenon in question. Strauss and Corbin (1990) suggest a linear sequence here: open coding to axial coding to selective coding. Whether such linearity is acceptable is contestable, as recursion and iteration can occur.

Open coding involves exploring the data and identifying units of analysis to code for meanings, feelings, actions, events and so on. The researcher codes the data, creating new codes and categories and sub-categories where necessary, and integrating codes where relevant until the coding is complete. *Axial coding* seeks to make links between categories and codes, 'to integrate codes around the axes of central categories' (Ezzy, 2002, p. 91); the essence of axial coding is the interconnectedness of categories (Creswell, 2012). Hence codes are explored, their interrelationships are examined and codes and categories are compared to existing theory. In *selective coding* a core code or category is identified, the relationship between that core code/category and other codes/categories is made clear (Ezzy, 2002, p. 93), and the coding scheme is compared with pre-existing theory. Creswell (1998, p. 57) writes that here the researcher identifies a 'story line' and proceeds to construct the story that draws together all the axial codes.

As coding proceeds the researcher develops concepts and makes connections between them. Flick *et al*. (2004, p. 19) argue that 'repeated coding of data leads to denser concept-based relationships and hence to a theory', i.e. that the richness of the data is included in the theoretical formulation.

We strongly advise readers here to consult Chapter 34 on coding, as it provides much more detail.

Memoing

Chapter 33 introduced memos, and here we take the matter further. Memos are simply notes written to oneself, logging ideas, abstract thoughts, insights, observations, conjectures and possibilities etc. (cf. Waring, 2012, p. 302; Denscombe, 2014, p. 285; Birks and Mills, 2015). They are typically written by the researcher to herself/himself and contain analysis which contributes to the formulation of the emergent theory (Strauss and Corbin, 1990, p. 197). They can contain notes on a wide field of matters; they can be short, long, detailed, general, focused, wide-ranging etc. They can be, for example, conceptual, theoretical, operational, reflexive and coding-related; they are what the researcher wants them to be.

In memoing, the researcher writes ideas, notes, comments, notes on surprising matters, themes or metaphors, reminders, hunches, draft hypotheses, references to literature, diagrams questions, draft theories, methodological points, personal points, suggestions for further enquiry etc. that occur to him/her during the process of constant comparison and data analysis (Lempert, 2007, p. 245; Flick, 2009, p. 434).

Hutchison *et al*. (2010) note that memos can be: *a research diary* (e.g. containing conceptual developments and general events); *reflective and reflexive; conceptual* (often attached to codes, nodes and categories); *emergent questions* and summaries of *emergent themes* and *explanatory* (e.g. related to literature, technical matters, models). Waring (2012) suggests three main types of memo: *code notes* (e.g. containing the names of codes and how these were derived); *theoretical notes* (extensions of code notes, e.g. containing the products of inductive and deductive thinking in relation to properties of, and relationships between, data, codes and theorizing); and *operational notes* (e.g. concerning the conduct of the data collection, research and data analysis) (p. 302).

Memos cover many aspects of the research and data analysis. They can address many matters, for example, those set out here in alphabetical order:

- analytical notes and ideas;
- codes, categories and the products of coding;

- comments on sampling;
- comments on saturation;
- concepts and key concepts;
- conditions and contingencies;
- conjectures and speculations;
- core category;
- cross-references and relationships;
- decisions taken;
- descriptive details;
- diagrams;
- directions and suggestions;
- emerging theory;
- explanatory ideas;
- feelings about the research;
- grounded theory;
- ideas;
- impressions;
- inductive and deductive material;
- issues and ideas arising in the research;
- models;
- observations;
- operational matters;
- philosophical matters;
- procedural matters;
- reflections on the research;
- relationships and comparisons;
- reminders;
- suggestions for further directions of investigation;
- summaries;
- themes;
- theoretical sampling;
- theoretical sensitivity;
- theoretical suggestions;
- theory.

Memos can be written at any stage of the data collection and analysis; they can vary in length and format, from informal to more formal. They may contain verbatim quotations, notes, jottings, key points underlined, diagrams (Strauss and Corbin, 1990, pp. 202–3); in short, nothing is ruled out.

Memos should bear a date, references to the data/data file about which they are written, a heading to identify what they are about and, where appropriate, references to relevant codes and categories (Strauss and Corbin, 1990, pp. 200–4). Memos, in turn, become data, and indeed memos about memos can become data (e.g. to enable reflexivity). Much software (e.g. NVivo) provides a repository and location for memos and links them to primary data sources.

Constant comparison

Constant comparison is the process 'by which the properties and categories across the data are compared continuously until no more variation occurs' (Glaser, 1996), i.e. saturation is reached. In constant comparison, data are compared across a range of situations, times and groups of people, and through a range of methods. The process resonates with the methodological notion of triangulation.

The application of open, axial and selective coding adopts the method of constant comparison. In constant comparison, the researcher compares the new data with existing categories, so that categories achieve a perfect fit with the data. If there is a poor fit between data and categories, or indeed between theory and data, then the categories and theories have to be modified until all the data are accounted for. New and emergent categories are developed in order to incorporate and accommodate data in a good fit, with no discrepant cases. Data collection and analysis proceed together.

Glaser and Strauss (1967, p. 102) note that constant comparison using coding and data analysis is the means for generating theory. The theory generated does not explicitly seek generalizability; rather the researcher seeks theoretical saturation, i.e. no further data modify the theory. Constant comparison is the process by which the properties and categories across all the data are compared continuously until no more variation is found (Glaser, 1996).

To accompany constant comparison, and to aid reflexivity, Glaser and Strauss (1967) suggest the value of memoing, discussed earlier. In constant comparison, discrepant, negative and disconfirming cases are also important in assisting the categories and emergent (grounded) theory to fit all the data.

Glaser and Strauss (1967, pp. 105–13) suggest that the constant comparison method involves four stages: (i) comparing incidents and data which are applicable to each category; (ii) integrating these categories and their properties; (iii) bounding the theory; (iv) setting out the theory.

The first stage here involves coding of incidents and comparing them with previous incidents in the same and different groups and with other data that are in the same category. For this to happen they suggest *unitizing* – dividing the narrative into the smallest pieces of information or text that are meaningful in themselves, for example, phrases, words, paragraphs. It also involves *categorizing*: bringing together those unitized texts which relate to each other and that can be put into the same category, plus devising rules to describe the properties of these categories and checking that there is

internal consistency within the unitized text contained in those categories.

The second stage involves memoing and further coding. Here the method of constant comparison involves moving beyond comparing one incident with another to comparison of one incident with the properties of the *category* which emerged after comparing incident with incident (Glaser and Strauss, 1967, p. 108).

The third stage – delimitation – occurs at the levels of the theory and the categories (p. 110), in which the major modifications reduce as underlying uniformities and properties are discovered and in which theoretical saturation takes place.

The final stage (writing theory) occurs when the researcher has gathered and generated coded data, memos and a theory which is then written in full.

By going through the previous data, particularly the search for confirming, negative and discrepant cases, the researcher is able to keep a 'running total' of these cases for a particular theory. The researcher also generates alternative theories for the phenomena under investigation (e.g. abduction) and performs the same count of confirming, negative and discrepant cases. Lincoln and Guba (1985, p. 253) argue that the theory with the greatest incidence of confirming cases and the lowest incidence of negative and discrepant cases is the most robust, though this is contestable.

Constant comparison combines the elements of inductive category coding with simultaneously comparing these with the other events and social incidents that have been observed and coded over time and location (LeCompte and Preissle, 1993, p. 256). This enables social phenomena to be compared across categories, where necessary giving rise to new dimensions, codes and categories. Glaser (1978) indicates that constant comparison can proceed from the moment of starting to collect data, seeking key issues and categories, discovering recurrent events or activities in the data that become categories of focus, and expanding the range of categories. This process can continue during the writing-up period, which should be ongoing, so that a model or explanation of the phenomena can emerge which accounts for fundamental social processes and relationships.

The core variable

Through the use of constant comparison a core variable (or core category) is identified: that variable/category which accounts for most of the data and to which as much as possible is related; that variable or category around which most data are focused and to which they relate (Strauss and Corbin, 1990, p. 116). As Flick *et al*. (2004, p. 19) suggest: 'the successive integration of concepts leads to one or more key categories and thereby to the core of the emerging theory'. The core variable is that variable that integrates the greatest number of codes, categories and concepts, and to which most of them are related and with which they are connected. It has the greatest explanatory power; as Glaser (1996) remarks: a concept has to 'earn its way into the theory by pulling its weight' without forcing.

A core variable/category must be central to the category system and the phenomena rather than peripheral to them; it must appear frequently in the data and must fit comfortably and logically to the data rather than be a strained fit. It should have an abstract title but one that is close to the categories and data in question, and it must enable variations to be explained (Strauss and Corbin, 1994).

Saturation

Saturation is reached when no new insights, properties, dimensions, relationships, codes or categories are produced even when new data are added, when all the data are accounted for in the core categories and subcategories and when the coding, categories and data support the emerging theory (Glaser and Strauss, 1967, p. 61; Creswell, 2002, p. 450; Ezzy, 2002, p. 93), and when the variable covers variations and processes (Moghaddam, 2006). Of course one can never know for certain that the categories are saturated, as fresh data may come along that refute the existing theory. The partner of saturation is theoretical completeness, when the theory is able to explain the data fully and satisfactorily.

Theoretical sensitivity

Researchers must possess theoretical sensitivity, i.e. the ability to perceive and notice the important parts of data and to accord them meaning (Strauss and Corbin, 1990, p. 46). It concerns personal qualities in the researcher (p. 41), and sensitivity to the subtleties and complexities of the data and ability to develop theoretical insights into the research. Birks and Mills (2015) comment that it is the researcher's ability to 'recognize and extract from the data' (p. 58) those elements which have relevance and meaning for the emerging theory, without 'forcing' the data into a theory (p. 59). Such sensitivities can be developed from studying relevant literature, professional and personal experience, the processes and procedures followed in the data analysis, continually interacting with the data, reflexivity, standing back from the data to review what is happening, maintaining a critical, perhaps sceptical, attitude to possible explanation, categories and hypotheses concerning the data, i.e. regarding them as provisional only (Strauss and Corbin, 1990, pp. 42–5).

37.5 The strength of the grounded theory

As a consequence of theoretical sampling, coding, constant comparison, the identification of the core variable and the saturation of data, categories and codes, the grounded theory (of whatever is being theorized) emerges from the data in an unforced manner, accounting for all of the data. The adequacy of the derived theory can be evaluated against several criteria. Glaser and Strauss (1967, p. 237) suggest four such main criteria:

1. the closeness of the *fit* between the theory and the data;
2. how readily *understandable* the theory is by laypersons working in the field, i.e. that it makes sense to them;
3. the ability of the theory to apply to a wide range of everyday situations in the same field, i.e. not simply to specific kinds of situation (p. 237);
4. the user of the theory must have sufficient control over their everyday lives so that applying the theory is possible and worthwhile (p. 245).

Strauss and Corbin (1994, pp. 253–6) suggest several criteria for evaluating the theory:

- the adequacy and power of the theory to account for the main concerns of the data;
- the relevance and utility of the theory for the participants;
- the closeness of the fit of the theory to the data and phenomenon being studied, and under what conditions the theory holds true;
- the fit of the axial coding to the categories and codes;
- the ability of the theory to embrace negative and discrepant cases;
- the fit of the theory to literature;
- the appropriateness of the original sample selection, and on what basis;
- what major categories emerged, and what were some of the events, incidents, actions etc. (as indicators) that pointed to some of the major categories?
- on the basis of what categories did theoretical sampling proceed? Was it representative of the categories?
- what were some of the hypotheses pertaining to conceptual relations (that is, among categories), and on what grounds were they formulated and tested?
- were there instances when hypotheses did not hold up against what was actually seen? How were these discrepancies accounted for? How did they affect the hypotheses?
- how and why was the core category selected (sudden, gradual, difficult, easy), and on what grounds?
- were concepts generated and systematically related?
- were there many conceptual linkages between concepts, and were the categories well developed?
- was much variation built into the theory? Were variations explained? Were the broader conditions built into its explanation?
- were change and movement taken into account in the development of the theory?

37.6 Evaluating grounded theory

Strauss and Corbin (1990) indicate that the grounded theory generated should be judged against several criteria (pp. 252–6):

- the reliability, validity and credibility of the data;
- the adequacy of the research process;
- the empirical grounding of the research findings;
- the sampling procedures;
- the major categories that emerged;
- the adequacy of the evidence base for the categories that emerged;
- the adequacy of the basis in the categories that led to the theoretical sampling;
- the formulation and testing of hypotheses and their relationship to the conceptual relations among the categories;
- the adequacy of the way in which discrepant data were handled;
- the adequacy of the basis on which the core category was selected;
- the generation of the concepts;
- the quality of the concepts and the extent to which they are systematically related;
- the number and strength of the linkages between categories, and their conceptual density, leading to their explanatory power;
- the extent of variation that is built into the theory;
- the extent to which the explanations take account of the broader conditions that affected the phenomenon being studied;
- the account taken of emergent processes over time in the research;
- the significance of the theoretical findings.

The emphasis here is on the procedures and not only on the outcomes of the grounded theory research. To this list can be added the criteria of: originality; resonance

(the data, the phenomenon, the participants' experiences and views); usefulness (for different people and groups, for identifying generic processes, for further research, for advancing the field) (Charmaz, 2006, pp. 182–3); 'workability' (practicality and explanatory power); fit with the data; 'relevance' (to the situation, to groups, to researchers, to the field); and 'modifiability' (in light of additional data) (Glaser and Strauss, 1967). Grounded theory is not exempted from the conventional criteria of rigorous research.

37.7 Preparing to work in grounded theory

Glaser (1996) offers some useful practical and personal advice for researchers working with grounded theory. He suggests that researchers must be able to: (a) tolerate uncertainty (as there is no preconceived theory), confusion (cf. Buckley and Waring, 2009, p. 330) and setbacks (e.g. when data disconfirm an emergent theory); (b) avoid premature formulation of the theory, but, by constant comparison, enable the final theory to emerge. They need to be open to what is emerging and not to try to force data to fit a theory but, rather, to ensure that data and theory fit together in an unstrained manner. As he says, 'forcing is a consequence of an inability to handle confusion and regression [feeling stupid] while you study'. Grounded theory, he avers, is an 'experiential methodology', and he advises researchers to 'just do it'! He also indicates that it might not be useful to do much pre-reading since, as he says, 'you never know what you're going to find, so how do you know what to read' (though this is contentious, as discussed earlier and below). He makes the point that, since grounded theory is not easy, the researcher has to be prepared to work hard to be faithful to the rigour of the process.

37.8 Some concerns about grounded theory

There are several concerns raised about grounded theory.

Thomas and James (2006) mount a withering critique of grounded theory, arguing that it 'oversimplifies complex meanings and inter-relationships in data' (p. 768) by focusing on the 'immediately apparent and observable' (p. 769), that it 'constrains analysis' by putting the cart of procedures (theoretical sampling, coding, categorizing, constant comparison, saturation, identification of the core category) before the horse of interpretation, and that it unfairly privileges induction over explanation and prediction (p. 768). They argue that, since grounded theory has many versions, its identity is unclear.

We set out below four further main areas of dispute and criticism with regard to grounded theory.

The meaning and status of theory

Thomas and James (2006) suggest that the term 'theory' is ill-defined and vague in grounded theory, and has many meanings: 'theory' here is 'merely a narrative' rather than an explanation (p. 778), and what grounded theory generates is not a 'theory' at all (p. 780) but simply 'mental constructions', with little explanatory, empirical or predictive power (see also Silverman, 1993, p. 47).

Bryant and Charmaz (2007) comment that grounded theory is epistemologically unclear, makes varied, incommensurate epistemological assumptions (e.g. positivist, inductivist and objectivist versus constructivist, interactionist, deductivist and subjectivist) and is insufficiently related to sociological theory. Waring (2012) notes the contention that there is an unclear separation between discovery and verification. In short, the status and definition of 'theory' in 'grounded theory' is unclear on many fronts. We refer the reader to Chapter 4 for a fuller discussion of 'theory'.

The role of literature and prior disciplinary knowledge

As mentioned earlier, Glaser and Strauss (1967) suggested that the reader should not conduct a literature review in advance of the data analysis, or bring advanced disciplinary knowledge to bear on the analysis, so that the data can speak for themselves, unaffected or contaminated by prior researcher knowledge or preconceptions which might stifle the process of theory generation, and to avoid being '"awed out" by the work of others' (Dunne, 2011, p. 115). Indeed Glaser (1998) argues that, since the researcher does not know in advance what literature will be relevant in the data, conducting a literature review may be time-wasting and inefficient, as it may engage irrelevant material.

This view has attracted much criticism for being artificial (in reality researchers do have some knowledge of the field), unnecessary, disproportionate, unworkable (e.g. for students and researchers who have to provide a literature review as part of a research proposal), over-prescriptive, ideological and, in practice, impossible (e.g. Dunne, 2011; Thornberg, 2012a). The researcher has, and needs to have, prior knowledge in order to understand the field, to be sensitive to the issues and to be able to reflect on the research. Further, as the post-positivists note in Chapter 1, there is no such thing as theory-free observation or a neutral 'God's eye view of the world' (Thornberg, 2012b,

p. 246). Rather, researchers are embedded in a socio-historical, spatio-temporal and ideological world which they cannot simply set aside (cf. Thomas, 2006, pp. 783–4). As social beings, they cannot 'quarantine themselves … from the data they are analysing' (Thomas and James, 2006, p. 781) in their attempts to find an emergent theory.

Silverman (1993, p. 47) suggests that eschewing early literature reviews and disciplinary knowledge fails to acknowledge the implicit theories which guide research from its earliest stages (i.e. data are not theory-neutral but theory saturated), and this should feed into the process of reflexivity in qualitative research.

Dunne (2011) notes that Glaser's insistence on having no advance literature review might be just as time-wasting and inefficient as if one does have one. Literature can provide a rationale for the study, can ensure originality to the study (i.e. that a similar study has not already been conducted and that the study is, indeed, innovative), can avoid the researcher making the same mistakes as other studies and can provide a context for the study (Dunne, 2011; Thornberg, 2012a). It can enable the researcher to be familiar with key concepts ('sensitising concepts'), to spot and circumvent problems (both methodologically and conceptually), to be aware of their own previously unconsciously held preconceptions, and promote clarity in thinking about the concepts and possible theory (Dunne, 2011, p. 116). Indeed literature is a source of inspiration, opening up rather than closing down possibilities and creativity (Thornberg, 2012b, p. 249).

The question of the 'ground' in 'grounded theory'

The grounds – the warrants – for accepting a theory are unclear in grounded theory; are they observation, interpretation, logic, deduction, inference or what? Glaser and Strauss (1967) note that theory is grounded in data and 'discovered', i.e. it has an objective existence in the data that is waiting to be discovered. However, Charmaz (2002), in her constructivist version of grounded theory, suggests that the 'ground' is people, i.e. that the theory is grounded in the meanings and meaning-making that people give to, or construct from, the data, i.e. theory has no objective existence that is waiting to be discovered but is defined by people. Theory is constructed and co-constructed, not discovered, by researchers and participants who bring their own biographies, experiences, contexts and backgrounds to bear on their theories (Charmaz, 2002, 2006; Thornberg, 2012a).

Thomas and James (2006) contend that 'theory' in grounded theory is 'invented' – created – rather than pre-existent and 'discovered' and, anyway, a theory is merely conjectural rather than certain. Indeed they suggest that the fixity and firmness implied in the term 'ground' is inappropriate if one inclines towards Charmaz's view of the 'construction' of a more tenuous, mutable and multiplicity of theory. Hence they suggest replacing the title of the canonical text *The Discovery of Grounded Theory* with *The Invention of Grounded Theory*.

Induction and deduction

Whilst Glaser and Strauss (1967) staunchly advocate induction as the only way of conducting grounded theory and its related data analysis, Strauss and Corbin (1990, 1998) and Corbin and Strauss (2008; 2015) accord a place to deduction and abduction. This marks a major split between Glaser and Strauss. At issue here is that, once deduction and abduction are introduced, the epistemology of grounded theory changes from the generation of emergent theory and hypotheses to the testing and verification of prior existing theory and hypotheses. Glaser adheres to induction, creativity and the imagination in generating theory from the data, whilst Strauss and Corbin allow for hypothesis testing and deductive reasoning, looking *for* data rather than looking *at* data (Robrecht, 1995; Buckley and Waring, 2009, p. 330), which, Glaser (1992, 1998) avers, can lead to 'forcing' data to fit a preconceived theory. Pure induction, argues Thornberg (2012a), is simply impossible.

Generalizability

A concern of grounded theory is how generalizable is the emergent theory. Is it restricted, for example, to being an explanation of the phenomenon in question or does it have wider application, being of a more abstract and lawlike generalization (with the rider that there may not be laws in social science, in contrast to laws in the natural sciences). Does grounded theory aspire to being a 'grand theory' a 'middle-range' theory or an 'empirical theory', as set out in Chapter 4? Is it for the reader to decide whether the theory can apply to a new situation (e.g. Glaser, 1998)? Glaser (1998) argues that a grounded theory must have 'transferability', i.e. must not be bound by the specificities of the particular study in question and must be able to apply to other situations (e.g. through conceptual similarities). This suggests that it is more like the 'middle-range' theory set out in Chapter 4.

Transferability can be, for example, from sample to population and from case to case; the reader may decide how transferable the theory is from one situation to another (Corbin and Strauss, 1990, p. 15). However, this raises questions as to whether a robust theory

should be decided on the grounds of reader judgement alone, though Corbin and Strauss also indicate that theoretical sampling in grounded theory should enable greater generalizability to be achieved. Further, they argue that the generalizability of a grounded theory is achieved, in part through the level of abstraction of the concepts used in the research, particularly in relation to the core category, and in part through the specification of the particular situations to which it might apply.

The dependence on coding

Finally, some versions of grounded theory are heavily dependent on coding, and we refer readers also to the critiques of coding set out in Chapter 34.

Grounded theory, then, though widely used, is not without its challenges (cf. Birks and Mills, 2015). Researchers must decide on its fitness for purpose and, if working with it, must be mindful of its challenges and criticisms.

Companion Website

The companion website to the book provides additional material, data files and PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Approaches to quantitative data analysis

CHAPTER 38

Many research data are numerical, and many numerical data are bewildering to researchers. Before moving to specific statistical tests for analysing data, we introduce some important foundational concepts in this chapter. These include:

- scales of data
- parametric and non-parametric data
- descriptive and inferential statistics
- kinds of variables
- hypotheses
- one-tailed and two-tailed tests
- distributions

38.1 Introduction

The prospect of analysing numerical data sends shivers down the spines of many novice researchers who not only baulk at the thought of statistics but hold fundamental objections to what they see as 'the mathematization of nature' (Horkheimer, 1972). Most concepts in education, some assert, are simply not reducible to numerical analysis. Statistics, they say, combine refinement of process with crudity of concept. We do not hold with any of this. Quantitative data analysis has no greater or lesser importance than qualitative analysis and *vice versa*. Its use is entirely dependent on *fitness for purpose*. Arbitrary dismissal of numerical analysis is mere ideology or prejudice.

Quantitative data analysis is a powerful research form. It is often associated with large-scale research, but can also serve smaller-scale investigations, with case studies, action research, correlational research and experiments. In the following chapters we show how numerical data can be reported and introduce some of the most widely used statistics that can be employed in their analysis.

Numerical analysis can be performed using software, for example, the Statistical Package for Social Sciences (SPSS), Minitab, Excel, SAS, Statistica, R. Software packages apply statistical formulae and carry out computations. With this in mind, we avoid extended outlines of statistical formulae, though we do provide details where considered useful. Our primary aim is to explain the concepts that underpin statistical analyses and to do this in as user-friendly a way as possible. Lest our approach should raise purist eyebrows, we provide greater detail in references and we signal these where appropriate. Our outline commentary is closely linked to SPSS, a widely used statistical package for social sciences. An introductory SPSS manual to this volume is provided in an accompanying website (including print-outs of data analysis), together with comments on what they show. It is often the case that such outputs can clarify issues more straightforwardly than extended prose. We also include a guide to all the SPSS files held on the companion website to this chapter.

In this chapter we identify some key concepts in numerical analysis (scales of data, parametric and non-parametric data, descriptive and inferential statistics, dependent and independent variables). Throughout this chapter and subsequent chapters we indicate how to report analysis; these are collected together in a single file on the accompanying website. Material in the accompanying web site also refers to statistical tables, which can also be found on the website.

In this chapter we introduce some basic concepts and terms, which are taken up in later chapters on descriptive statistics and inferential statistics. Bearing in mind the range of statistics covered, Chapter 44 maps out key statistics that are available to the researcher.

38.2 Scales of data

Before one can advance very far in the field of data analysis one needs to distinguish the kinds of numbers with which one is dealing. This takes us to the commonly reported issue of scales or levels of data, and four are identified, each of which, in the order given below, subsumes its predecessor.

The *nominal* scale simply denotes categories, 1 means such-and-such a category, 2 means another and so on, for example, '1' might denote males, '2' might denote females. The categories are mutually exclusive and have no numerical meaning. For example, consider

numbers on a football shirt: we cannot say that the player wearing number 4 is twice as anything as a player wearing a number 2, nor half as anything as a player wearing a number 8; the number 4 simply identifies a category, and indeed nominal data are frequently termed categorical data. The data classify, but have no order. Nominal data include items such as sex, age group (e.g. 30–35, 36–40), subject taught, type of school, socio-economic status. Nominal data denote discrete variables, entirely separate categories, for example, according females the number 1 category and males the number 2 category (there cannot be a 1.25 or a 1.99 position). The figure is simply a conveniently short label.

The *ordinal* scale classifies and also introduces an order into the data. These might be rating scales where, for example, 'strongly agree' is stronger than 'agree', or 'a very great deal' is stronger than 'very little'. It is possible to place items in an order, weakest to strongest, smallest to biggest, lowest to highest, least to most and so on, but there is still an absence of a standard metric – a measure using calibrated or equal intervals. Therefore one cannot assume that the distance between each point of the scale is equal, i.e. the distance between 'very little' and 'a little' may not be the same as the distance between 'a lot' and 'a very great deal' on a rating scale. One could not say, for example, that, in a five-point rating scale (1=strongly disagree; 2=disagree; 3=neither agree nor disagree; 4=agree; 5=strongly agree), point 4 is in twice as much agreement as point 2, or that point 1 is in five times more disagreement than point 5. However, one could place them in an order: 'very little', 'a little', 'somewhat', 'a lot', 'a very great deal', or 'strongly disagree', 'disagree', 'neither agree nor disagree', 'agree', 'strongly agree', i.e. it is possible to rank the data according to rules of 'lesser than' or 'greater than', in relation to whatever value is included on the rating scale. Ordinal data include items such as rating scales and Likert scales, and are frequently used in asking for opinions and attitudes.

The *interval* scale introduces a metric – a regular and equal interval between each data point – as well as keeping the features of the previous two scales, classification and order. This lets us know 'precisely how far apart are the individuals, the objects or the events that form the focus of our inquiry' (Cohen and Holliday, 1996, p. 9). As there is an exact and same interval between each data point, interval level data are sometimes called *equal-interval scales* (e.g. the distance between 3 degrees Celsius and 4 degrees Celsius is the same as the distance between 98 degrees Celsius and 99 degrees Celsius). However, in interval data, there is no true zero. Let us give two commonly cited examples. In Fahrenheit degrees, the freezing point of water is 32 degrees, not zero, so we cannot say, for example, that 100 degrees Fahrenheit is twice as hot as 50 degrees Fahrenheit, because the measurement of Fahrenheit did not start at zero. In fact, twice as hot as 50 degrees Fahrenheit is 68 degrees Fahrenheit (({50–32}×2)+32). Let us give another example. Many IQ tests commence their scoring at point 70, i.e. the lowest score possible is 70. We cannot say that a person with an IQ of 150 has twice the measured intelligence as a person with an IQ of 75 because the starting point is 70; a person with an IQ of 150 has twice the measured intelligence as a person with an IQ of 110, as one has to subtract the initial starting point of 70 ({150–70}/2). In practice, the interval scale is rarely used, and the statistics that one can use with this scale are, to all intents and purposes, the same as for the fourth scale: the ratio scale. In fact, some statistical software packages (e.g. SPSS) combine interval and ratio scales in a single type; in SPSS this is called 'scale'.

The *ratio* scale embraces the main features of the previous three scales – classification, order and an equal-interval metric – but adds a fourth, powerful feature: a true zero. This enables the researcher to determine proportions easily – 'twice as many as', 'half as many as', 'three times the amount of', and so on. Because there is an absolute zero, all of the arithmetical processes of addition, subtraction, multiplication and division are possible. Measures of distance, money in the bank, population, time spent on homework, years teaching, income, marks on a test and so on are all ratio measures as they are capable of having a 'true' zero quantity. If I have $1,000 in the bank then it is twice as much as if I had $500 in the bank; if I score 90 per cent in an examination then it is twice as many as if I had scored 45 per cent. The opportunity to use ratios and all four arithmetical processes renders this the most powerful level of data. Interval and ratio data are continuous variables that can take on any value within a particular, given range. Interval and ratio data typically use more powerful statistics than nominal and ordinal data.

The delineation of these four scales of data is important, as much hinges on this. The consideration of which statistical test to use depends on the scale of data; it is incorrect to apply many statistics which can only be used at interval or ratio scales of data to nominal or ordinal data. For example, one should not apply averages (means) to nominal data, nor use t-tests and Analysis of Variance (discussed later) to ordinal data. Which statistical tests can be used with which data are set out clearly in subsequent chapters.

To close this section we record Wright's (2003, p. 127) view that the scale of measurement is not always inherent to a particular variable, but something that researchers 'bestow on it based on our theories of that variable'. For example, are the five points in an ordinal scale (e.g. 'very little', 'a little', 'somewhat', 'a lot', 'a very great deal') really better described as categorical, and are the categories in the ordinal scale (e.g. 'strongly disagree', 'disagree', 'neither agree nor disagree', 'agree', 'strongly agree') more fittingly described as categorical, two of them being categories of disagreement, two being categories of agreement and one being neutrality? What is being suggested here is that we have to justify classifying a variable as nominal, ordinal, interval or ratio, and not just assume that it is self-evident. Much of the time this is beyond dispute, but ordinal data may be problematic here.

38.3 Parametric and non-parametric data

Non-parametric data are those which make no assumptions about the population, usually because the characteristics (numerical parameters) of the population are unknown. Parametric data assume knowledge of the characteristics of the population, in order for inferences to be able to be made securely; inferential statistics are premised on a normal, Gaussian curve of distribution, as, for example, in reading scores, in order to be able to generalize to the wider population (though Wright (2003, p. 128) suggests that normal distributions are actually rare). In practice this distinction means the following: nominal and ordinal data are often considered to be non-parametric, whilst interval and ratio data are often considered to be parametric data (unless, for example, the data are skewed). The distinction is important, as, for the four scales of data, the consideration of which statistical test to use is dependent on the kinds of data: it is often incorrect to apply parametric statistics to non-parametric data, though it is possible to apply non-parametric statistics to parametric data if those data do not conform to the curve of distribution, being skewed or unevenly distributed. Statistics for parametric data tend to be more powerful than those for non-parametric data, though such power is bought at the price of, for example, conformity to the normal curve of distribution and random samples. Non-parametric data are often derived from questionnaires and surveys (though these can also include parametric data), whilst parametric data tend to be derived from experiments and tests (e.g. examination scores).

38.4 Descriptive and inferential statistics

Descriptive statistics do exactly what they say: they describe and present data, for example, in terms of summary frequencies. No attempt is made to infer or predict population parameters, and they are concerned simply with enumeration and organization. This includes:

- the mode (the score obtained by the greatest number of people);
- the mean (the average score);
- the median (the score obtained by the middle person in a ranked group of people, i.e. it has an equal number of scores above it and below it);
- minimum and maximum scores;
- the range (the distance between the highest and the lowest scores);
- the variance (a measure of how far scores are from the mean, calculated as the average of the squared deviations of individual scores from the mean);
- the standard deviation (a measure of the dispersal or range of scores, calculated as the square root of the variance, yielding the average of all the individual deviations of scores from the mean);
- the standard error (the standard deviation of sample means);
- the skewness (how far the data are asymmetrical in relation to a 'normal' curve of distribution);
- kurtosis (how steep or flat is the shape of a graph or distribution of data; a measure of how peaked a distribution is and how steep is the slope or spread of data around the peak).

Such statistics make no inferences or predictions; they simply report what has been found, in a variety of ways.

Inferential statistics, by contrast, strive to make inferences and predictions based on the data gathered. They infer or predict population parameters or outcomes from simple measures, for example, from sampling and from statistical techniques, and they use information from a sample to reach conclusions about a population, based on probability. Such statistics include hypothesis testing, regression and multiple regression, difference testing (e.g. t-tests and Analysis of Variance), factor analysis and structural equation modelling. Sometimes simple frequencies and descriptive statistics may speak for themselves, and the careful portrayal of descriptive data may be important. However, often it is inferential statistics that are more valuable for researchers, and typically these are more powerful.

38.5 Kinds of variables

A variable is a condition, factor or quality that, as its name suggests, can vary, for example, in quantity, intensity etc., from one case to another; it is the opposite of a constant, which does not vary between cases.

Dependent and independent variables

Research often concerns relationships between variables (a variable can be considered as a construct, operationalized construct or particular property in which the researcher is interested). An independent variable is, as its name suggests, a variable which is not affected by another variable, it is independent of other variables. Typically it is a variable that the researcher can manipulate or control; it is often considered to be a stimulus that influences a response, an antecedent which may be manipulated or modified (e.g. under experimental or other conditions that might control the amount or frequency of something) to affect an outcome. A dependent variable, on the other hand, is, as its name suggests, a variable whose (numerical) value depends to some degree on that of one or more independent variables. This is a fundamental concept in many statistics and it is the basis of a lot of statistical modelling.

For example, we may wish to see if doing more homework (independent variable) increases students' performance in, say, mathematics (dependent variable). We increase the homework and measure the result, and we notice, for example, that the performance increases on the mathematics test. The independent variable has produced a measured outcome. Or has it? Maybe: (a) the threat of the mathematics test increased the students' concentration, motivation and diligence in class; (b) the students liked mathematics and the mathematics teacher, and this caused them to work harder, not the mathematics test itself; (c) the students had a good night's sleep before the mathematics test and, hence, were refreshed and alert; (d) the students' anticipated performance in the mathematics test, in fact, influenced how much homework they did – the higher the anticipated marks, the more they were motivated to doing mathematics homework; (e) the increase in homework increased the students' motivation for mathematics and this, in turn may have caused the increased performance in the mathematics test; (f) the students were told that if they did not perform well on the test then they would be punished, in proportion to how poorly they scored.

What one can observe here is important. In respect of (a) there are other *extraneous* variables which must be factored into the causal relationship (i.e. in addition to the homework). In respect of (b) the assumed relationship is not really present; behind the coincidence of the rise in homework and the rise in the test result is a stronger causal relationship of the liking of the subject and the teacher which caused the students to work hard, a by-product of which was the rise in test scores. In respect of (c) an *intervening* variable was at work (a variable which affected the process of the test but which was not directly observed, measured or manipulated). In respect of (d), in fact the anticipated test result caused the increase in homework, and not *vice versa*, i.e. the direction of causality was reversed. In respect of (f), the amount of increase was negatively correlated with the amount of punishment: the greater the mark, the lesser the punishment. In fact, what may be happening here is that causality may be less in a linear model and more multi-directional and multi-related, more like a web than a line (cf. Morrison, 2009, 2012).

This example indicates a range of issues in the discussion of dependent and independent variables:

- the direction of causality is not always clear (an independent variable may, in turn, become a dependent variable and *vice versa*);
- causality may be bi-directional or multi-directional;
- assumptions of association may not be assumptions of causality;
- there may be a range of other factors which have a bearing on a dependent variable;
- there may be causes (independent variables) behind the identified causes (independent variables) that have a bearing on the dependent variable;
- the independent variable may cause something else, and it is the something else that causes the outcome (dependent variable);
- causality may be non-linear rather than linear;
- the direction of the relationship may be negative rather than positive;
- the strength/magnitude of the relationship may be unclear.

Many statistics operate with dependent and independent variables (e.g. experiments using t-tests and Analysis of Variance, regression and multiple regression); others do not (e.g. correlational statistics, factor analysis). If one uses tests which require independent and dependent variables, caution has to be exercised in assuming which is or is not the dependent or independent variable, and whether causality is as simple as the test assumes. Further, many statistical tests are based on linear relationships (e.g. correlation, regression and multiple regression, factor analysis) when, in fact the relationships may not be linear (some software programs, e.g. SPSS, have the capability for handling non-linear relationships). The researcher has to make

a fundamental decision about whether, in fact, the relationships are linear or non-linear, and select the appropriate statistical tests with these considerations in mind.

Moderator and mediator variables

In addition to independent and dependent variables, there are also moderator and mediator variables. In conducting a correlation one might calculate the correlation coefficient between two variables, say hours of study and performance in a test of mathematics, to be 0.95, i.e. very strong indeed, but, when a third variable is introduced (as in a partial correlation, see Chapter 40), say motivation level for mathematics, the correlation coefficient drops to 0.12, a very weak correlation; in other words, the third variable (motivation for mathematics) is exerting a strong moderation effect.

A moderator variable is one which affects the strength and/or the direction of a relationship between two other variables, for example, between an independent and a dependent variable, i.e. whose values influence the values of another variable. For example, school leadership might moderate the relationship between teacher commitment and school effectiveness: a highly effective leader might increase teacher commitment and, hence, school effectiveness, while a weaker leader might reduce teacher commitment and, hence, reduce school effectiveness.

Moderators are synonymous with interactions. For example, in Analysis of Variance, a moderating variable, say hours of part-time study, might affect the interaction between stress level and performance in the history test, i.e. the interaction of stress level and hours of study might exert an effect on the dependent variable (performance in the history test).

An example of a moderator variable is thus: socio-economic status (A) might have a relationship to performance in the international mathematics test (C), but this might be affected by the age of the student (moderator variable B), so, for example, (A) may have only a small effect on performance in the international mathematics test (C) for a student aged 11 but a larger effect on a student aged 15, and a much larger effect on a student aged 17. Indeed, Bourdieu's work on cultural capital (1976) suggests that this is the case. Here the moderator variable B appears to have an influence on the strength of the relationship between A and C.

A mediator variable is one which explains the relationship between an independent and dependent variable, or between two other variables (Baron and Kenny, 1986). A mediator variable (B) receives the effect of one independent variable (A) and this affects the outcome variable (C). Here the relationship between A and C is indirect because it is mediated by B; it goes through B.

For example, consider the relationship between (A) socio-economic status and (C) performance on, say, an international test of mathematics. Here hours of study (B) may be a mediating variable as it explains the relationship between A and C: socio-economic status (A) affects hours of study (B) which affects performance in the international mathematics test (C). Socio-economic status (A), here, has an indirect relationship with performance in the international mathematics test (C) as it goes through variable (B); B is a conduit which renders A an indirect independent variable: A→B→C.

Moderator and mediating variables can be explored through controlling for variables, for example in partial correlations and structural equation modelling. Moderator and mediator variable are intimately connected to causal modelling, and we refer the reader to Chapter 6.

To draw these points together, the researcher will need to consider:

- What scales of data are there?
- Are the data parametric or non-parametric?
- Are descriptive or inferential statistics required?
- Do dependent and independent variables need to be identified?
- Do the research and data analysis need to take account of moderating and mediating variables?
- Are the relationships considered to be linear or non-linear?

The prepared researcher will need to consider the mode of data analysis that will be employed. This is very important as it has a specific bearing on the form of the instrumentation used. For example, a researcher will need to plan the layout and structure of a questionnaire survey very carefully in order to assist data entry for computer reading and analysis; an inappropriate layout may obstruct data entry and subsequent computer processing. The planning of data analysis will need to consider:

- what needs to be done with the data when they have been collected – how the data will be processed and analysed;
- how the results of the analysis will be verified, cross-checked and validated.

Decisions will need to be taken with regard to which statistical tests to use in data analysis, as this affects the layout of items (e.g. in a questionnaire) and the computer packages that are available for processing

quantitative and qualitative data, for example, SPSS and NVivo respectively.

Categorical, discrete and continuous variables

A categorical variable is a variable which has categories of values. For example, the variable 'sex' has two values: male and female; it is a dichotomous variable. In a rural community with, say, four local schools, the variable 'school attended' will have four values, one for each school. If we are looking at the types of food in school meals we may want to have three categories: carbohydrates, proteins and fats; each of these is a category of the variable 'food'.

A discrete variable has a finite number of values of the same item, with no fractions of the value (e.g. the number of illnesses a person has had, the number of mealtimes a person has each day). Here there are no fractions of a value – a person cannot have half an illness or half a mealtime; they either have the illness or not, they either have the mealtime or not.

A continuous variable, as its name suggests, can vary in quantity, for example, money in the bank, monthly earnings, numbers of students present in a class. Here there are equal intervals, and, for ratio data, a zero (it is possible to have no money in the bank, or to have no earnings, or for a class of students to have none present that day).

Categorical variables yield categorical data. Continuous variables yield interval and ratio data (though in SPSS these are combined in the classification of 'scale' data). Depending on the kind of variable one has will be the kinds of statistics that can be used. This is addressed in subsequent chapters.

Kinds of analysis

Univariate analysis examines differences among cases within one variable. Bivariate analysis looks for a relationship between two variables. Multivariate analysis looks for a relationship between two or more variables. Different statistics are used, depending on whether one is working with univariate, bivariate or multivariate analysis.

Hence, in approaching statistical processing and analysis, the researcher will need to decide:

- the scales of the data being used (categorical, ordinal, interval, ratio);
- the kind of data being used (parametric, non-parametric);
- the kinds of variables being used (categorical, discrete, continuous, independent, dependent, moderator, mediator);
- the kinds of statistics to be used (descriptive, inferential).

38.6 Hypotheses

Research in a hypothetico-deductive mode and research that uses statistics often commence with one or more hypotheses. This is the essence of hypothesis testing in quantitative research. Typically hypotheses fall into different types. The *null hypothesis*, a major type of hypothesis, states that, for example, there is *no* relationship between two variables, or that there has been *no* change in participants between a pre-test and a post-test, or that there is *no* difference between three school districts in respect of their examination results, or that there is *no* difference between the voting of males and females on such-and-such a factor. Null hypothesis significance testing (NHST) is addressed in Chapter 39.

The point here is that by casting the hypothesis in a null form, the burden of proof is placed on the researcher *not* to support that null hypothesis. The task is akin to a jury starting with a presumption of innocence and having to prove guilt beyond reasonable doubt. Not only is it often easier simply to support a straightforward positive hypothesis, but, more seriously, even if that positive hypothesis is supported, there may be insufficient grounds for accepting that hypothesis, as the finding may be consistent with other hypotheses. For example, let us imagine that our hypothesis is that a coin is weighted and, therefore, unfair. We flip the coin 100 times, and find that 60 times out of 100 it comes out as heads. It would be easy to jump to the conclusion that the coin is weighted, but, equally easily, other reasons may account for the result. Of course, if the coin were to come out as heads 99 times out of 100 then perhaps there would be greater truth in the hypothesis. Null hypothesis testing is a stronger version of evidence, requiring not only that the negative hypothesis be 'not supported', but also indicating a cut-off point only above which the null hypothesis is 'not supported', and below which the null hypothesis is supported. In our coin example, it may be required to find that heads comes up 95 times out of 100, or 99 times out of 100, or even 999 times out of 1,000, to say, with increasing confidence in respect of these three sets of figures, that the null hypothesis is not supported. We discuss this in terms of statistical significance in Chapter 39.

We use terminology carefully here. Some researchers state that the null hypothesis is 'rejected'; others say that it is 'confirmed' or 'not confirmed'; others say that it is 'accepted' or 'not accepted'. We prefer the

terminology of 'supported' or 'not supported'. This is not mere semantics or pedantry; rather it signals caution. Rejecting a null hypothesis is not the same as 'not confirming' or 'not supporting' that null hypothesis, as rejection implies an absolute and universal state which the research will probably not be able to demonstrate, being bounded within strict parameters and not being applicable to all cases. Further, 'confirming' and 'not confirming', like 'rejecting', is too strong, absolute and universal a set of terms for what is, after all, research that is bounded and within delineated boundaries. Similarly, one cannot 'accept' a null hypothesis as a null hypothesis can seldom be proved unequivocally (though there are occasions when it can, e.g. if the means and standard deviations between, say, the maths test scores of two groups are equal).

A second type of hypothesis is termed the *alternative hypothesis*. Whereas the null hypothesis states that there is *no* such-and-such (e.g. change, relationship, difference), the alternative hypothesis states that there *is* such-and-such, for example: there *is* a change in behaviour of the school students; there *is* a difference between students' scores on mathematics and science; there *is* a difference between the examination results of five school districts; there *is* a difference between the pre-test and post-test results of such-and-such a class. This kind of hypothesis is often supported when the null hypothesis is 'not supported', i.e. if the null hypothesis is not supported then the alternative hypothesis is.

The two kinds of hypothesis are usually written thus:

H_0: the null hypothesis
H_1: the alternative hypothesis

Sometimes the alternative hypothesis is written as H_A. So, for example, the researcher could write null hypotheses and alternative hypotheses thus:

H_0: There is no statistically significant difference between the results of the control group and experimental group in the post-test of mathematics
or There is no statistically significant difference between males and females in the results of the English examination
or There is no statistically significant correlation between the importance given to a subject and the amount of support given to it by the headteacher

H_1: There is a statistically significant difference between the control group and experimental group in the post-test of mathematics
or There is a statistically significant difference between males and females in the results of the English examination
or There is a statistically significant positive correlation between examination scores in mathematics and science

(We address statistical significance in Chapter 39.) The null hypothesis requires rigorous evidence *not* to support it. The alternative hypothesis is taken up when the first – null – hypothesis is not supported. The latter is the logical opposite of the former. One commences with the former and casts the research in the form of a null hypothesis, only turning to the latter if it is found that the null hypothesis is not supported.

A hypothesis can be directional or non-directional. A directional hypothesis states the kind of difference or relationship between two conditions or two groups of participants. For example:

- Students who do homework without the television switched on in their room whilst working produce *better* results than those who do homework with the television switched on.
- Students who have a computer at home do better in exams than people who do not.
- People remember the words that appear early in a list better than the words that appear later.
- People who are given a list of emotionally charged words recall more than participants given a list of neutral words.

Here one can see the direction of the hypothesis ('better', 'more than').

By contrast, a non-directional hypothesis simply predicts that there will be a difference or relationship between two conditions or two groups of participants, but it does not state the direction of the difference (e.g. 'more than', 'less than, 'better than', 'worse than'), for example:

- Students who do homework without the television switched on in their room whilst working produce different results from those who do homework with the television switched on.
- Students who have a computer at home perform differently in exams than people who do not.
- People remember a different number of words that appear early in a list than the words that appear later.

- People who are given a list of emotionally charged words recall a different number than participants given a list of neutral words.

Here there is a difference, but the *direction* of that difference is not made explicit. The stronger of these two types of hypothesis is the directional hypothesis because it makes a stronger claim than the non-directional hypothesis. In hypothesis testing the researcher:

1. formulates a hypothesis;
2. measures the variables involved and examines the relationship between them;
3. calculates the probability of obtaining such a relationship if there were no relationship by chance, i.e. if the null hypothesis is true. If the calculated probability is small enough, it suggests that the pattern of findings is unlikely to have arisen by chance, and probably reflects a genuine relationship.

38.7 One-tailed and two-tailed tests

In using statistics, researchers are sometimes confronted with the decision of whether to use a one-tailed or a two-tailed test. Which to use is a function of the kind of result one might predict. In a one-tailed test one predicts, for example, that one group will score more highly than the other, whereas in a two-tailed test one makes no such prediction. The one-tailed test is a stronger test than the two-tailed test as it makes assumptions about the population and the direction of the outcome (i.e. that one group will score more highly than another), and hence, if supported, is more powerful than a two-tailed test. A one-tailed test is used with a directional hypothesis (e.g. 'students who do homework *without* the TV on produce *better* results than those who do homework with the TV playing'). A two-tailed test is used with a non-directional hypothesis (e.g. 'there is a *difference* between homework done in noisy or silent conditions'). Here the directional hypothesis indicates 'more' or 'less', whereas the non-directional hypothesis indicates only difference, and not where the difference may lie.

For example, let us imagine that we run a 'true' experiment to see if students who do homework *without* the TV on produce *better* results than those who do homework with the TV playing. The results are shown in Figure 38.1.

We can see here that there is an overlap between the two sets of scores, but that the scores of the group which did not have the television switched on whilst doing homework are much higher than the scores of the group whose television is switched on whilst doing homework. Our directional hypothesis is supported, and we have used a one-tailed test to test the hypothesis.

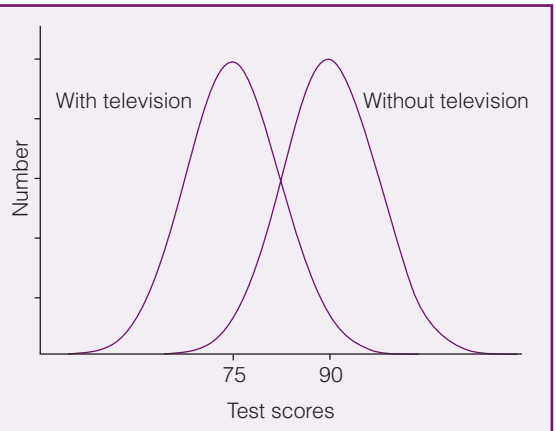

FIGURE 38.1 Test scores of two groups

In graphical terms, we can portray the results of a one-tailed test that predicts high scores in Figure 38.2.

Here the prediction is that those students who work without the television switched on score more highly (the shaded area at one end (tail) of the graph). The '5%' indicates that we are predicting with a 95 per cent degree of certainty that the results will be higher.

By contrast, we can portray the results of a one-tailed test that predicts low scores in Figure 38.3.

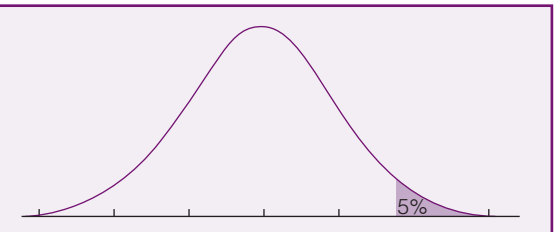

FIGURE 38.2 The predictions of a one-tailed test that predicts a higher score

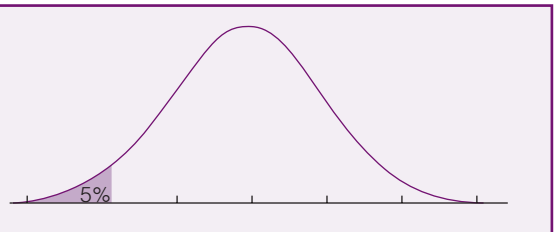

FIGURE 38.3 The predictions of a one-tailed test that predicts a lower score

Here the prediction is that those students who work with the television switched on score lower (the shaded area at one end (tail) of the graph). Again, because we predict the direction of the result, we use a one-tailed test. Here the '5%' indicates that we are predicting with a 95 per cent degree of certainty that the results will be lower.

Figure 38.4 indicates the results for a two-tailed test. Here we can see that there are two shaded areas, one at each end (tail) of the graph. Because we have not predicted the direction of the result (it could be higher or lower), the burden of proof is higher, i.e. instead of having a 95 per cent certainty (the 5 per cent of the two previous figures), we distribute that 5 per cent between the two tails, each of which is 2.5 per cent, i.e. we need to demonstrate a 97.5 per cent certainty level in the result.

38.8 Confidence intervals

In working with statistics, researchers need to know the confidence that they can have in the accuracy of their findings. Indeed the American Psychological Association (2010, p. 34) requires confidence intervals to be included in publications of research findings. A confidence interval is a range of values for the results obtained, and researchers need to know how confident they can be that their particular result falls within that acceptable range, i.e. that the range will include the result in question. For example, a researcher may say 'my survey finding, that 15 per cent of students prefer to have a female teacher of mathematics, is true, give or take 5 per cent', i.e. the percentage range could be from 10 to 20 per cent (15–5 and 15+5). For example, if the researcher had repeated her survey with a different group, her result might be that 17 per cent of students preferred to have a female teacher of mathematics; this still falls within the acceptable range of 10–20 per cent. Confidence intervals indicate that the acceptable range, and how much confidence can be placed in suggesting that this range, includes the particular finding in question.

FIGURE 38.4 The predictions of a two-tailed test

Researchers may know, for example, that their finding of an average score from a sample is an approximation of the likely average score in the population, but they need to know how good their approximation is (Dancey and Reidy, 2011, p. 109). Here confidence intervals feature, as they indicate the range of possible scores in the population, and the confidence that this range will include the researcher's score.

Many statistics packages have a default setting of returning a 95 per cent confidence interval. Confidence intervals are important in inferential statistics, as they enable the researcher to state how confident they can be in inferring that the score found will be in the range (the interval) of acceptable scores for that result.

Say, for example, a researcher wishes to calculate whether the difference between the means of two test results (maths and history) is reliable. She conducts a t-test (see Chapter 41) and finds that the average difference in scores between the maths test and the history test is 0.350, with a standard error of the difference being 0.464 (here we do not go into how these scores are computed, as this requires knowledge of the t-test, and we address this in Chapter 41; for the present we ask the reader simply to accept these data). Now the computer software (in this case SPSS) shows that a 95 per cent confidence interval indicates that the range of an average difference should be between –0.579 and +1.278. In other words, the researchers could be 95 per cent confident that the score she found for the average difference (0.350) should lie between –0.579 and +1.278. In the instance here, this was found.

Confidence intervals can be used with descriptive and inferential statistics, and effect size calculations (cf. Ellis, 2010, p. 19). They are affected by sample size; Torgerson and Torgerson (2008, p. 135) note that small sample sizes tend to have wider confidence intervals, suggesting, conversely, that a large sample will reduce the range of the confidence interval, i.e. a large sample will give greater precision to the result and the researcher can have 95 per cent certainty of her result being included in that narrower range. A confidence interval, as its name suggests, sets out the range (the interval) of likely results, and the often-used 95 per cent confidence interval is a measure of certainty, i.e. that the researcher can have a 95 per cent confidence that the range of possible results here (the interval) will include the result that she found for her research.

38.9 Distributions

In everyday life many variables tend to be normally distributed. For example, we may say that most men are about such-and-such an average height. Some of

course will be taller, and some shorter; there is a range. A smaller number will be *much* taller or *much* shorter; an even smaller number will be *very much* taller or *very much* shorter; a very small number will be *extremely* tall or *extremely* short. We can present the results on a normal curve of distribution (Figure 38.5).

Many statistics (e.g. inferential statistics) assume a normal curve of distribution and, indeed, researchers should test for the nature of the distributions to see if they conform to the normal curve, as this has an effect on the choice of statistics. For example, if the distribution of the data conforms to the normal curve then this might enable inferential parametric statistics to be calculated, whereas if the distribution does not conform to the normal curve, even if the data are interval or ratio, then this might require the use of distribution-free, i.e. non-parametric, statistics.

The normal curve of distribution is a smooth, perfectly symmetrical (bell-shaped) curve; it is symmetrical about the inflection point, with the mean (the average score) at the point of inflection, and its tails are assumed to meet the x-axis at infinity. Here 68.3 per cent of people will fall within one standard deviation of the mean (a measure of the average variance from the mean). In our example we might assume that the majority of men (68.3 per cent) will be either just about or just below the mean height. Then, if we look at Figure 38.5, we can see that a smaller proportion (95.4 per cent minus 68.3 per cent = 27.1 per cent) are *much* taller or *much* shorter (between one standard deviation and two standard deviations away from the mean), and an even smaller proportion (99.7 per cent minus 95.4 per cent = 4.3 per cent) are *very* tall or *very* short, (even further away from the mean (between two and three standard deviations)), and only a very tiny proportion (100 per cent minus 99.7 per cent = 0.3 per cent) are *extremely* tall or *extremely* short (more than three standard deviations away from the mean).

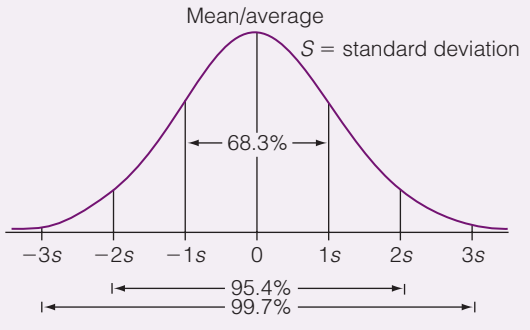

FIGURE 38.5 The normal curve of distribution

In educational research that uses statistics, many statistical calculations assume that the population is distributed normally and then compare the data collected from the sample to the population, allowing inferences to be made about the population (e.g. in random sampling). The assumption of the normal curve of distribution enables researchers to measure all normal distributions of a variable, regardless of the units in which that variable is initially measured, and to be able to generalize to a wider population.

Of course this is not always the case; rarely, if ever, in real life are data distributed so neatly. Rather than being symmetrical, data might be skewed in different ways. They may be positively or negatively skewed, as in Figure 38.6.

Skewed distributions are not symmetrical; a positively skewed distribution has the tail skewed to the

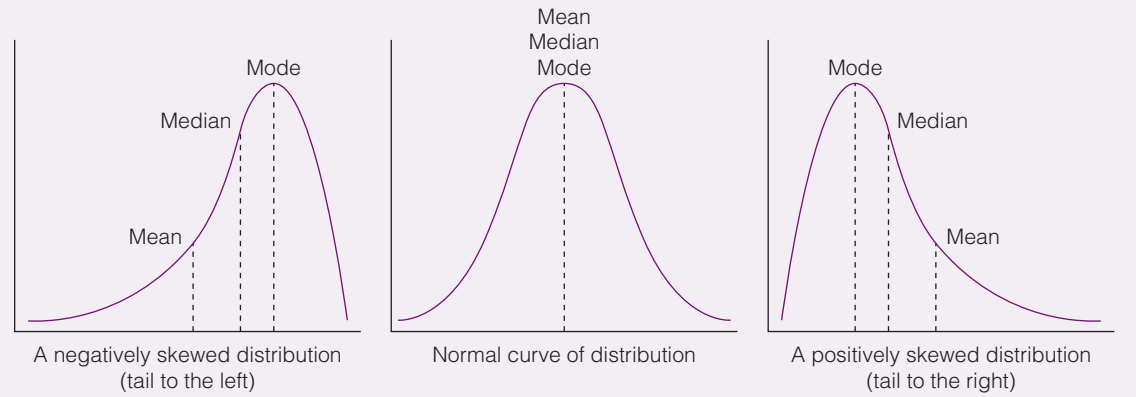

FIGURE 38.6 Skewed distributions

right, whilst a negatively skewed distribution has the tail skewed to the left. This has important implications for even the simplest statistics calculated. For example, whilst the mean (average) may be useful for normal distributions, in skewed distributions it is an unreliable measure, as it is affected by the long tail (positive or negative). Similarly the mode (the particular score registered by the most voters) may not be an accurate measure of the distributions. In both of these cases, the median score (the score which is given by the middle person, e.g. in a test) is more reliable.

An example of skewness is given in Figure 38.7. The figure presents a line graph to show how respondents voted on how well learners are guided and supported in their learning, awarding marks out of ten for the voting, with a sample size of 400 respondents.

Here the data are skewed, with more votes being received at the top end of the scale. There is a long tail going to the negative end (left-hand side) of the scores, so, even though the highest scores are given at the top end of the scale, we say that this graph has a negative skew because there is a long tail down.

By contrast, let us look at a graph of how much staff voluntarily take on roles in the school, with 150 votes received and awarding marks out of ten (Figure 38.8).

Here a long tail goes towards the upper end of the scores, and the bulk of the scores are in the lower range. Even though most of the scores are in the lower range, because the long tail is towards the upper end (right-hand side) of the scale this is termed a positive skew.

Further, a graph of distribution may not always have the same bell-shaped features of the normal curve. For example it may be flatter than normal (platykurtic) or steeper than normal (leptokurtic) (see Figure 38.9).

The measure of steepness of the curve is termed 'kurtosis'; many statistics packages calculate the measure of kurtosis. Normal distributions have a skewness of zero and a measure of kurtosis of zero: a platykurtic distribution has a negative value of kurtosis, whilst a leptokurtic distribution has a positive value of kurtosis. The degree of kurtosis may affect the reliability of the statistics that are used or the inferences that are made from them. For example, a platykurtic distribution may not have a problem with outliers, whilst a leptokurtic distribution may; further, many statistics assume normal kurtosis, rather than unduly flat or steep kurtosis.

The skewness and kurtosis of the data are important features to observe in data, and to which to draw attention. Researchers must check to see if the distributions of their data conform to the normal curve. There are different ways of doing this. One way is simply to construct a histogram and look at its overall shape to see if

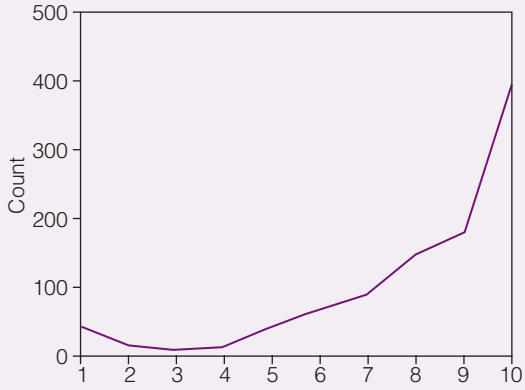

FIGURE 38.7 How well learners are cared for, guided and supported

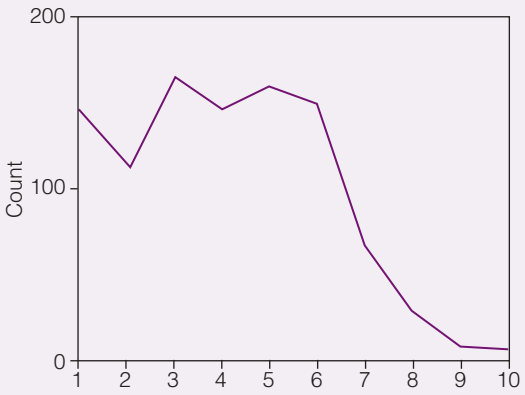

FIGURE 38.8 Staff voluntarily taking on coordination roles

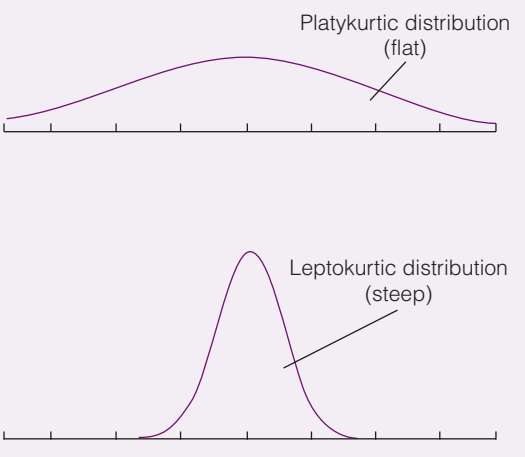

FIGURE 38.9 Types of kurtosis

it conforms to a normal curve of distribution. Another way is to conduct specific tests of skewness and kurtosis, and many statistics packages (e.g. SPSS) do this. Another way is to conduct an overall test of how normal the distribution is, for example the Shapiro-Wilk and the Kolmogorov-Smirnov tests (available in SPSS, and many researchers prefer the Shapiro-Wilk test here as being more reliable). If the distributions are too far away from a normal curve of distribution then it may be unwise to use statistics for parametric data; instead, statistics for non-parametric data should be used. On the other hand Pallant (2016) suggests that having a large sample (she suggests a size of >30) can attenuate problems of violations of normality, though other researchers adopt a more stringent position here.

The question is raised of what constitutes an acceptable level of skewness and kurtosis for a distribution to be acceptably 'normal', i.e. conforming sufficiently closely to the normal curve of distribution. There is no hard and fast rule here. Some researchers suggest that scores anywhere between –1 and +1 on skewness and on kurtosis are acceptable. Others would argue that an acceptably 'normal' degree of skewness (the figure, for example, given in software calculations of skewness) should not exceed twice the standard error of skewness, i.e. it should be within the range from minus twice the standard error of skewness to plus twice the standard error of skewness. So, for example, if the standard error of skewness (which is given in statistics software, e.g. SPSS) is 0.132 (i.e. as mild skew) then the range of acceptable skewness should be between –0.264 to +0.264; if the standard error of skewness is 0.436 then the range of acceptable skewness should be between –0.872 and +0.872. The same procedure can be adopted for calculating an acceptably 'normal' degree of kurtosis, this time working with the standard error of kurtosis (again, statistics software such as SPSS calculates this), though several researchers would not regard abnormal kurtosis as such a problem as skewness, and might even be overlooked. Small samples might be vulnerable to problems of skewness and kurtosis, and this argues for the benefits of large samples in statistics.

Normal distributions are often affected by outliers: those extreme cases/scores which are outside the normal pattern of the distribution, i.e. which are an abnormal distance from other cases/scores, often taken to be more than 1.5 times the interquartile range away from the 75th and 25th percentile. Outliers can be spotted by constructing a histogram and looking at those which do not fit the pattern, or, more technically, by constructing boxplots (see Chapter 40). Many software packages (e.g. SPSS) have a function to detect outliers and to inform the researcher of which cases/scores are outliers.

Box 38.1 provides the SPSS command sequence for calculating skewness and kurtosis.

The Shapiro-Wilk and the Kolmogorov-Smirnov tests of normality can also be used to identify outliers in SPSS (often the Shapiro-Wilk test is the preferred statistics here). The SPSS command sequence is set out in Box 38.2.

SPSS then produces output with a box marked 'Extreme Values' (Table 38.1), in which the column 'Case number' indicates those cases which are outliers, being either exceptionally/unusually low or exceptionally/unusually high. Table 38.2 presents the tests of normality. Here both the Shapiro-Wilk and the Kolmogorov-Smirnov tests indicate statistical significance (discussed in Chapter 39), and this suggests a non-normal distribution, i.e. the distributions are statistically significantly different from a normal distribution.

BOX 38.1 SPSS COMMAND SEQUENCE FOR CALCULATING SKEWNESS AND KURTOSIS

The command sequence for SPSS to calculate kurtosis and skewness is: 'Analyze' → 'Descriptive Statistics' → 'Frequencies' → Send to the 'variables' box the variables of interest → Click 'Statistics'. This opens a new window → In the 'Distributions' area, check the boxes marked 'Skewness' and 'Kurtosis' → Click 'Continue' → Click 'OK'.

BOX 38.2 SPSS COMMAND SEQUENCE FOR THE SHAPIRO-WILK AND THE KOLMOGOROV-SMIRNOV TESTS OF NORMALITY

The command sequence to calculate these is: 'Analyze' → 'Descriptive Statistics' → 'Explore' → Send to the 'Dependent List' box the variables of interest → Click 'Statistics' box → Check the 'Outliers' box → Click 'Continue' → Click the 'Plots' box → Check the boxes marked 'Normality plots with tests' and 'Histogram' → Click 'Continue' → Click 'OK'.

38.10 Conclusion

In this chapter we have introduced some key foundations of statistical analysis:

- scales of data: nominal (categorical), ordinal, interval, ratio;
- parametric and non-parametric data, which inform the decision on whether to adopt parametric statistics or distribution-free statistics;
- descriptive and inferential statistics; inferential statistics often require conformity to the normal curve of distribution;
- kinds of variables: categorical, discrete, continuous, independent, dependent, moderator, mediator;
- hypotheses: the null hypothesis and the alternative hypothesis;
- one-tailed and two-tailed tests: those which predict the direction of results and those which do not, respectively;
- confidence intervals: the confidence that a researcher can have that his or her found result will fall within an acceptable range (interval) of results;
- distributions: the normal curve of distribution, skewness, kurtosis and the influence of outliers.

We have alerted researchers to the desirability of having as large a sample size as possible when working with statistics, as this reduces problems of standard error, confidence intervals and normal distributions. We have also alerted researchers against using parametric statistics willy-nilly, and to use them for non-parametric data or for parametric data whose distribution is insufficiently close to a normal distribution to warrant the use of those statistics which assume a normal distribution. We have indicated that many of the 'safety checks' for normality of distributions and confidence intervals are routinely available in statistics packages, and we advocate the use of such packages and such checks. Each of the bullet points above is an important consideration in deciding which statistics to use, which can be used and which should not be used. We return to this in the subsequent chapters.

Finally, the following chapters introduce some widely used Greek letters in statistics. Table 38.3 provides a brief list of widely used Greek letters.

TABLE 38.3 FREQUENTLY USED GREEK LETTERS IN STATISTICS

Greek letter	*Name*	*Use in statistics*
α	Alpha	Probability of making a Type I error. The statistical significance level
β	Beta	Probability of making a Type II error. The beta value in multiple regression is a measure of how strongly each independent (predictor) variable influences the dependent variable.
$\Delta\ \delta$	Delta	Difference: Δ. Standard deviation: δ
η	Eta	The partial regression coefficient, measure of effect size: η (usually used as 'partial eta squared' η^2)
$\Lambda\ \lambda$	Lambda	A test of mean differences in multivariate analyses (Wilks's lambda)
μ	Mu	Population mean: μ
ν	Nu	Degrees of freedom: ν
π	Pi	Population proportion: π
ρ	Rho	Correlation coefficient. Significance level: ρ
$\Sigma\ \sigma$	Sigma	The sum of: Σ. Population standard deviation (lower case: σ). Population variance: σ^2
$\Phi\ \phi\ \phi$	Phi	The phi coefficient is a measure of the degree of association between two binary variables (a binary variable has only two values, e.g. male/female).
χ	Chi	Goodness of fit and independence of two or more variables (chi-square: χ^2)

Companion Website

The companion website to the book provides additional materials, data files and PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Statistical significance, effect size and statistical power

CHAPTER 39

This chapter builds on the previous chapter by introducing some key points in statistical analysis: statistical significance, effect size and statistical power. These are essential ingredients of statistics, though, as we suggest below, statistical significance has become increasingly questionable. Not only will researchers need to understand them, what they are used for and how they are used, but they will need to understand the cautions that accompany them. This chapter is designed to address these points, and it includes discussions of:

- statistical significance
- concerns about statistical significance
- hypothesis testing and null hypothesis significance testing
- effect size
- statistical power

39.1 Introduction

Though statistical significance is widely used in educational research, this chapter suggests that it has serious limitations and may not be fit for purpose in some research. It is argued that effect size can be more meaningful for educational research, and the chapter indicates the concept, practice and interpretation of effect size. Statistical significance is frequently used to test hypotheses ('null hypothesis significance testing': NHST) (Kline, 2004; Cumming, 2012), and the present chapter indicates how this operates and what are its limitations and some of its problems.

Finally, the chapter addresses an important area of statistically based research, that of statistical power. Statistical power draws on issues of sample size (see Chapter 12), statistical significance and effect size, and the discussion below shows how to put all of these together to determine how powerful a piece of research can be: how far it can find a true effect – a true positive or a true negative – and avoid a false positive or a false negative. Statistical power is an essential ingredient of quantitative research, and this chapter shows how to proceed with it.

We provide some formulae in discussing effect size; the novice researcher does not need to be put off by these as the text alone can be sufficient in introducing the issue in question.

39.2 Statistical significance

Much statistical analysis hinges on the notion of statistical significance. Kirk (1999, p. 337) indicates that 'a statistically significant result is one for which chance is an unlikely explanation'. Statistical significance purports to be a test of whether or not a result has been found by chance, a test of the 'rareness' of chance alone (Carver, 1978, p. 381).

Let us take an example from correlational research to unpack statistical significance. A correlation enables a researcher to ascertain whether, and to what extent, there is a degree of association between two variables (discussed more fully later in this chapter). Let us imagine that we observe that many people with large hands also have large feet and that people with small hands also have small feet (see Morrison, 1993, pp. 136–40). We decide to conduct an investigation to see if there is any correlation or degree of association between the size of feet and the size of hands, or whether it is just by chance that some people have large hands and large feet. We measure the hands and the feet of 100 people and observe that, 99 times out of 100, people with large feet also have large hands. Convinced that we have discovered an important relationship, we run the test on 1,000 people, and find that the relationship holds true in 999 cases out of the 1,000. That seems to be more than mere coincidence; it would seem that we could say with some certainty that if a person has large hands then she/he will also have large feet. How do we know when we can make that assertion? When do we know that we can have confidence in this prediction?

For statistical purposes, if we observe this relationship occurring 95 times out of 100, then we could say with some confidence that there seems to be a high degree of association between the two variables hands and feet, i.e. not by chance alone; no correlation would

be found in only 5 people in every 100, reported as the 0.05 level of significance (0.05 being five-hundredths). If we observe this relationship occurring 99 times out of every 100 (as in the example of hands and feet), then we could say with even greater confidence that there seems to be a very high degree of association between the two variables, i.e. not by chance alone; no correlation would be found only once in every 100, reported as the 0.01 level of significance (0.01 being one-hundredth). If we observe this relationship occurring 999 times out of every 1,000 (as in the example of hands and feet), then we could say with even greater confidence that there seems to be a very high degree of association between the two variables, i.e. not by chance alone; no correlation would be found only once in every 1,000, reported as the 0.001 level of significance (0.001 being one-thousandth).

We begin with a null hypothesis, which states that there is *no* correlation/relationship between the size of hands and the size of feet. The task is not to support the null hypothesis, i.e. the burden of responsibility is to disconfirm it. If we can show that this hypothesis is not supported for 95 per cent or 99 per cent or 99.9 per cent of the population, then we have demonstrated that there is a statistically significant relationship between the size of hands and the size of feet at the 0.05, 0.01 and 0.001 levels of significance respectively. These three levels of significance – the 0.05, 0.01 and 0.001 levels – are the levels at which statistical significance is frequently taken to have been demonstrated, usually the first two of these three levels. The researcher would say that the null hypothesis (that there is no statistically significant relationship between the two variables) has not been supported and that the level of significance observed (ρ) is at the 0.05, 0.01 or 0.001 level.

Note here that we have used the terms 'statistically significant', and not simply 'significant'; this is important, for we are using the term in a specialized way. 'Significant', as in 'statistically significant', does not mean 'important'; many inexperienced researchers incorrectly confuse these. Similarly a very high level of statistical significance does not mean that an effect (e.g. a difference, a correlation) is large, and its converse – a very low level of statistical significance – does not mean that an effect is small (Torgerson and Torgerson, 2008, p. 128; Cumming, 2012, p. 28). A high level of statistical significance (e.g. p=0.001) simply means that it is assumed that the likelihood of the found effect occurring by chance alone is very slim, and a low level of statistical significance simply means that it is assumed that the likelihood of the found effect occurring by chance alone is greater.

Let us take a second example. Let us say that we have devised a scale of 1–8 which can be used to measure the sizes of hands and feet. Using the scale we make the following calculations for eight people, and set out the results thus:

	Hand size	*Foot size*
Subject A	1	1
Subject B	2	2
Subject C	3	3
Subject D	4	4
Subject E	5	5
Subject F	6	6
Subject G	7	7
Subject H	8	8

We can observe a perfect correlation between the size of hands and the size of feet, from the person who has a size 1 hand and a size 1 foot to the person who has a size 8 hand and also a size 8 foot. There is a perfect positive correlation (as one variable increases, e.g. hand size, so the other variable – foot size – increases, and as one variable decreases, so does the other). We can use the mathematical formula for calculating the Spearman correlation (this is calculated automatically in SPSS):

$$r = 1 - \frac{6\sum d^2}{N(N^2 - 1)}$$

where d=the difference between each pair of scores, Σ=the sum of the population, and N=the size of the population. We calculate that this perfect correlation yields an index of association – a coefficient of correlation – which is +1.00.

Suppose that this time we carry out the investigation on a second group of eight people and report the following results:

	Hand size	*Foot size*
Subject A	1	8
Subject B	2	7
Subject C	3	6
Subject D	4	5
Subject E	5	4
Subject F	6	3
Subject G	7	2
Subject H	8	1

This time the person with a size 1 hand has a size 8 foot and the person with the size 8 hand has a size 1 foot. There is a perfect negative correlation (as one variable increases, e.g. hand size, the other variable – foot

size – decreases, and as one variable decreases, the other increases). Using the same mathematical formula we calculate that this perfect negative correlation yields an index of association – a coefficient of correlation – which is –1.00.

Now, clearly it is very rare to find a *perfect* positive or a perfect negative correlation; the truth of the matter is that looking for correlations will yield coefficients of correlation which lie somewhere between –1.00 and +1.00. How do we know whether the coefficients of correlation are statistically significant or not? So let us say that we take a third sample of eight people and undertake an investigation into their hand and foot size. We enter data case by case (Subject A to Subject H), indicating their hand size and then foot size. This time the relationship is less clear because the size is more mixed, for example, Subject A has a hand size of 2 and foot size of 1, Subject B has a hand size of 1 and foot size of 2 etc.:

	Hand size	*Foot size*
Subject A	2	1
Subject B	1	2
Subject C	3	3
Subject D	5	4
Subject E	4	5
Subject F	7	6
Subject G	6	7
Subject H	8	8

Using the mathematical formula for calculating the correlation statistic, we find that the coefficient of correlation for the eight people is 0.7857. Is it statistically significant or has it occurred by chance alone? From a table of significance, we read off whether the coefficient is statistically significant or not for a specific number of cases, for example:

Number of cases	*Level of significance*	
	0.05	*0.01*
6	0.93	0.96
7	0.825	0.92
8	0.78	0.875
9	0.71	0.83
10	0.65	0.795
20	0.455	0.595
30	0.36	0.47

We see that for eight cases in an investigation, the correlation coefficient has to be 0.78 or higher if it is to be statistically significant at the 0.05 level, and 0.875 or higher if it is to be statistically significant at the 0.01 level of significance. As the correlation coefficient in the example of the third experiment with eight subjects is 0.7857 we can see that it is higher than that required for significance at the 0.05 level (0.78) but not as high as that required for significance at the 0.01 level (0.875). We are safe, then, in stating that the degree of association between the hand and foot sizes does not support the null hypothesis and demonstrates statistical significance at the 0.05 level.

The first example above of hands and feet is very neat because it has 100 people in the sample. If we have more or fewer than 100 people how do we know if a relationship between two factors is statistically significant? Let us say that we have data on 30 people; in this case, because the sample size is so small, we might hesitate to say that there is a strong association between the size of hands and size of feet if we observe it occurring in 27 people (i.e. 90 per cent of the population). On the other hand, let us say that we have a sample of 1,000 people and we observe the association in 700 of them. In this case, even though only 70 per cent of the people in the sample demonstrate the association of hand and foot size, we might say that because the sample size is so large we can have greater confidence in the data than in the case of the small sample.

To ascertain statistical significance from a table the researcher can read off the significance level from a table of significance according to the sample size (or computer software calculates this automatically). There are many online sites that perform such calculations, as well as statistical packages (e.g. SPSS; GPower (a free source)), and these enable researchers to conform to conventional reporting standards, which are to report the absolute significance level (e.g. $\rho = 0.016$) as well as the relative level, for example, $\rho < 0.05$. In the selection from the table of significance for the third example above, concerning hand and foot size, the first column indicates the number of people in the sample and the other two columns indicate significance at the two levels. Hence, if we have thirty people in the sample then, for the correlation to be statistically significant at the 0.05 level, we would need a correlation coefficient of 0.36, whereas if there were only ten people in the sample, we would need a correlation coefficient of 0.65 for the correlation to be statistically significant at the same 0.05 level. Most statistical packages (e.g. SPSS) automatically calculate and report the level of statistical significance. Indeed SPSS automatically asterisks each case of statistical significance at the 0.05 and 0.01

levels or smaller. We discuss correlational analysis in more detail later in Chapter 40, and we refer the reader to that discussion.

39.3 Concerns about statistical significance

One has to be cautious in using statistical significance, as it has attracted so much criticism that some journals have ceased to accept papers that rely on null hypothesis significance testing (NHST) alone. For decades authors have gone so far as to aver that it is a discredited approach to research (Carver, 1978; Falk and Greenbaum, 1995; Ziliak and McCloskey, 2008; Gorard, 2016), even though it survives to the present. In an influential paper, Carver (1978) dismisses significance testing as a 'corrupt scientific method' (p. 387), though Cortina and Landis (2011) still see some value in it. There are several serious concerns about significance testing; we introduce key concerns here and we advise researchers to reconsider strongly the use of significance testing on its own.

The null hypothesis

Significance testing (NHST) works on the basis of commencing with the null hypothesis, seeking to support it or not to support it from the data. It claims to determine whether or not findings occur by chance. However, this relies on random sampling, but in practice such sampling occurs very rarely (Gorard, 2016). Further, even if we assume that true random sampling has occurred, this does not solve the problem of assuming the null hypothesis, as in significance testing for most of the time we simply do not know the truth of the null hypothesis, i.e. whether it is safe to make such an assumption. Indeed, in reality, it is extremely unlikely that the null hypothesis will be true; it is a straw man (Carver, 1978, p. 380; Cohen, 1994; Krueger, 2001, p. 17), a false assumption or construct. However, significance testing is built on this assumption, and this fundamentally undermines its validity. If we have no grounds for believing that the null hypothesis is true, then making such assumptions is unwise (Carver, 1978, p. 382). (Of course, there may be occasions when the null hypothesis can be demonstrated to be true, e.g. if the means and standard deviations of two groups on, say, the marks on a maths test, are shown to be the same, i.e. no difference between them.)

Statistical significance, as Carver (1978) suggests, 'simply means statistical rareness' (p. 381), not certainty. For example, accepting a significance level of 0.05 means that five times in 100 the researcher should accept the null hypothesis, and that the 'calculated risk' (p. 381) in rejecting the null hypothesis is wrong. NHST *assumes* that the null hypothesis is acceptable (Carver, 1978), but, as he remarks, this is questionable, since 'there is no way that we can be absolutely sure the null hypothesis is true. If we could be sure, we would never test for statistical significance at all' (p. 381) (see also Falk and Greenbaum, 1995; Gorard, 2016).

Though one can compute the probability of the data being statistically significant, given the assumption of the null hypothesis, the researcher cannot perform the opposite, which is to consider the likelihood of the null hypothesis, given the data (Carver, 1978; Falk and Greenbaum, 1995). In other words, logically speaking, we cannot assume the acceptability of the null hypothesis in the first place; we do not know if the initial null hypothesis is true or false (Carver, 1978; Falk and Greenbaum, 1995; Krueger, 2001; Gorard, 2016).

Ziliak and McCloskey (2008) draw attention to this error of the 'fallacy of the transposed conditional' (p. 41) in using statistical significance. In this, the 'probability of the data, given the hypothesis' is falsely transposed to be 'the probability of the hypothesis, given the data' (p. 41). Carver (1978) provides a very clear example of the danger here: the probability of obtaining a dead person, given that the person was hanged, is extremely high (e.g. 0.97 or higher), but the probability that a person has been hanged, given that he is dead, is extremely low (e.g. 0.01 or lower). It is unlikely that, in real life, the two would be confused, but in working with statistical significance, this is often exactly what happens. Put simply, it is mistaken to assume that the null hypothesis is an acceptable starting point and usually we have no way, using significance testing, of knowing if this assumption is safe; indeed it is likely to be unsafe.

If the assumption of the null hypothesis is either false or unable to be proved by the data, then this seriously questions the validity of significance testing which is based on the assumption of the null hypothesis (NHST) (Carver, 1978; Falk and Greenbaum, 1995; Gorard, 2016). Indeed Gorard (2016) show that tests of statistical significance 'are more likely to produce the wrong answer than the right one' (p. 1) and he comments that significance tests cannot even meet their supposed claim which is to indicate whether or not a finding is or is not by chance (p. 3), i.e. they are fundamentally flawed.

Statistical significance and sample size

Statistical significance is calculated as a function of sample size, and it is highly likely that statistical significance will be found if large samples are used (e.g. Ziliak and McCloskey, 2008). Statistical

significance varies according to the size of the number in the sample (see the table of significance reproduced above). In order to determine statistical significance we must have two facts in our possession: the size of the sample and, in correlational research, the coefficient of correlation or, in other kinds of research, the appropriate coefficients or data (there are many kinds, depending on the statistical test being used). Here, as the selection from the table of significance reproduced above shows, the coefficient of correlation can decrease and still be statistically significant as long as the sample size increases. (This resonates with Krejcie's and Morgan's (1970) principles for sampling, observed in Chapter 12, namely, as the population increases, the sample size increases at a diminishing proportion in addressing randomness.)

This is a major source of debate for critics of statistical significance and NHST, who argue that it is almost impossible *not* to find statistical significance when dealing with large samples, as the coefficients can be very low and still attain statistical significance. Statistical significance might be easy to find with large samples, even though the size of the difference or the correlation might be very small indeed (Cumming, 2012, p. 29). Statistical significance varies with sample size and brings with it the possibility of a Type II error (a false negative) if only significance testing is used, particularly with small samples (e.g. Torgerson and Torgerson, 2008; Ziliak and McLoskey, 2008; Ellis, 2010).

Statistical significance on its own has come to be seen as an unacceptable index of effect (Thompson and Snyder, 1997; Wilkinson and the Task Force on Statistical Inference, APA Board of Scientific Affairs, 1999; Thompson, 2002; Wright, 2003; Kline, 2004; Ziliak and McLoskey, 2008; American Psychological Association (APA), 2010; Ellis, 2010), for the reasons given above and because it depends on both sample size and the coefficient (e.g. of correlation). Statistical significance can be attained *either* by having a large coefficient together with a small sample *or* having a small coefficient together with a large sample. The problem is that one is not able to deduce which is the determining effect from a study using statistical significance (Coe, 2000, p. 9). It is important to be able to tell whether it is the sample size or the coefficient that is making the difference.

False dichotomies

Statistical significance is seen as arbitrary in its cut-off points and an unhelpful obstacle rather than a facilitator in educational research (even though the 0.05 significance level corresponds to approximately two standard deviations above the mean and the 0.01 significance level corresponds to approximately three standard deviations above the mean). One also has to be cautious in null hypothesis significance testing (NHST), as it may encourage dichotomous thinking, i.e. a finding is or is not statistically significant, because of these arbitrary cut-off points, and this may discourage thinking of alternative ways of testing a hypothesis (Kline, 2004, pp. 76–9).

Statistical and educational significance

Statistical significance is not the same as educational significance (cf. Ziliak and McCloskey, 2008, p. 110). For example, I might find a statistically significant correlation between the amount of time spent on mathematics and the amount of time spent shopping. This may be completely unimportant. Significance testing does not say anything about whether a finding is highly likely, or important or trivial (Carver, 1978).

Similarly I might find that there is no statistically significant difference between males and females in their liking of physics. However, closer inspection might reveal that there is a difference. Say, for example, that males prefer physics to females, but that the difference does not reach the 'cut-off' point of the 0.05 level of significance; maybe it is 0.065. To say that there is no difference or simply to support the null hypothesis here might be inadvisable. There are two issues here: (a) the cut-off level of significance is comparatively arbitrary, though high; (b) one should not ignore coefficients that fall below the conventional cut-off points. This leads us into a discussion of effect size as an alternative to significance levels (discussed below). Statistical significance, as Ziliak and McCloskey (2008) and Ellis (2010) note, is a putative indicator of chance, for example, that something exists by chance and not by chance (but in light of all the cautions that we set out above), whilst effect size is an indicator which has greater practical significance as researchers may be less interested in chance or proof of existence and more interested in size. We discuss effect size below.

Utility value for research

Statistical significance says nothing about what many researchers really want to know: the size of an effect (e.g. the *amount* of difference or correlation) (Ziliak and McLoskey, 2008; Ellis, 2010); how much. A measure of effect size may be more useful than statistical significance. Statistical significance on its own is no indication of impact, and impact is what researchers (and politicians and funding bodies) are keen to establish.

Given these concerns about statistical significance, we suggest that researchers note where significance testing is and is not fit for purpose and address possible alternatives to significance testing. These include, for example, effect size, statistical power (discussed below)

and counterfactual analysis, i.e. the number of 'counterfactual cases needed in order to disturb a finding' (Gorard and Gorard, 2015, p. 484).

39.4 Hypothesis testing and null hypothesis significance testing

The example that we gave above, of correlational analysis, illustrates a wider issue of NHST (Kline, 2004; Ellis, 2010; Cummings 2012), so we introduce here how this might proceed and then we inject a note of great caution into the use of NHST. NHST has been widely used, and it is for this reason that we retain it in this chapter, but we recognize the sometimes serious problems that inhere in it, and we argue that hypothesis testing can, indeed should, proceed without reliance on NHST. NHST can follow four stages, set out below. However, we strongly counsel readers to question the assumption that hypothesis testing relies on statistical significance testing alone: the two are not the same and, as we have indicated above, NHST has problems and limitations that are so serious as to discredit it in the eyes of many researchers.

Stage 1

In quantitative research, as mentioned above, we commence with a null hypothesis, for example:

- there is *no* statistical significance in the distribution of the data in a contingency table (crosstabulation);
- there is *no* statistically significant correlation between two factors;
- there is *no* statistically significant difference between the means of two groups;
- there is *no* statistically significant difference between the means of a group in a pre-test and a post-test;
- there is *no* statistically significant difference between the means of three or more groups;
- there is *no* statistically significant difference between two sub-samples;
- there is *no* statistically significant difference between three or more sub-samples;
- there is *no* significant prediction capability between one independent variable X and dependent variable Y;
- there is *no* significant prediction capability between two or more independent variables X, Y, Z … and dependent variable A.

The task of the research is to support or not to support the null hypothesis. We remind readers here that the starting point of NHST, which assumes the null hypothesis to be true, in fact is questionable or even false (Kline, 2004, p. 70; Ziliak and McCloskey, 2008).

Stage 2

Having set the null hypothesis, the researcher then sets the level of significance (α) that will be used to support or not to support the null hypothesis; this is the alpha (α) level. The level of alpha is determined by the researcher. Typically it is 0.05, i.e. the chance of a finding being by chance alone – the null hypothesis being supported – is 5 per cent. In writing this we could say 'Let $\alpha=0.05$'. If one wished to be more robust then one would set a higher alpha level ($\alpha=0.01$ or $\alpha=0.001$). This is the level of risk that one wishes to take in supporting or not supporting the null hypothesis.

Stage 3

Having set the null hypothesis and the level at which it will be supported or not supported, one then computes the data as appropriate for the research in question (e.g. measures of association, measures of difference, regression and prediction measures).

Stage 4

Having analysed the data one is then in a position to support or not to support the null hypothesis, and this is what is reported.

In hypothesis testing one has to avoid Type I and Type II errors (see also Chapter 12). A Type I error occurs when one does not support the null hypothesis when it is in fact true (a false positive). This is a particular problem as the sample size increases, as the chances of finding a statistically significant association increases; to overcome this one can set a higher alpha (α) limit (e.g. 0.01 or 0.001) for statistical significance to be achieved. A Type II error occurs when one supports the null hypothesis when it is in fact not true (a false negative), which is often the case if the levels of significance are set too stringently; to overcome this the researcher can set a lower alpha level (α) (e.g. 0.1 or 0.2). Type I and Type II errors are represented in Table 39.1.

In considering hypothesis testing, however, given the serious questions which we have raised earlier

TABLE 39.1 TYPE I AND TYPE II ERRORS

Decision	*H_0 true*	*H_0 false*
Support H_0	Correct	False negative Type II error (β)
Do not support H_0	False positive Type I error (α)	Correct

against NHST, we suggest here that hypothesis testing moves away from NHST and towards alternative ways of hypothesis testing, for example, effect size, statistical power, falsification (in the tradition of Popper) and counterfactual analysis, conducting replication studies, using mixed methods and triangulation, ruling out alternative hypotheses and theories, and giving weight to the power of evidence, rather than simply to a questionable reliance on significance testing. Hypothesis testing is not the same as null hypothesis significance testing.

39.5 Effect size

Statistical significance only purports to tell the researcher whether a particular result (e.g. a difference, a correlation) has or has not occurred by chance. That is all, and even then, as we saw above, the assumptions of the null hypothesis and of NHST are highly questionable. How many researchers are actually interested in whether something does or does not occur by chance, even if the assumptions underpinning NHST are true? Most researchers are more concerned with the size, the magnitude, of an effect, be it, for example, a difference or an association. As Ziliak and McLoskey (2008) note, statistical significance is not only a 'sizeless stare' but omits the very thing in which researchers are interested: how much.

What is required either to accompany or replace statistical significance is information about *effect size* (Wilkinson and the Task Force on Statistical Inference, APA Board of Scientific Affairs, 1999; Kline, 2004; APA, 2010). Indeed effect size is so much more important than statistical significance that, as indicated earlier, many international journals have either abandoned statistical significance in favour of reporting effect size, or have insisted that statistical significance be accompanied by indications of effect size (Thompson, 2002; APA, 2010). Some measures of effect size are standardized, for example, Cohen's *d*, regression weights (β); others use the original units, for example, means, medians, regression weights (*b*); and others are unit-free, for example, percentages, correlation coefficients, proportion of explained variance.

Effect size is a measure of magnitude: the amount of something; how much (e.g. Cohen 1988; Cumming, 2012, p. 34). It operates in two spheres: (i) measures of difference and (ii) measures of association (cf. Kline, 2004, p. 97; Ellis, 2010, p. 7; Cumming, 2012). It is in fact an inaccurate term as 'effect' implies causality, whereas none is actually inferred. With regard to difference, effect size is a way of quantifying the difference between two or more groups. For example, with two groups, if an experimental group has received an intervention whilst the control group has not, then the effect size is a measure of *how big* the effect/difference is between the two groups, which is something that statistical significance does not tell us (Coe, 2000; Wright, 2003, p. 125).

There are many ways of calculating effect size. Glass *et al.* (1981) calculates the effect size as:

$$\frac{\text{(mean of experimental group – mean of control group)}}{\text{standard deviation of the control group}}$$

Coe (2000, p. 7), whilst acknowledging that there is a debate on whether to use the standard deviation (SD) of the experimental or control group as the denominator, suggests that the SD of the control group is preferable as it provides 'the best estimate of standard deviation, since it consists of a representative group of the population who have not been affected by the experimental intervention'. Many calculations of effect size use a 'pooled' estimate of standard deviation, as this is more accurate than that provided by the control group alone. To calculate the pooled deviation Coe provides the formula:

$$SD\ pooled = \sqrt{\frac{(N_E - 1)SD_E^2 + (N_C - 1)SD_C^2}{N_E + N_C - 2}}$$

where N_E = number in the experimental group, N_C = number in the control group, SD_E = standard deviation of the experimental group and SD_C = standard deviation of the control group.

The formula for the pooled deviation is (Ellis, 2010; Cumming, 2012):

$$\frac{\text{(mean of experimental group – mean of control group)}}{\text{pooled standard deviation}}$$

where the pooled standard deviation = (standard deviation of group 1 + standard deviation of group 2).

Morris (2008) suggests that effect size can be calculated thus:

$$\frac{(\mu_{T,post}(\mu_{T,pre}))(\mu_{C,post}(\mu_{C,pre}))}{\text{pooled standard deviation}}$$

where:

$\mu_{T,post}$ = the post-test mean of the treatment (experimental) group

$\mu_{T,pre}$ = the pre-test mean of the treatment (experimental) group

$\mu_{C,post}$ = the post-test mean of the control group

$\mu_{C,pre}$ = the pre-test mean of the control group

This is attractive, as it takes account of changes over time in both groups (see also Figure 20.1 and the 'subtraction' method set out in Chapter 20).

There are several different calculations of effect size, and we list these in Table 39.2, together with summary guidelines on whether these are small, medium or large. However, these guidelines are not absolute; they are *guideline*s only, and are not fixed and/or immutable. Nevertheless Cohen (1988) indicated that these guidelines are useful for researchers. Some researchers (e.g. Kline, 2004; Ellis, 2010; Cumming, 2012) argue against simply 'reading off' effect sizes into 'small', 'medium' and 'large', and they suggest that context and comparative value also have to be taken into account.

For difference tests, Cohen's *d* is the most widely used. Glass's delta can be used if group sizes in the sample are different or if the standard deviation of the groups is different. Hedges' *g* can be used if the group sizes in the sample are unequal or if the sample size is small. These tests report in standardized units, i.e. 0.5 means a difference of half of a standard deviation. This is useful in comparing studies which may have used different scales or units.

Different kinds of statistical treatments use different effect size calculations. Many calculations of effect size give an estimate between 0 and 1; other formulae can yield an effect size that is larger than 1 (see Coe, 2000). In using Cohen's *d*:

0–0.20 = weak effect
0.21–0.50 = modest effect
0.51–1.00 = moderate effect
>1.00 = strong effect

In correlational data the coefficient of correlation is used as the effect size in conjunction with details of the direction of the association (i.e. a positive or negative correlation). The coefficient of correlation (effect size) is interpreted thus:

<0 +/–1 weak
<0 +/–3 modest
<0 +/–5 moderate
<0 +/–8 strong
≥ +/–0.8 very strong

We provide more detail on interpreting correlation coefficients later in this chapter. Thompson (2001, 2002) argues forcibly against simplistic interpretations of effect size as 'small', 'medium' and 'large', as to do this commits the same folly of fixed benchmarks as that of statistical significance, i.e. 'we would merely be being stupid in another metric' (Thompson, 2001, pp. 82–3). Rather, he avers, it is important to avoid fixed benchmarks (i.e. cut-off points), and relate the effect sizes found to those of prior studies, confidence intervals and power analyses (discussed below). We discussed the *confidence interval* in Chapters 12 and 38; it is reported as, for example 90 per cent, 95 per cent, 99 per cent, and is calculated as 1–α, i.e. the level of confidence that one can have in the view that a score falls within a prespecified range of scores (e.g. 95 per cent, 99 per cent) (Ellis, 2010). Software for calculating confidence intervals for many measures can be found at:

- www.surveysystem.com/sscalc.htm
- www.danielsoper.com/statcalc3/calc.aspx?id=96.

TABLE 39.2 EFFECT SIZES FOR DIFFERENCE AND ASSOCIATION

Type	*Statistic*	*Effect sizes*		
		Small	*Medium*	*Large*
Difference testing (t-tests)	Cohen's d (*d*)	0.20	0.50	0.80
	Glass's delta (*d*)	0.20	0.50	0.80
	Hedges' (*g*)	0.20	0.50	0.80
Correlation analysis	Pearson's *r* (scale data)	0.10	0.30	0.50
	Spearman's rho (r_s) (ordinal data)	0.10	0.30	0.50
Crosstabulation (correlation)	Phi (φ) coefficient (2×2 crosstabs)	0.10	0.30	0.50
	Cramer's V (any size crosstabs)	0.10	0.30	0.50
Multiple regression (correlation)	R^2	0.02	0.13	0.26
	Adjusted R^2 ($^{adj}R^2$)	0.02	0.13	0.26
ANOVA (correlation)	Eta squared (η^2)	0.01	0.06	0.14
	Cohen's *f*	0.10	0.25	0.40
MANOVA (correlations)	Partial eta squared (η^2)	0.01	0.06	0.14

Wright (2003, p. 125) also suggests that it is important to report the units of measurement of the effect size, for example in the units of measurement of the original variables as well in standardized units (e.g. standard deviations), the latter being useful if different scales of measures are being used for the different variables.

In calculating the effect size (eta squared) for independent samples in a t-test (see Chapter 41), the following formula can be used:

$$\text{Eta squared} = \frac{t^2}{t^2 + (N_1 + N_2 - 2)}$$

Here t = the t-value (calculated by SPSS); N_1 = the number in the sample of group one and N_2 = the number in the sample of group 2.

Let us take an example of the results of an evaluation item to see how large is the difference in the voting between two groups – (a) leaders/senior managers (SMT) of schools, and (b) teachers – on the item 'How well learners are cared for, guided and supported', referring to Tables 39.3 and 39.4.

Here the t-value is 1.923, N_1 is 347 and N_2 is 653. Hence the formula is:

$$\text{Eta squared} = \frac{t^2}{t^2 + (N_1 + N_2 - 2)} = \frac{1.923^2}{1.923^2 + (347 + 653 - 2)} = \frac{3.698}{3.698 + 998} = 0.0037$$

Using the guidance on interpreting effects sizes above, the result of 0.003 is a tiny effect size, i.e. only 0.3 per cent difference between the two groups on the item 'How well learners are cared for, guided and supported'.

For a paired sample t-test (Chapter 41) the effect size (eta squared) is calculated by the following formula:

$$\text{Eta squared} = \frac{t^2}{t^2 + (N_1 - 1)}$$

As another example, let us imagine that the same group of students had scored marks out of 100 in 'Maths' and 'Science' (Tables 39.5 and 39.6).

The effect size can be worked out thus (using SPSS):

$$\text{Eta squared} = \frac{t^2}{t^2 + (N_1 - 1)} = \frac{16.588^2}{16.588^2 + (1000 - 1)} = \frac{275.162}{275.162 + 999} = 0.216$$

In this example the effect size is 0.216, a large effect, i.e. there was a substantial difference between the scores of the two groups.

For Analysis of Variance (discussed in Chapter 41) the effect size is calculated thus:

$$\text{Eta squared} = \frac{\text{Sum of squares between groups}}{\text{Total sum of squares}}$$

In SPSS this is given as 'partial eta squared'. For example, let us imagine that we wish to compute the effect size of the difference between four groups of schools on mathematics performance in a public examination. The four groups of schools are: (a) rural primary; (b) rural secondary; (c) urban primary; (d) urban secondary. Analysis of Variance yields the following result (Table 39.7):

Working through the formula yields the following:

$$\text{Eta squared} = \frac{\text{Sum of squares between groups}}{\text{Total sum of squares}} = \frac{7078.619}{344344.8} = 0.021$$

The figure of 0.021 indicates a small effect size, i.e. that there is a small difference between the four groups

TABLE 39.3 MEAN AND STANDARD DEVIATION IN AN EFFECT SIZE (SPSS OUTPUT)

Within Groups	337266.2	601	561.175		
Total	344344.8	604			

in their mathematics performance (note that this is a much smaller difference than that indicated by the significance level of 0.006, which suggests a highly statistically significant difference between the four groups of schools).

In regression analysis (discussed in Chapter 42) the effect size of the predictor variables is given by the beta weightings. In interpreting effect size here Muijs (2004, p. 194) gives the following guidance:

0–0.1	weak effect
0.1–0.3	modest effect
0.3–0.5	moderate effect
>0.5	strong effect

For a discussion of the importance of attending to both small and large effect sizes, see Wang (2008). Wang argues that small effect sizes could indicate an important finding (p. 130), i.e. effect size and importance are two separate concepts.

Hedges (1981) and Hunter *et al.* (1982) suggest alternative equations to take account of differential weightings due to sample size variations. The two most frequently used indices of effect sizes are standardized mean differences and correlations, though with non-parametric statistics, for example, the median, can be used. Lipsey (1992, pp. 93–100) sets out a series of statistical tests for working on effect sizes, effect size means and homogeneity.

Muijs (2004, p. 126) indicates that a measure of effect size for crosstabulations, instead of chi-square, should be *phi*, which is the square root of the calculated value of chi-square divided by the overall valid sample size. For example, if chi-square is 23.716 and the sample size is 900, then *phi*=23.716/900=0.02635, and then take the square root of this=0.1623.

Effect sizes are susceptible to a range of influences. These include (Coe, 2000):

- *restricted range*: the smaller the range of scores, the greater the possibility of a higher effect size, therefore it is important to use the pooled standard deviation (not just that of one group) in calculating the effect size. It is important to report the possible restricted range or sampling here (e.g. a group of highly able students rather than, for example, the whole ability range);
- *non-normal distributions*: effect size usually assumes a normal distribution, so any non-normal distributions should be reported;
- *measurement reliability*: the reliability (accuracy, stability and robustness) of the instrument being used (e.g. the longer the test, or the more items that are used to measure a factor, the more reliable it could be).

The researcher also has to keep in mind that effect size operates at the group level rather than the individual level, and that, thereby, individual differences may be overlooked. Researchers also have to be mindful that small samples may not be able to detect a small effect size, thereby committing a Type II error (a false negative) (Torgerson and Torgerson, 2008, p. 128); the advice here, then, is to have as large a sample as possible. Additionally the researcher can set the beta level (β) at a lower significance level in order to avoid a Type II error.

There are downloadable software programs available that calculate effect size straightforwardly, and we indicate these in the companion website. More information on effect sizes can be found in Leech and Onwuegbuzie (2004), Kline (2004) and Ellis (2010).

39.6 Statistical power

For any test to be worth its salt, it is important for it to have strong statistical power. Statistical power is the probability that a study will detect an effect where it exists and will not find an effect when none exists, i.e. find a true positive and a true negative and avoid a false positive and false negative. A large sample helps the researcher to achieve statistical power.

Addressing statistical power takes us into consideration of Type I and Type II errors. A Type I error is a false positive: rejecting the null hypothesis (H_0) when, in reality, it is true. A Type II error is a false negative, accepting the null hypothesis (H_0) when, in reality, it is false. Decisions to accept or reject a null hypothesis are usually made on the basis of statistical significance (discussed earlier).

The probability of committing a Type I error (false positive) is termed 'alpha' (α) (the significance level of a test). Alpha can range from 0 to 1, and should be <0.05 to avoid a Type I error (i.e. only a 5 per cent chance of making the error). A low alpha (e.g. ≤0.05) indicates statistical significance in conventional terms, and the closer it is to 0, the lower the chance of a Type I error. A high alpha (e.g. 0.65) suggests no real statistical significance (i.e. the result is by chance).

The probability of committing a Type II error (false negative) is termed 'beta' (β). If the statistical power is high then the probability of making a Type II error (i.e. concluding that there is no effect when, in fact, there is an effect) goes down. Beta can range from 0 to 1 and should be >0.05 to avoid a Type II error (i.e. only a 5 per cent chance of making the error). A low beta (e.g. ≤0.05) indicates statistical significance, and the closer it is to 1, the lower the chance of a Type II error.

If we decrease alpha then beta will increase, and if we increase alpha then beta will decrease. If we choose

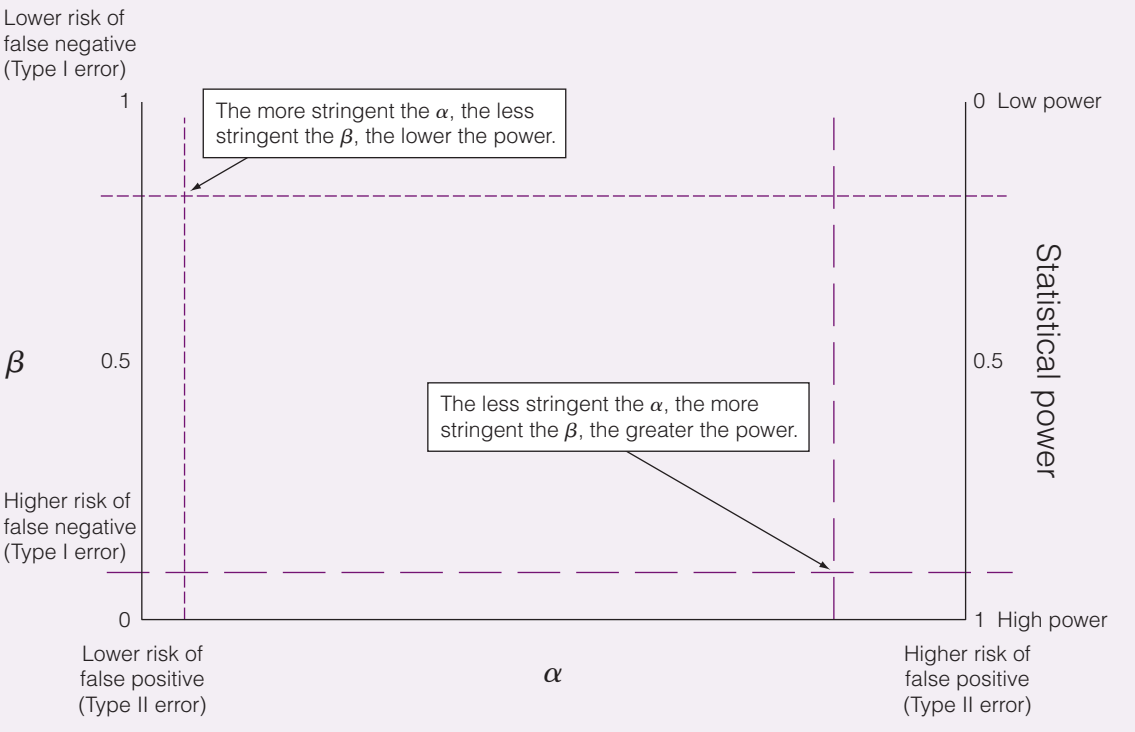
a very small alpha (e.g. $\alpha=0.001$), then we make it difficult to reject the null hypothesis, i.e. we may be making a Type II error: failing to find an effect which is actually present (a false negative). If we choose a large alpha (e.g. $\alpha=0.25$), i.e. easier to reject the null hypothesis, then we reduce the chance of making a Type II error but increase the chance of making a Type I error (false positive). If we choose a very small beta (e.g. $\beta=0.05$) then we may commit a Type I error: finding an effect that is not really present (false positive). If we choose a large beta (e.g. $\beta=0.30$), then we reduce the chance of a Type II error.

Statistical power ranges from 0 to 1, and the closer it is to 1, the greater the statistical power, and the greater the power, the higher the decimal fraction, i.e. 0.80 is more powerful than 0.50. Ziliak and McCloskey (2008) remark that high power is good whilst low power is bad (p. 132). A power of 0.50 (a 50 per cent chance of making a Type II error) has less statistical power than a power of 0.80. Beta is calculated as $\beta=1$ – power, and the power of a test is $1-\beta$. In other words, power is inversely related to beta (the probability of making a Type II error). A power level of 0.50 or lower is problematic, as a power level of 0.50 means that there is a 50/50 chance of rejecting a true null hypothesis (a false negative) or accepting a false alternative hypothesis (a false positive) (Kline, 2004, p. 43).

The relationship between α, β and statistical power is set out in Figure 39.1. Here one can see a trade-off: the more one wishes to avoid a Type I error, the greater is the chance of committing a Type II error, and the more one wishes to avoid a Type II error, the greater is the chance of committing a Type I error.

The researcher will have to make several decisions here, for example:

- what to set as the appropriate level of the alpha (α) in order to avoid a Type I error (the lower the alpha, the more rigorous and stringent is the test);
- what to set as the appropriate level of the beta (β) in order to avoid a Type II error (the lower the beta, the greater the chance of finding a true positive);
- whether to set a stringent α (e.g. 0.01), which may have low power but decreases the chance of a Type I error;



Figures for α and β are significance levels

FIGURE 39.1 Balancing alpha, beta and statistical power

- whether to set a less stringent α (e.g. 0.10), which may have high power but increases the chance of committing a Type II error;
- whether to set a stringent β (e.g. 0.05), which may have high power but increases the chance of committing a Type I error;
- whether to set a less stringent β (e.g. 0.8), which may have low power but decreases the chance of committing a Type II error.

The power level is, in part, a function of the alpha. If the researcher chooses a very small value of α (e.g. 0.05), this makes it very difficult to reject the null hypothesis but much easier to commit a Type II error (a false negative). If the researcher chooses a larger value of α (e.g. 0.10), this makes it easier to reject the null hypothesis but more difficult to commit a Type II error.

Researchers have to set the power level for themselves, deciding the power level required, and, *inter alia*, this affects the sample size. Power analyses are usually run before a study is conducted (often to determine the sample size needed). How can the researcher proceed here? The researcher looks at the relationship between α, β and power. One can set the α very stringently (e.g. 0.05) but set the β less stringently (e.g. 0.20). Cohen (1988) held that Type I errors should be treated four times more seriously than Type II errors: a four to one weighting of beta to alpha. Researchers often set an α of 0.05, and a β of 0.20, giving a power of 0.80 (80 per cent power level), i.e. a 5 per cent chance of a Type I error and a 20 per cent chance of a Type II error, thereby setting a good likelihood of finding a true positive. This is shown in Figure 39.2.

Statistical power analysis has four main parameters:

1. the effect size;
2. the sample size (number of observations);
3. the alpha (α) significance level (usually 0.05 or lower);
4. the power of the statistical test (setting the acceptable β level and the desired power (1 – β), e.g. β of 0.20 and power of 0.80).

Larger effect sizes are easier to detect than smaller effect sizes, and in larger samples effects are easier to detect than in smaller samples (Ellis, 2010). Statistical power, then, influences sample size. Further, it can be affected by the variation in the population: the greater the heterogeneity (variation), the lower the power, and the calculation of statistical power depends on the test used and on whether it is one-tailed or two-tailed (see also Chapter 12). Cohen (1988) and Ellis (2010) provide tables for determining sample sizes depending on the power required, and indeed there are many web sites that provide a similar service.

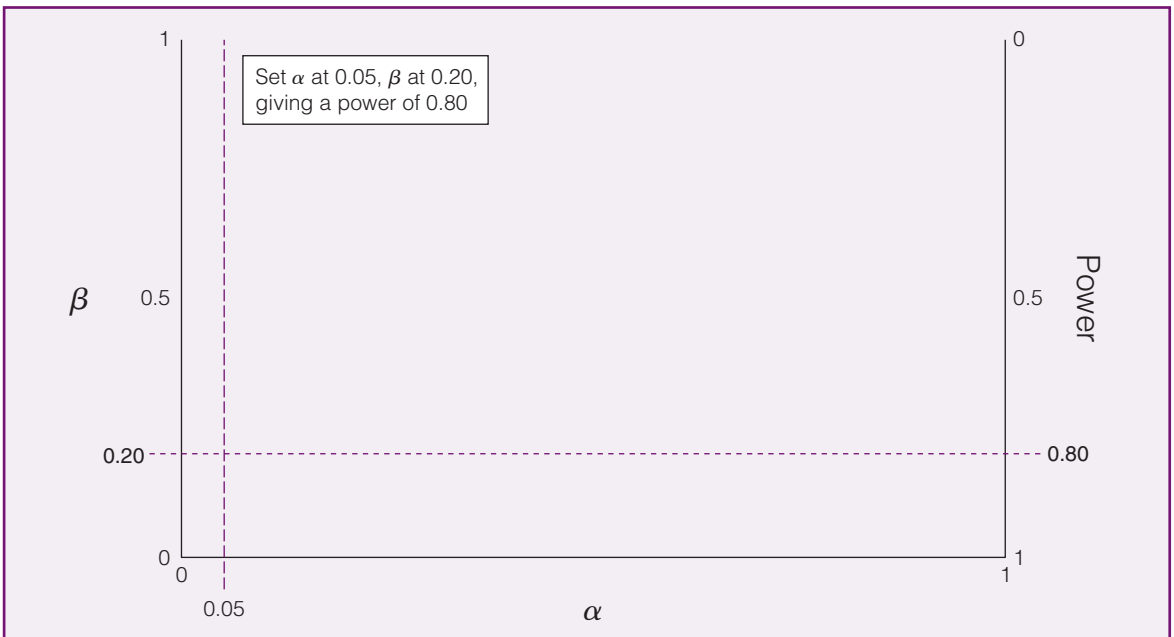


FIGURE 39.2 Setting the alpha, beta and power size

Overall, to improve the statistical power of the test, researchers should strive for the following (Kline, 2004; Ellis, 2010; Cumming, 2012):

- use a large sample;
- look for a larger effect size;
- lower the α level, as this increases the chance of rejecting the null hypothesis, i.e. reducing the chance of a Type II error;
- use a homogeneous sample;
- use a one-tailed test and ensure that the direction of the alternative hypothesis is the same as the direction of the population effect;
- ensure high reliability scores; and
- use parametric tests rather non-parametric tests (where appropriate).

Tables of sample size for statistical power, with an α of 0.05, and a power level of 0.80 suggest the following:

- For a one-tailed difference test, seeking an effect size of 0.5, the sample size is approximately 100.
- For a two-tailed difference test, seeking an effect size of 0.5, the sample size is approximately 130.
- For a one-tailed correlation, seeking an effect size of 0.5, the sample size is approximately 20.
- For a two-tailed correlation test, seeking an effect size of 0.5, the sample size is approximately 30.

These are gross approximations (i.e. heavily rounded), and only by way of indication, so readers are very strongly advised to go to tables of more exact sample sizes by power levels, alpha levels and effect size sought (see Cohen, 1988; and Ellis, 2010).

39.7 Conclusion

Statistical significance, effect size and statistical power carry great weight in educational research. However this chapter has deliberately cast a serious doubt over significance testing other than to demonstrate that a result is or is not by chance, and it has suggested that even this is highly questionable. It has argued that null hypothesis significance testing (NHST), though widely used, should be regarded with caution not only because it has serious shortcomings, for example, in its questionable assumption of the null hypothesis, but also because it does not address issues in which researchers are typically interested – the magnitude of an effect, be that effect a matter of difference or association (the two main types of effect size). Hence we have argued for the importance of calculating effect size in quantitative educational research. Measures of effect size, be they in terms of standardized units, original units or unit-free measures, vary according to the statistical tests used to calculate them. We have also indicated the possibility of using 'the number of counterfactual cases need to disturb a finding' (Gorard and Gorard, 2015, p. 484) as an alternative to significance testing. We have suggested that hypothesis testing does not commit the researcher to using only NHST, as there are other ways of testing a hypothesis.

However this is not to jettison significance testing altogether. We have indicated how it is used in determining statistical power, and that statistical power – the probability that the research will detect a true effect (a true positive) where there is one and will not find an effect where none exists (a true negative) – is a key factor in judging how important the research might be and how reliable is the instrument used. Statistical power is an essential, if often overlooked, ingredient of high-quality educational research. We have indicated that it should be decided in advance of the research and that it draws on effect size, sample size and statistical significance (in terms of alpha (α) and beta (β)), and that a trade-off has to be made between alpha and beta in addressing Type I and Type II errors, requiring the researcher to set appropriate alpha and beta levels. We have suggested that many researchers set statistical power at 0.80, alpha at 0.05 and beta at 0.20. Researchers should consult tables of sample size that take into account alphas, betas, effect size sought and statistical power.

These three elements of quantitative research – significance testing, effect size and statistical power analysis – combine with the issues raised in Chapter 38 to ensure rigorous and reliable quantitative research.

Companion Website

The companion website to the book provides additional material, data files and PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Descriptive statistics

CHAPTER 40

This chapter introduces descriptive statistics. Descriptive statistics do what they say: they describe, so that researchers can then analyse and interpret what these descriptions mean. This chapter introduces some key descriptive statistics and how to use them. This includes:

- a cautionary note about missing data
- frequencies, percentages and crosstabulations
- measures of central tendency and dispersal
- taking stock
- correlations and measures of association
- partial correlations
- reliability

Descriptive statistics include frequencies, measures of dispersal (standard deviation), measures of central tendency (means, modes, medians), standard deviations, crosstabulations and standardized scores. With the exception of standardized scores, which we keep for Chapter 42, we address all of these in this chapter. In this chapter we refer to the Statistical Package for the Social Sciences (SPSS) in many of the calculations and examples.

40.1 Missing data

For all the statistics introduced in this and subsequent chapters, we alert the reader to the issue of missing data. Missing data can damage the precision or correctness of analysis and some statistics assume that there are no missing data.

There are many reasons why data might be missing. For example, respondents might simply have overlooked entering a result, or they might have deliberately left a survey answer blank, or they may drop out of the research (attrition) and so on. For whatever reason, data frequently are missing. Data may be Missing Completely At Random (MCAR) (Rubin, 1976), i.e. there is no pattern to the missing data for any variables. Data may be Missing At Random (MAR) (*ibid.*), where there is a pattern to the missing data, but not for the main dependent variable. Data may be Missing Not At Random (MNAR) (*ibid.*), where there is a pattern in the missing data that affects the main dependent variable (e.g. low-income families may not respond to a survey item).

What is the researcher to do here? It is impossible and maybe very dangerous to guess what data the respondent would have entered. Of course, the researcher could try to go back to the respondent and ask him/her to complete the missing item, but often this is impossible.

The researcher will need to ascertain how many cases for each variable have missing data (SPSS automatically calculates this using its 'Descriptives' function) and what the distribution of the missing values is, for example, whether the missing data are randomly scattered or whether there is a systematic pattern in the missing data (again, SPSS can indicate this). If the missing data are randomly scattered, then, provided that the number of missing cases is so small that it is impossible for the results to seriously distort the overall findings, the researcher might simply exclude those cases (SPSS can do this automatically). If the missing data are not randomly scattered but are systematically missing, i.e. if there is a pattern in the non-response, then this presents a major problem for the researcher, as it is impossible to determine what result/data the respondents would have given if they had given a response. In this case the researcher may decide not to pursue that part of the analysis or may use imputation methods (see below).

To decide whether the number of missing cases in a variable is sufficiently high to seriously distort the results, the researcher can conduct a sensitivity analysis (Gorard, 2013, p. 88). This involves calculating the number of *different* responses/cases (i.e. different from the non-missing data) that would be required to overturn or seriously change the findings of the analysis. If the number is so low that it could not upset the findings then the researcher might wish to proceed, reporting the number of missing cases.

The researcher can adopt a *deletion method* for missing data, excluding any cases (e.g. people) whose data are incomplete on *any* variable (SPSS does this in

its 'Exclude cases listwise' function, only using those cases which are complete on *all* the variables). Alternatively, the researcher can exclude those cases which are incomplete on only the variables of interest for a specific statistical calculation (SPSS does this in its 'Exclude cases pairwise' function). For example, if we want to calculate the difference between the scores on two tests which students have taken – say mathematics and English – then, if some students have completed the mathematics test but not the English test, or *vice versa*, then those students are excluded from the calculation and this is reported in the research.

The cost of the deletion method is in the power of the analysis, as the number of cases is reduced. For the exclusion of every incomplete case (person) (i.e. listwise deletion), this reduces the total number of cases, often quite considerably (as it only takes one missing value to exclude an entire case/person), whilst in the pairwise exclusion it means that exact comparison between sets of results may be impossible, given different sample sizes on each set of variables.

An alternative to the deletion method of excluding missing cases is the *imputation method* (e.g. single and multiple imputation). Imputation is a general term given to the many methods of trying to calculate what the missing values might be so that they can be included in the analysis, i.e. substituting missing values with plausible, calculated values (e.g. Rubin, 1987). This is beyond the scope of the present book, but it rests on techniques for making educated guesses in calculating probabilities, though there is no guarantee that this is 100 per cent accurate.

In single imputation, substitution (e.g. of means) takes place, for example entering the sample mean for the missing value. However, this reduces the chance of having true variability in the distributions and may compromise some statistical calculations such as correlational analysis. Multiple imputation methods rely on modelling the data, with maximum likelihood estimation and regression models used to predict and estimate missing values. Imputation can be used if the missing data are systematically missing, but they risk underestimating standard errors and are reliant on the robustness of the model being used. SPSS can calculate and enter missing values.

For more on missing values, we refer readers to Enders (2010), Carpenter and Kenward (2013), Little and Rubin (2014) and Raghunathan (2015).

40.2 Frequencies, percentages and crosstabulations

Frequencies and percentages

In descriptive statistics much is made of visual techniques of data presentation. Hence frequencies, percentages and forms of graphical presentation are often used. Many graphical forms of data presentation are available in software packages, including:

- frequency and percentage tables;
- bar charts (for nominal, ordinal and discrete data);
- histograms (for continuous – interval and ratio – data);
- line graphs;
- pie charts;
- high and low charts;
- scatterplots;
- stem and leaf displays;
- boxplots (box and whisker plots).

With most of these forms of data display there are various permutations of the ways in which data are displayed within the type of chart or graph chosen. Whilst graphs and charts may look appealing and have the benefit of visual immediacy, often they tell the reader no more than could be seen in a simple table of figures, and figures take up less space in a report and often carry more information. Pie charts, bar charts and histograms are particularly prone to this problem, and the data could be placed more succinctly into tables. Clearly the issue of fitness for audience is important here: some readers may find charts more accessible and comprehensible than tables of figures. Other charts and graphs can add greater value than tables, for example, line graphs, boxplots and scatterplots with regression lines, and these are helpful. Here are some guides on usage:

- bar charts are useful for presenting categorical and discrete data, highest and lowest (see Figure 40.1);
- avoid using a third dimension (e.g. depth) in a bar chart or histogram when it is unnecessary; a third dimension must provide additional information;
- histograms are useful for presenting continuous data;
- line graphs (single lines: one variable; or many lines: many variables) are useful for showing trends, particularly in continuous data, for one or more variables over time;
- pie charts and bar charts are useful for showing proportions;
- inter-dependence and relatedness can be shown through crosstabulations (discussed below);

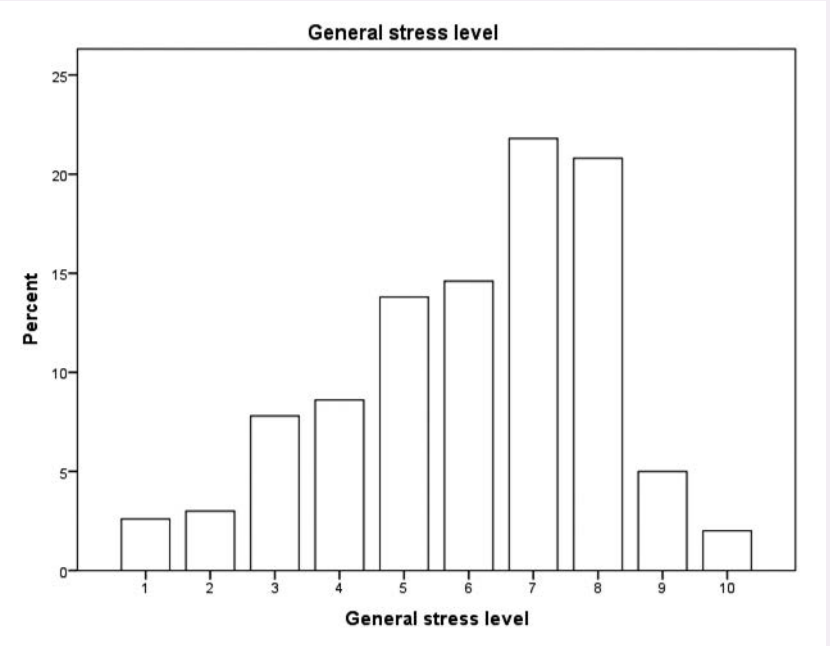

FIGURE 40.1 Bar chart of distribution of discrete stress levels amongst teachers (SPSS output)

- boxplots are useful for showing the distribution of values for several variables in a single chart, together with their range and medians (see Figure 40.2);
- stacked bar charts are useful for showing the frequencies or percentages of different groups within a specific variable for two or more variables in the same chart;
- scatterplots are useful for showing the relationship between two variables (see Figure 40.3).

With regard to bar charts, Figure 40.1 presents an example of teachers' reported stress levels.

In compiling Figure 40, 1,500 teachers reported their stress levels (from 1 to 10), and the bar chart sets out the percentages of respondents in each category. There are several points to observe here:

- the data are not normally distributed: they are negatively skewed (a long tail down to the left) and more respondents voted in the categories 7–10 (some 50 per cent) than in the categories 1–4 (22 per cent), i.e. more teachers were at the higher than the lower levels of stress'
- over 40 per cent of respondents voted in the categories 7 and 8'
- most of the results clustered around categories 5–8 (71 per cent).

The bar chart gives a powerful visual message but it does not present exact percentages. Compare this to Table 40.1 which lacks the visual impact but actually provides more detail. Researchers will need to decide which is fitter for purpose and audience.

With regard to boxplots, Figure 40.2 is rich in detail. It reports the mathematics test scores (marks out of 10)

TABLE 40.1 FREQUENCIES AND PERCENTAGES OF GENERAL STRESS LEVEL OF TEACHERS

Stress level	*Frequency*	*Percent*
1	13	2.6
2	15	3.0
3	39	7.8
4	43	8.6
5	69	13.8
6	73	14.6
7	109	21.8
8	104	20.8
9	25	5.0
10	10	2.0
Total	500	100.0

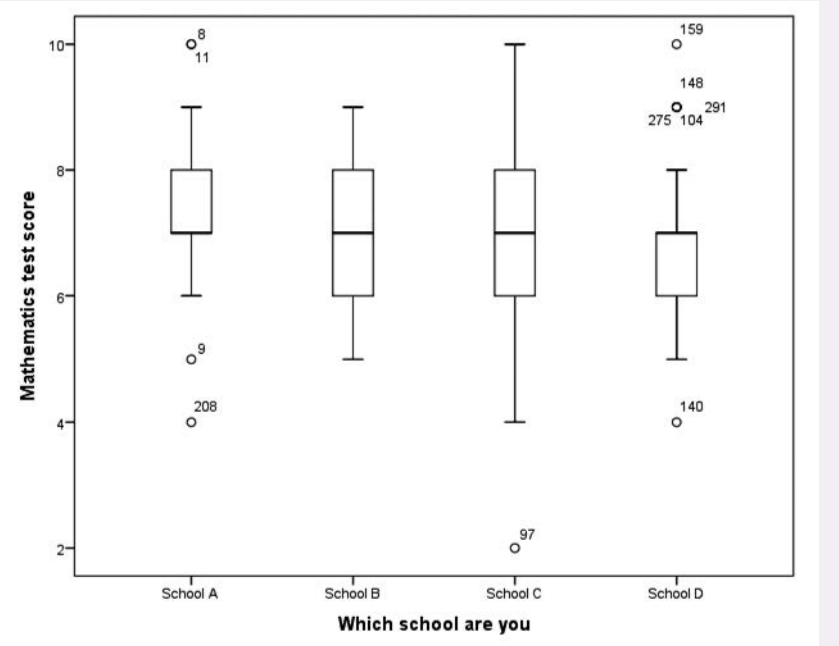

FIGURE 40.2 Boxplot of mathematics test scores in four schools (SPSS output)

for four schools, with 500 students in total, 125 from each school. There are several points to note from Figure 40.2:

- Each rectangular box contains the middle 50 per cent of cases for each school (the second and third quartile: a quartile is 25 per cent). We can see that School A and School D have small boxes, i.e. the middle 50% of cases (students) are in a narrow range of marks, whilst School B and School C have larger boxes, indicating that their middle 50 per cent of cases (students) are in a wider range of marks.
- the lines above and below each box (the 'whiskers' in this 'box and whisker' chart) indicate the range of the highest and lowest scores excluding outliers (some versions of the 'whiskers' have different definitions). Here we can see that Schools A, B and D have short whiskers (i.e. a narrow range), whilst School C has long whiskers, indicating a wider range of marks.
- the thick horizontal line in each box is the median value (the score of the middle case/person). As can be seen, in this instance the median value is the same for each school (the mark of 7 out of 10), but the distributions around that median are different. For example, in School A the median is at the bottom of the box, whereas in School D it is at the top, i.e. in School A the box (middle 50 per cent) contains marks of 7 and 8, whereas for School D the box (the middle 50 per cent) contains marks of 6 and 7, i.e. they are generally lower than the marks from School A.
- The small circles with numbers are outliers, i.e. those cases (students) whose scores are more than 1.5 times outside the interquartile range (discussed later in this chapter). The numbers next to these small circles are the case numbers in the SPSS file, so that the researcher can easily trace the exact outlier case (person) in the data set (each case has a number). School A has four outliers; School B has none; School C has one; and School D has six. Researchers will need to decide whether to remove or retain outliers. Outliers are true scores, but they may skew the mean and standard deviation (discussed below).

With regard to the scatterplot, Figure 40.3 shows the scores of students on a final university examination in relation to the number of hours per week that student spent on private study. Figure 40.3 contains several pieces of information:

- The small circles indicate the cases (the students), and the line from the lower left to the upper right is

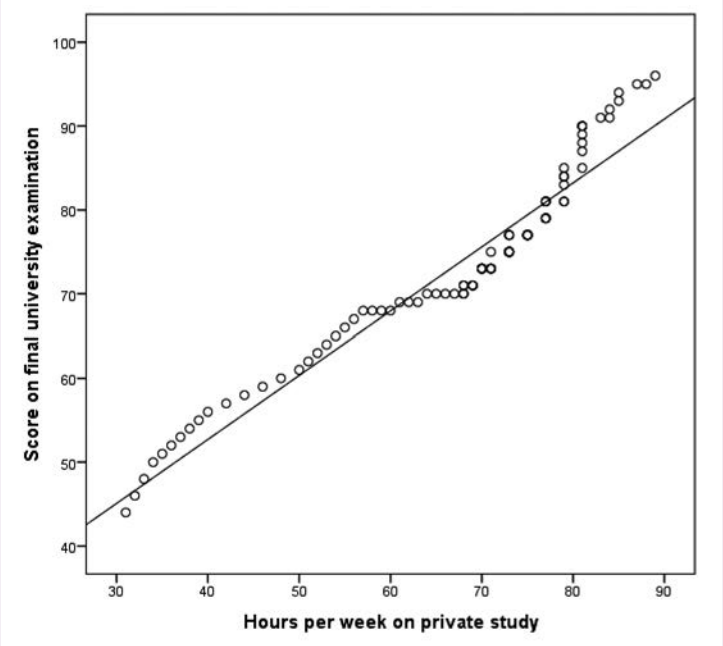

FIGURE 40.3 Scatter-plot with line of best fit (SPSS output)

the line of best fit of the scatter of the data. Many cases are close to the line of best fit, and some are a little further away from it; that is usual. The line of best fit is acceptable here, given that the cases are close to the line; in cases where the data are not close to the line of best fit, it may not be so useful. The line of best fit is a straight line, i.e. clearly there is a linear relationship between the two variables here.

- The scales of each axis do not start at zero, i.e. there were no students who studied for fewer than 30 hours each week, and there were no students who scored lower than 43 marks out of 100 (SPSS automatically calculates and presents the scale of marks to be used for each axis, and this can be edited at will).
- The more hours per week the students spent on private study, the higher was their university examination mark.
- The researcher can use this chart to predict scores, for example, a student who studies for fifty hours a week is likely to score 61 per cent in the examination, and a student who studies for seventy hours a week is likely to score 76 per cent on the examination.

At a simple level one can present data in terms of a table of frequencies and percentages (a piece of datum about a course evaluation), as shown in Table 40.2. From this table we can tell that:

a 191 people completed the item;
b most respondents thought that the course was 'a little' too hard (with a clear modal score of 98, i.e. 51.3 per cent); the modal score is that category or score which is given by the highest number of respondents;
c the results were skewed, with only 10.5 per cent being in the categories 'quite a lot' and 'a very great deal';

TABLE 40.2 FREQUENCIES AND PERCENTAGES FOR A COURSE EVALUATION (SPSS OUTPUT)

The course was too hard

		Frequency	Percentage
Valid	not at all	24	12.6
	very little	49	25.7
	a little	98	51.3
	quite a lot	16	8.4
	a very great deal	4	2.1
	Total	191	100.0

d more people thought that the course was 'not at all too hard' than thought that the course was 'quite a lot' or 'a very great deal' too hard;
e overall the course appears to have been slightly too difficult but not much more.

Crosstabulations

Let us imagine that we wished to explore further this piece of datum from Table 40.2. We may wish to discover, for example, the voting on this item by males and females. This can be presented in a simple crosstabulation, following the convention of placing the nominal data (male and female) in rows and the ordinal data (the five-point scale) in the columns (or independent variables as row data and dependent variables as column data). A crosstabulation is simply a presentational device, whereby one variable is presented in relation to another, with the relevant data inserted into each cell (automatically generated by software packages, such as SPSS) (Table 40.3).

Table 40.3 shows that, of the total sample, nearly three times more females (38.2 per cent) than males (13.1 per cent) thought that the course was 'a little' too hard, between two-thirds and three-quarters more females (19.9 per cent) than males (5.8 per cent) thought that the course was a 'very little' too hard, and around three times more males (1.6 per cent) than females (0.5 per cent) thought that the course was 'a very great deal' too hard. However, one also has to observe that the size of the two sub-samples was uneven. Around three-quarters of the sample was female (73.8%) and around one-quarter (26.2 per cent) was male.

There are two ways to overcome the problem of uneven sub-sample sizes. One is to adjust the sample, in this case by multiplying up the sub-sample of males by an exact figure in order to make the two sub-samples the same size (141/50=2.82). Another way is to examine the data by each row rather than by the overall totals, i.e. to examine the proportion of males voting such-and-such, and, separately, the proportion of females voting for the same categories of the variable, thus, as shown in Table 40.4.

If you think that these two calculations and re-calculations are complicated or difficult (overall-percentaged totals and row-percentaged totals), then be reassured: many software packages, for example, SPSS (the example used here) do this at one keystroke.

In Table 40.4 one can observe that:

- there was consistency in the voting by males and females in terms of the categories 'a little' and 'quite a lot';
- more males (6 per cent) than females (0.7 per cent) thought that the course was 'a very great deal' too hard;
- a slightly higher percentage of females (91.1 per cent: {12.1%+27%+52%}) than males (86 per cent: {14%+22%+50%}) indicated, overall, that the course was not too hard;
- the overall pattern of voting by males and females was similar, i.e. for both males and females the strong to weak categories in terms of voting percentages were identical.

We suggest that Table 40.4 is more helpful than Table 40.3, as, by including the row percentages, it renders fairer the comparison between the two groups: males and females. Further, we suggest that it is usually preferable to give *both* the actual frequencies and percentages, but to make the comparisons by percentages. We say this, because it is important for the reader to know the actual numbers used. For example, in Table 40.3, if we were simply to give the percentage of males voting that the

TABLE 40.3 CROSSTABULATION BY TOTALS (SPSS OUTPUT)

sex * The course was too hard: crosstabulation

		the course was too hard					
		not at all	very little	a little	quite a lot	a very great deal	Total
male	Count	7	11	25	4	3	50

	% within sex	12.1%	27.0%	52%	8.5%	.7%	100%
Total	Count	24	49	98	16	4	191
	% within sex	12.6%	25.7%	51%	8.4%	2.1%	100%

course was a 'very great deal' too hard (1.6 per cent), as course planners we might worry about this. However, when we realize that 1.6 per cent is actually only three out of 141 people then we might be less worried. Had the 1.6 per cent represented, say, fifty people of a sample, then this would have given us cause for concern. Percentages on their own can mask the real numbers, and the reader needs to know the real numbers.

Researchers can comment on particular cells of a crosstabulated matrix in order to draw attention to certain factors (e.g. the very high 52 per cent in comparison to its neighbour 8.5 per cent in the voting of females in Table 40.4). It is also useful, on occasions, to combine data from more than one cell, as we have done in the example above. For example, if we combine the data from the males in the categories 'quite a lot' and 'a very great deal' (8%+6%=14%) we can observe that, not only is this equal to the category 'not at all', but it also contains fewer cases than any of the other single categories for the males, i.e. the combined category shows that the voting for the problem of the course being too difficult is still very slight.

Combining categories can be useful in showing the general trends or tendencies in the data. For example, in Tables 40.2–40.4, combining 'not at all', 'very little' and 'a little', all of these measures indicate that it is only a very small problem of the course being too hard, i.e. generally speaking the course was not too hard.

Combining categories can also be useful in rating scales of agreement to disagreement. For example, consider the following results in relation to for example, a survey of 200 people on a particular item (Table 40.5).

There are several ways of interpreting Table 40.5, for example: (a) more people 'strongly agreed' (20 per cent) than 'strongly disagreed' (15 per cent); (b) the modal score was for the central neutral category (a central tendency) of 'neither agree nor disagree'. However one can go further. If one wishes to ascertain an overall indication of disagreement and agreement then adding together the two disagreement categories yields 35 per cent (15%+20%) and adding together the two agreement categories yields 30 per cent (10%+20%), i.e. there was more disagreement than agreement, despite the fact that more respondents 'strongly agreed' than 'strongly disagreed', i.e. the *strength* of agreement and disagreement has been lost. Adding together the two disagreement and agreement categories gives us a general rather than a detailed picture; this may be useful for our purposes. However, if we do this then we also have to draw attention to the fact that the total of the two disagreement categories (35 per cent) is the same as the total in the category 'neither agree nor disagree', in which case one could suggest that the modal category of 'neither agree nor disagree' has been superseded by bi-modality, with disagreement being one modal score and 'neither agree nor disagree' being the other.

Combining categories can be useful, though it is not without its problems; for example let us consider three tables (Tables 40.6–40.8). The first presents the overall results of an imaginary course evaluation, in which

TABLE 40.5 RATING SCALE OF AGREEMENT AND DISAGREEMENT

Strongly disagree	*Disagree*	*Neither agree nor disagree*	*Agree*	*Strongly agree*

	Satisfaction with course		
	Low (1–3)	*High (4–7)*	*Total*
Male	60 (41.4%)	85 (58.6%)	145 (100%)
Female	35 (43.7%)	45 (56.3%)	80 (100%)
Total	95 (42.6%)	130 (57.4%)	225 (100%)
Difference	–2.1%	+1.9%	

three levels of satisfaction have been registered (low, medium, high) (Table 40.6).

Here one can observe that the modal category (the category with the most votes) is 'low' (95 votes: 42.2 per cent) and the lowest category is 'high' (45 votes: 20 per cent), i.e. overall the respondents are dissatisfied with the course. The females seem to be more satisfied with the course than the males, if the category 'high' is used as an indicator, and the males seem to be more moderately satisfied with the course than the females.

However, if one combines categories (low and medium) then a different story could be told (Table 40.7). By looking at the percentages in Table 40.7, it appears that the females are more satisfied with the course overall than males, and that the males are more dissatisfied with the course than females.

However, if one were to combine categories differently (medium and high) then a different story could be told (Table 40.8). By looking at the percentages in Table 40.8, it appears that there is not much difference between the males and the females, and that both males and females are highly satisfied with the course. At issue here are dangers in combining categories (collapsing tables), and we advocate great caution in doing this. Sometimes it can provide greater clarity, and sometimes it can distort the picture. In the example it is wiser to keep with the original table rather than collapsing it into fewer categories.

Crosstabulations for categorical data can be bivariate (two variables presented), for example Table 40.9, in which two forms of primary students (Primary 3 and Primary 4) are asked how interesting they find a course. The rows are the nominal, categorical variable and the columns are the values of the ordinal variable. This is a commonplace organization.

Let us give another example. Suppose that we wished to examine the views of parents from socially advantaged and disadvantaged backgrounds of primary school children on traditional school examinations (in favour/against), using simple dichotomous variables (two values only in each variable). Table 40.10 presents the results. It shows us clearly that parents from socially advantaged backgrounds are more in favour of formal, written public examinations than those from socially disadvantaged backgrounds.

Additionally, a trivariate crosstabulation can be constructed (and SPSS enables researchers to do this), with three variables included. In the example here, let us say that we are interested in their socio-economic status (socially advantaged/socially disadvantaged) and their philosophies of education (traditionalist/child-centred). Our results appear in Table 40.11.

The results here are almost the reverse of Table 40.10: now the socially advantaged are more likely than socially disadvantaged parents to favour forms of assessment other than formal, written public examinations, and socially disadvantaged parents are more likely than socially advantaged parents to favour formal, written public examinations. The educational philosophies of each of the two groups (socially advantaged and socially disadvantaged) have dramatically altered the scenario. A trivariate analysis can give greater subtlety to the data and their analysis. (Introducing a third variable can be used as a control variable, and we address this in the discussion of correlations.)

Box 40.1 provides the SPSS command sequence for crosstabulations.

BOX 40.1 SPSS COMMAND SEQUENCE FOR CROSSTABULATIONS

The SPSS command sequence for Crosstabulations is: 'Analyze' → 'Descriptive Statistics' → 'Crosstabs' → Enter the row variable in the 'Rows' box and the column variable in the 'Columns' box → Click the 'Cells' box, which opens a new window → In the 'Percentages' area, check the 'Total' box' → Click 'Continue' → Click 'OK'.

40.3 Measures of central tendency and dispersal

Central tendency: means, modes and medians

The central tendency of a set of scores investigates how they cluster round the middle of the set of scores, or where the majority of scores are located. For categorical data the measure of central tendency is the mode: that score which is given by the most people, that score which has the highest frequency (there can be more than one mode: if there are two clear modal scores then this is termed 'bi-modal'; if there are three then this is termed 'tri-modal'). For continuous data (e.g. ratio data), in addition to the mode, the researcher can calculate the mean (the average score) and the median (the middle score, e.g. of the middle person): half of the scores fall above it and half below it (the median is also sometimes used for ordinal data). If there is an even number of observations then the median is the average of the two middle scores. We cannot calculate the median score for nominal data, as the data have to be rank-ordered from the lowest to the highest in terms of the quantity of the variable under discussion. Measures of central tendency are used with univariate data, and indicate the typical score (the mode), the middle score (the median) and the average score (the mean).

As a general rule, the mean is a useful statistic if the data are not skewed (i.e. if they are not bunched at one end of a curve of distribution or do not conform to the normal curve of distribution) or if there are no outliers that may be exerting a disproportionate effect (including a high standard deviation, see below). One has to recall that the mean, as a statistical calculation only, can sometimes yield some strange results, for example fractions of a person!

The median is useful for ordinal data, but, to be meaningful, there have to be many scores rather than just a few. The median overcomes the problem of outliers, and hence is useful for skewed results or those with a wide dispersal (i.e. high standard deviation). The modal score is useful for all scales of data, particularly nominal and ordinal data, i.e. discrete and categorical data, rather than continuous data, and it is unaffected by outliers, though it is not strong if there are many values and many scores which occur with similar frequency.

The standard deviation

Are scores widely dispersed around the mean, do they cluster close to the mean, or are they at some distance from the mean? The measures used to determine this are measures of dispersal. If we have interval and ratio data then, in addition to the modal score and crosstabulations, we can calculate the mean (the average) and the standard deviation. The standard deviation is the average distance that each score is from the mean, i.e. the average difference between each score and the mean, and how much the scores, as a group, deviate from the mean. It is a standardized measure of dispersal. For small samples (fewer than thirty scores), or for samples rather than populations, it is calculated as:

$$SD = \sqrt{\frac{\sum d^2}{N-1}}$$

where

d^2 = the deviation of the score from the mean (average), squared

$\sum$ = the sum of

N = the number of cases

For populations rather than samples, it is calculated as:

$$SD = \sqrt{\frac{\sum d^2}{N}}$$

A low standard deviation indicates that the scores cluster together, whilst a high standard deviation indicates that the scores are widely dispersed. This is calculated automatically by software packages such as SPSS, at the click of a single button.

Let us imagine that we have the test scores for 1,000 students, on a test that was marked out of 10

TABLE 40.12 DISTRIBUTION OF TEST SCORES (SPSS OUTPUT)

Test scores

(Table 40.12). Here we can calculate that the average score was 5.48. We can also calculate the standard deviation. In the example here the standard deviation in the example of scores was 2.134. What do these tell us? Firstly, it suggests that the average mark was not very high (5.48). Secondly, it tells us that there was quite a variation in the scores. Thirdly, the scores were unevenly spread, indeed there was a large cluster of scores around the categories of 3 and 4, and another large cluster of scores around the categories 7 and 8. This is where a line graph could be useful in representing the scores, as it shows two peaks clearly, as shown in Figure 40.4.

It is important to report the standard deviation. For example, let us consider the following. Look at these three sets of numbers:

(1)	1	2	3	4	20	mean = 6
(2)	1	2	6	10	11	mean = 6
(3)	5	6	6	6	7	mean = 6

If we were to plot the points in (1), (2) and (3) onto three separate graphs we would see very different results (Figures 40.5–40.7). Figure 40.5 shows the mean being heavily affected by the single score of 20 (an 'outlier': an extreme score a long way from the others); in fact all the other four scores are some distance below the mean. The score of 20 is exerting a disproportionate effect on the data and on the mean, raising it. Some statistical packages (e.g. SPSS) can exclude outliers. If the data are widely spread then it may be more suitable not to use the median score; SPSS performs this automatically at the click of a key.

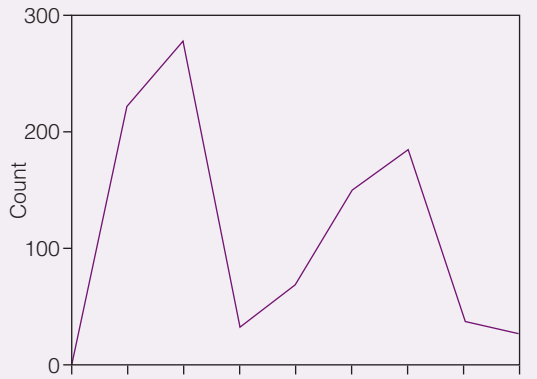

FIGURE 40.4 A line graph of test scores

Figure 40.6 shows one score actually on the mean but the remainder some distance away from it. The scores are widely dispersed and the shape of the graph is flat (a platykurtic distribution).

Figure 40.7 shows the scores clustering very tightly around the mean, with a very peaked shape to the graph (a leptokurtic distribution).

The point is this: it is not enough simply to calculate and report the mean; for a fuller picture of the data we need to look at the dispersal of scores. For this we can use the standard deviation, though the standard deviation is susceptible to the disproportionate effects of outliers. Some scores will be widely dispersed (the first graph), others will be evenly dispersed (the second graph) and others will be bunched together (the third graph). A high standard deviation will indicate a wide dispersal of scores, a low standard deviation will indicate clustering or bunching together of scores.

The range

A second way of measuring dispersal is to calculate the range, which is the difference between the lowest (minimum) score and the highest (maximum) score in a set of scores. This incorporates extreme scores, and is susceptible to the distorting effect of outliers: a wide range may be found if there are outliers, and if these outliers are removed then the range may be much reduced. Further, the range tells the researcher nothing about the distributions of scores within the range.

The interquartile range

Another measure of dispersal is the interquartile range. If we arrange a set of scores in order, from the lowest to the highest, then we can divide that set of scores into four equal parts: the lowest quarter (quartile) that contains the lowest quarter of all the scores, the lower-middle quartile, the upper-middle quartile, and the highest quarter (quartile) that contains the highest quarter of the scores. The interquartile range is the difference between the first quartile and the third quartile, or more precisely the difference between the 25th and the 75th percentile, i.e. the middle 50 per cent of scores (the second and third quartiles). This, thereby, ignores extreme scores and, unlike the simple range, does not change significantly if the researcher adds some scores that are some distance away from the average. For example, let us imagine that we have a set of test scores thus, ordered into quartiles:

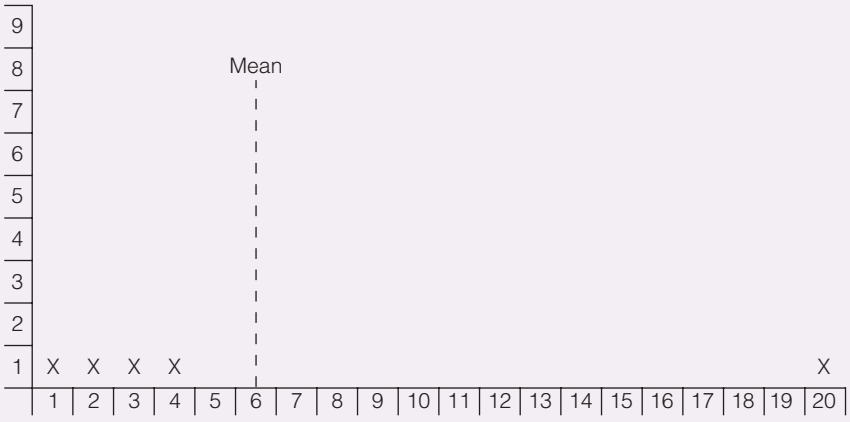

FIGURE 40.5 Distribution around a mean with an outlier

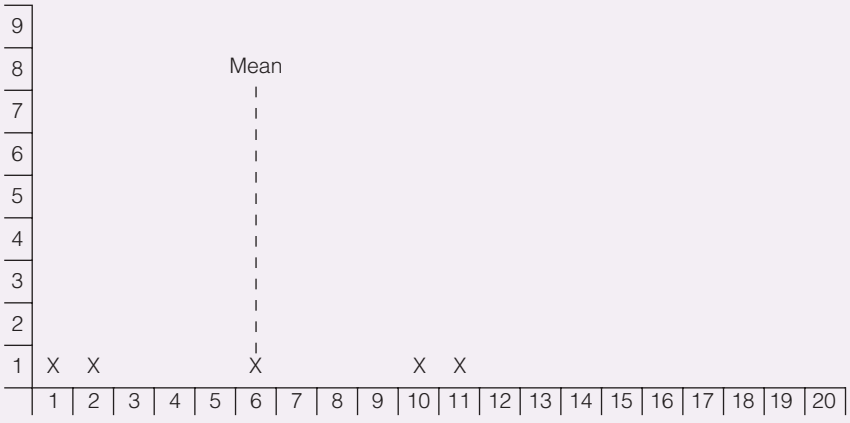

FIGURE 40.6 A platykurtic distribution of scores

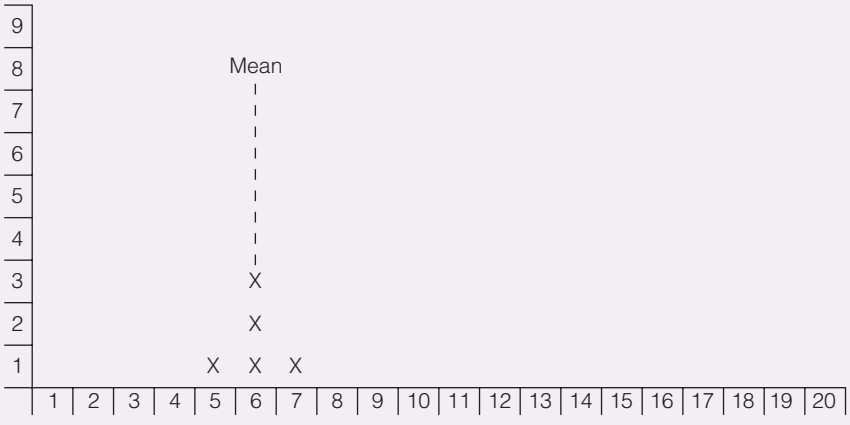

FIGURE 40.7 A leptokurtic distribution of scores

FIRST QUARTILE	*SECOND QUARTILE*	*THIRD QUARTILE*	*FOURTH QUARTILE*
40	50	**65**	83
41	55	70	86
43	58	75	90
47	63	77	93

The interquartile range is 47–65 (emboldened figures), which is 18. There are other ways of calculating the interquartile range (e.g. the difference between the medians of the first and third quartiles, the difference between the median of the lower half of the data and the median of the upper half of the data), and the reader may wish to explore these.

Though there are several ways of calculating dispersal, by far the most common is the standard deviation.

The SPSS command sequence for frequencies, standard deviations, Standard Error, skewness and kurtosis, range, means, modes and median is provided in Box 40.2.

40.4 Taking stock

What we do with simple frequencies and descriptive data depends on the scales of data that we have (nominal, ordinal, interval and ratio) (NB interval and ratio data are combined as 'scale' data in SPSS). For all four scales we can calculate frequencies and percentages, and present these in a variety of forms. We can also calculate the mode and present crosstabulations, both bivariate and trivariate crosstabulations. We can combine categories and collapse tables into smaller tables, providing that the sensitivity of the original data has not been unfairly lost. We can calculate the median score, which is particularly useful if the data are spread widely (with high standard deviations) or if there are outliers. For interval and ratio data we can also calculate the mean and the standard deviation; the mean yields an average and the standard deviation indicates the range of dispersal of scores around that average, i.e. to see whether the data are widely dispersed (e.g. a platykurtic distribution), or close together with a distinct peak (a leptokurtic distribution). We can use other measures of dispersal such as the range and the interquartile range. In examining frequencies and percentages, researchers can investigate whether the data are skewed, i.e. over-represented at one end of a scale and under-represented at the other end. A positive skew has a long tail at the positive end and the majority of the data at the negative end, and a negative skew has a long tail at the negative end and the majority of the data at the positive end.

40.5 Correlations and measures of association

Much educational research is concerned with establishing relationships between variables. We may wish to know, for example, how achievement is related to social class background; whether an association exists between the number of years spent in full-time education and subsequent income; whether there is a link between personality and achievement. What, for example, is the relationship, if any, between membership of a public library and social class status? Is there a relationship between social class background and placement in different strata of the secondary school curriculum, or between gender and success/failure in 'first-time' driving test results?

There are several simple measures of association readily available to researchers to help them test these sorts of relationships. We have selected the most widely used ones and set them out in Table 40.13. Of these, the two most commonly used correlations are the Spearman rank order correlation for ordinal data and the Pearson product moment correlation for interval and ratio data, and we advise readers to use these as the main kinds of correlation statistics. At this point it is pertinent to say a few words about some of the terms used in Table 40.13 to describe the nature of variables. Cohen and Holliday (1982, 1996) provide worked examples of the appropriate use and limitations of the

BOX 40.2 SPSS COMMAND SEQUENCE FOR DESCRIPTIVE STATISTICS

The SPSS command sequence for frequencies, standard deviations, Standard Error, skewness and kurtosis, range, means, modes and median is: 'Analyze' → 'Descriptive Statistics' → 'Frequencies' → Send over to the 'Variables' box the variables in which you are interested → Click the 'Statistics' box which will open a new window → Check the measures of central tendency which you wish to calculate (mean, mode, median). Check the measures of dispersion which you wish to calculate (standard deviation, variance, range, maximum, minimum, Standard Error of the mean). Check the measures of distribution which you wish to calculate (skewness, kurtosis) → Click 'Continue' → Click the 'Charts' box → Check the kind of chart which you wish to have (histogram, pie, bar) and the chart values (frequencies, percentages) → Click 'Continue' → Click 'OK'.

TABLE 40.13 COMMON MEASURES OF RELATIONSHIP

Measure	*Nature of variables*	*Comment*
Spearman's rho	Two ordinal variables	Relationship linear
Pearson product moment, *r*	Two continuous variables; interval or ratio scale	Relationship linear
Rank order or Kendall's tau	Two continuous variables; ordinal scale	
Correlation ratio, η (eta)	One variable continuous, other either continuous or discrete	Relationship non-linear
Intraclass	One variable continuous; other discrete; interval or ratio scale	Purpose: to determine within-group similarity
Biserial, r_{bis} Point biserial, $r_{pt\ bis}$	One variable continuous; other (a) continuous but dichotomized. r_{bis} or (b) true dichotomy, $r_{pt\ bis}$	Index of item discrimination (used in item analysis)
Phi coefficient, φ	Two true dichotomies; nominal or ordinal series	
Partial correlation $r_{12.3}$	Three or more continuous variables	Purpose: to determine relationship between two variables, with effect of third held constant
Multiple correlation $r_{1.234}$	Three or more continuous variables	Purpose: to predict one variable from a linear weighted combination of two or more independent variables
Kendall's coefficient of concordance (W)	Three or more continuous variables; ordinal series	Purpose: to determine the degree of (say, inter-rater) agreement

Source: Mouly (1978)

correlational techniques outlined in Table 40.13, together with other measures of association such as Kruskal's *gamma*, Somer's *d* and Guttman's *lambda*.

Look at the words used at the top of the table to explain the nature of variables in connection with the measure called the Pearson product moment, *r*. The variables are 'continuous' and at the 'interval' or the 'ratio' scale of measurement. A continuous variable is one that, theoretically at least, can take any value between two points on a scale. Weight, for example, is a continuous variable; so too is time, so also is height. Weight, time and height can take on any number of possible values between nought and infinity, the feasibility of measuring them across such a range being limited only by the variability of suitable measuring instruments.

Turning again to Table 40.13, we read in connection with the third measure shown there (rank order or Kendall's *tau*) that the two continuous variables are at the ordinal scale of measurement.

The variables involved in connection with the *phi* coefficient measure of association in Table 40.13 are described as 'true dichotomies' and at the nominal scale of measurement. Truly dichotomous variables (such as sex or driving test result) can take only two values (male or female; pass or fail).

To conclude our explanation of terminology, readers should note the use of the term 'discrete variable' in the description of the fourth correlation ratio (*eta*) in Table 40.13. We said earlier that a continuous variable can take on any value between two points on a scale. A discrete variable, however, can only take on numerals or values that are specific points on a scale. The number of players in a football team is a discrete variable. It is usually eleven; it could be fewer than eleven, but it could never be seven-and-a-quarter!

Box 40.3 provides the SPSS command sequence for correlations.

BOX 40.3 SPSS COMMAND SEQUENCE FOR CORRELATIONS

In SPSS the command sequence for correlations is: 'Analyze' → 'Correlate' → 'Bivariate' → Send to the box marked 'Variables' the variables which you wish to correlate. Check the box with the correlation statistic which you wish to calculate (Pearson, Spearman). Check the radio button for the test of significance (one-tailed, two-tailed) → Click 'OK'.

The percentage difference

The percentage difference is a simple asymmetric measure of association. An *asymmetric* measure is a measure of *one-way association*, that is to say, it estimates the extent to which one phenomenon implies the other but not *vice versa*. Gender, as we shall see shortly, may imply driving test success or failure. The association could never be the other way round. Measures which are concerned with the extent to which two phenomena imply each other are referred to as *symmetric* measures. Table 40.14 reports the percentage of public library members by their social class origin. What can we discover from the data set out in Table 40.14? By comparing percentages in different columns of the same row, we can see that 49 per cent more middle class persons are members of public libraries than working-class persons. By comparing percentages in different rows of the same columns we can see that 72 per cent more middle class persons are members rather than non-members. The data suggest an association between the social class status of individuals and their membership of public libraries.

A second way of making use of the data in Table 40.14 involves the computing of a *percentage ratio* (%R). Look, for example, at the data in the second row of Table 40.14. By dividing 63 by 14 (%R=4.5) we can say that four-and-a-half times as many working-class persons are not members of public libraries as are middle-class persons.

The *percentage difference* ranges from 0 per cent when there is complete independence between two phenomena to 100 per cent when there is complete association in the direction being examined. It is straightforward to calculate and simple to understand. Notice, however, that the percentage difference as we have defined it can only be employed when there are only two categories in the variable along which we percentage and only two categories in the variable in which we compare. In SPSS, using the 'Crosstabs' command can yield percentages, and we indicate this in the website manual that accompanies this volume.

TABLE 40.14 PERCENTAGE OF PUBLIC LIBRARY MEMBERS BY THEIR SOCIAL CLASS ORIGIN

Public library membership	*Social class status*	
	Middle class	*Working class*
Member	86	37
Non-member	14	63
Total	100	100

In connection with this issue, on the accompanying website we discuss the *phi* coefficient, the correlation coefficient tetrachoric r (r_t), the contingency coefficient C and combining independent significance tests of partial relations.

Explaining correlations

In our discussion of the principal correlational techniques shown in Table 40.13, three are of special interest to us and these form the basis of much of the rest of the chapter. They are the Pearson product moment correlation coefficient, multiple correlation and partial correlation.

Correlational techniques are generally intended to answer three questions about two variables or two sets of data. First, 'Is there a relationship between the two variables (or sets of data)?' If the answer to this question is 'yes', then two other questions follow: 'What is the direction of the relationship?' and 'What is the magnitude of the association?'

Relationship in this context refers to any tendency for the two variables (or sets of data) to vary consistently. Pearson's product moment coefficient of correlation, one of the best-known measures of association, is a statistical value ranging from –1.0 to +1.0 and expresses this relationship in quantitative form. The coefficient is represented by the symbol *r*.

Where the two variables (or sets of data) fluctuate in the same direction, i.e. as one increases so does the other, or as one decreases so does the other, a positive relationship is said to exist. Correlations reflecting this pattern are prefaced with a plus sign to indicate the positive nature of the relationship. Thus +1.0 indicates perfect positive correlation between two factors, as with the radius and diameter of a circle, and +0.80 a high positive correlation, as between academic achievement and intelligence, for example. Where the sign has been omitted, a plus sign is assumed.

A negative correlation or relationship, on the other hand, is found when an increase in one variable is accompanied by a decrease in the other variable. Negative correlations are prefaced with a minus sign. Thus –1.0 would represent perfect negative correlation, as between the number of errors children make on a spelling test and their score on the test, and –0.30 a low negative correlation, as, say, between absenteeism and intelligence. There is no other meaning to the signs used; they indicate nothing more than which pattern holds for any two variables (or sets of data).

Researchers are interested in the magnitude of an obtained correlation as well as in its direction.

Correlational procedures have been developed so that no relationship whatever between two variables is represented by zero (or 0.00), as between body weight and intelligence, possibly. This means that a person's performance on one variable is totally unrelated to her performance on a second variable. If she is high on one, for example, she is just as likely to be high or low on the other. Perfect correlations of +1.00 or –1.00 are rarely found and, as we shall see, most coefficients of correlation in social research are around +0.50 or less. The correlation coefficient may be seen, then, as an indication of the predictability of one variable given the other: it is an indication of covariation. The relationship between two variables can be examined visually by plotting the paired measurements on a graph, with each pair of observations being represented by a point. The resulting arrangement of points is a 'scatterplot' and enables us to assess graphically the degree of relationship between the characteristics being measured (see Figure 40.3). Figure 40.8 gives some examples of scatterplots in educational research.

Whilst correlations are widely used in research, and they are straightforward to calculate and to interpret, the researcher must be aware of four caveats in undertaking correlational analysis:

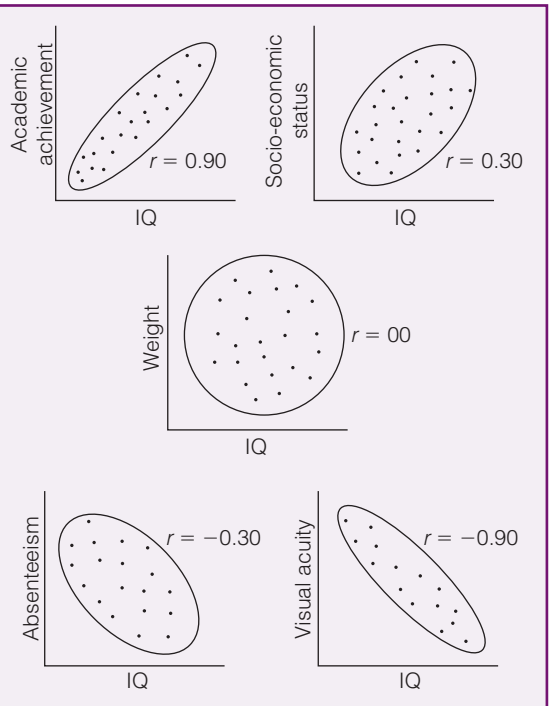

FIGURE 40.8 Correlation scatterplots
Source: Tuckman (1972)

i Do not assume that correlations imply causal relationships (i.e. simply because having large hands appears to correlate with having large feet does not imply that having large hands causes one to have large feet).
ii Be alert to a Type I error: not supporting the null hypothesis when it is in fact true (a false positive).
iii Be alert to a Type II error: supporting the null hypothesis when it is in fact not true (a false negative).
iv Given the problems of statistical significance set out in Chapter 39, it must be accompanied by an indication of effect size (the coefficient of correlation).

In SPSS a typical print-out of a correlation coefficient is given in Table 40.15. In this fictitious example, using 1,000 cases, there are four points to note:

i The cells of data to the right of the cells containing the figure 1 are the same as the cells to the left of the cells containing the figure 1, i.e. there is a mirror image and researchers can decide whether to look at only the variables to the right of the cell with the figure 1 (the perfect correlation, since it is one variable being correlated with itself), or to look at the cells to the left of the figure 1.
ii In each cell where one variable is correlated with a different variable there are three figures: the top figure gives the correlation coefficient, the middle figure gives the significance level and the lowest figure gives the sample size.
iii SPSS marks with an asterisk those correlations which are statistically significant.
iv All the correlations are positive, since there are no negative coefficients given.

These tables give us the magnitude of the correlation (the coefficient), the direction of the correlation (positive and negative) and the significance level. The correlation coefficient is the effect size. The significance level is calculated automatically by SPSS, based on the coefficient and the sample size: the greater the sample size, the lower the coefficient of correlation has to be in order to be statistically significant, and, by contrast, the smaller the sample size, the greater the coefficient of correlation has to be in order to be statistically significant (see also Chapter 39).

In reporting correlations one has to report the statistic used, the coefficient, the direction of the correlation (positive or negative) and the significance level (if considered appropriate). For example, one could write:

TABLE 40.15 A PEARSON PRODUCT MOMENT CORRELATION (SPSS OUTPUT)

		The attention given to teaching and learning at the school	How well students apply themselves to learning	Discussion and review by educators of the quality of teaching, learning and classroom practice
The attention given to teaching and learning at the school	Pearson Correlation	1	.060	.066*
	Sig. (2-tailed)	.	.058	.036
	N	1000	1000	1000
How well students apply themselves to learning	Pearson Correlation	.060	1	.585**
	Sig. (2-tailed)	.058	.	.000
	N	1000	1000	1000
Discussion and review by educators of the quality of teaching, learning and classroom practice	Pearson Correlation	.066*	.585**	1
	Sig. (2-tailed)	.036	.000	.
	N	1000	1000	1000

*. Correlation is significant at the 0.05 level (2-tailed).

**. Correlation is significant at the 0.01 level (2-tailed).

> Using the Pearson product moment correlation, a large effect size (correlation coefficient $r=0.87$) and a statistically significant correlation ($\rho=0.035$) were found between students' attendance at school and their examination performance. Those students who attended school the most tended to have the best examination performance, and those who attended the least tended to have the lowest examination performance.

Alternatively, there may be occasions when it is important to report when a correlation has *not* been found, for example:

> There was a very small effect size (correlation coefficient $r=0.16$) and no statistically significant correlation found ($\rho=0.43$) between the amount of time spent on homework and examination performance.

In both of these examples of reporting, exact significance levels have been given, assuming that SPSS has calculated these. An alternative way of reporting the significance levels (if appropriate) are: $\rho < 0.05$; $\rho < 0.01$; $\rho < 0.001$; $\rho=0.05$; $\rho=0.01$, $\rho=0.001$. In the case of statistical significance not having been found one could report this as $\rho > 0.05$ or $\rho=$N.S. (not significant).

Curvilinearity

The correlations discussed so far have assumed linearity, that is, the more we have of one property, the more (or less) we have of another property, in a direct positive or negative relationship. A straight line can be drawn through the points on the scatterplots (a line of best fit). However, linearity cannot always be assumed. Consider the case, for example, of stress: a little stress might enhance performance positively ('setting the adrenalin running'), whereas too much stress might lead to a downturn in performance. Where stress enhances performance there is a positive correlation, but when stress debilitates performance there is a negative correlation. The result is not a straight line of correlation (indicating linearity) but a curved line (indicating curvilinearity). This can be shown graphically (Figure 40.9). It is assumed here, for the purposes of the example, that muscular strength can be measured on a single scale. It is clear from the graph

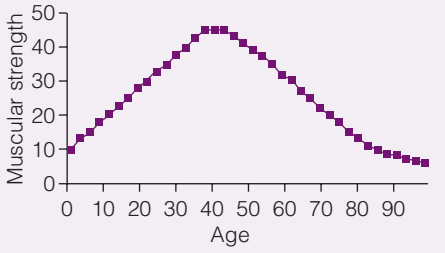

FIGURE 40.9 A line diagram to indicate curvilinearity

that muscular strength increases from birth until fifty years, and thereafter it declines as muscles degenerate. There is a positive correlation between age and muscular strength on the left-hand side of the graph and a negative correlation on the right-hand side of the graph, i.e. a curvilinear correlation can be observed.

Hopkins *et al*. (1996, p. 92) provide another example of curvilinearity: room temperature and comfort. Raising the temperature a little can make for greater comfort – a positive correlation – whilst raising it too greatly can make for discomfort: a negative correlation. Many correlational statistics assume linearity (e.g. the Pearson product moment correlation). However, rather than using correlational statistics arbitrarily or blindly, the researcher will need to consider whether, in fact, linearity is a reasonable assumption to make, or whether a curvilinear relationship is more appropriate (in which case more sophisticated statistics will be needed, e.g. η (*eta*)) (Glass and Hopkins, 1996, section 8.7; Cohen and Holliday, 1996, p. 84; Fowler *et al*., 2000) or mathematical procedures will need to be applied to transform non-linear relations into linear relations. Examples of curvilinear relationships might include:

- pressure from the principal and teacher performance;
- pressure from the teacher and student achievement;
- degree of challenge and student achievement;
- assertiveness and success;
- age and muscular strength;
- age and physical control;
- age and concentration;
- age and sociability;
- age and cognitive abilities.

Hopkins *et al*. (1996, p. 92) suggest that poorly constructed tests can give the appearance of curvilinearity if the test is too easy (a 'ceiling effect' where most students score highly) or if it is too difficult, but that this curvilinearity is, in fact, spurious, as the test does not demonstrate sufficient item difficulty or discriminability (see Chapter 27).

In planning correlational research, then, attention will need to be given to whether linearity or curvilinearity is to be assumed.

Coefficients of correlation

The coefficient of correlation tells us about the relations between two variables. Other measures exist, however, which allow us to specify relationships when more than two variables are involved. These are known as measures of 'multiple correlation' and 'partial correlation'.

Multiple correlation measures indicate the degree of association between three or more variables simultaneously. We may want to know, for example, the degree of association between delinquency, social class background and leisure facilities. Or we may be interested in finding out the relationship between academic achievement, intelligence and neuroticism. Multiple correlation, or 'regression' as it is sometimes called, indicates the degree of association between *n* variables. It is related not only to the correlations of the independent variable with the dependent variables, but also to the intercorrelations between the dependent variables.

Partial correlation aims at establishing the degree of association between two variables after the influence of a third has been controlled or partialled out. Guilford and Fruchter (1973) define a partial correlation between two variables as one which nullifies the effects of a third variable (or a number of variables) on the variables being correlated.

Consider, for example, the relationship between (a) success in basketball and (b) previous experience in the game. Suppose, also, that the presence of a third factor (c) – the height of the players – was known to have an important influence on the other two factors (a) and (b). The use of partial correlation techniques would enable a measure of the two primary variables (a) and (b) to be achieved, freed from the influence of the secondary variable (c).

Correlational analysis is simple and involves collecting two or more scores on the same group of subjects and computing correlation coefficients. Many useful studies have been based on this simple design. Those involving more complex relationships, however, utilize multiple and partial correlations in order to provide a clearer picture of the relationships being investigated.

One final point: it is important to stress again that correlations refer to measures of association and do not necessarily indicate causal relationships between variables. Correlation does not imply cause.

Interpreting the correlation coefficient

Once a correlation coefficient has been calculated, there remains the problem of interpreting it. A question often asked here is how large should the coefficient be for it to be meaningful. The question may be approached in three ways: by examining the strength of the relationship; by examining the square of the correlation coefficient; and, if the researcher adheres to the value of significance testing (see Chapter 39), by examining the statistical significance of the relationship (though significance testing does not indicate the magnitude of the correlation, only the likelihood of a chance relationship).

Inspection of the numerical value of a correlation coefficient yields clear indication of the strength of the relationship between the variables in question. Low or near zero values indicate weak relationships, while those nearer to +1 or –1 suggest stronger relationships. Imagine, for instance, that a measure of a teacher's success in the classroom after five years in the profession is correlated with her final school experience grade as a student and that it was found that $r=+0.19$. Suppose now that her score on classroom success is correlated with a measure of need for professional achievement and that this yielded a correlation of 0.65. It could be concluded that there is a stronger relationship between success and professional achievement scores than between success and final student grade.

Where a correlation coefficient has been derived from a sample and one wishes to use it as a basis for inference about the parent population, the statistical significance of the obtained correlation can be considered. Statistical significance, when applied to a correlation coefficient, indicates whether or not the correlation is different from zero at a given level of confidence. As we have seen earlier, a statistically significant correlation is indicative of an actual relationship rather than one due entirely to chance, even though its assumption of the null hypothesis is questionable (Chapter 39). The level of statistical significance of a correlation is determined to a great extent by the number of cases upon which the correlation is based: the greater the number of cases, the smaller the correlation need be to be statistically significant at a given level of confidence.

The second approach to interpreting a coefficient is provided by examining the square of the coefficient of correlation, r^2. This shows the proportion of variance in one variable that can be attributed to its linear relationship with the second variable. In other words, it indicates the amount the two variables have in common. If, for example, two variables A and B have a correlation of 0.50, then $(0.50)^2$ or 0.25 of the variation shown by the B scores can be attributed to the tendency of B to vary linearly with A. Figure 40.10 shows graphically the common variance between reading grade and arithmetic grade having a correlation of 0.65.

Third, many exploratory relationship studies are interpreted with reference to their statistical significance, whereas prediction studies depend for their efficacy on the strength of the correlation coefficients (the effect size). Here correlation coefficients need to be considerably higher than those found in exploratory relationship studies and for this reason rarely invoke the concept of statistical significance.

There are three cautions to be borne in mind when one is interpreting a correlation coefficient. First, a coefficient is a simple number and must not be interpreted as a percentage. A correlation of 0.50, for instance, does not mean a 50 per cent relationship between the variables. Further, a correlation of 0.50 does not indicate twice as much relationship as that shown by a correlation of 0.25. A correlation of 0.50 actually indicates more than twice the relationship shown by a correlation of 0.25. In fact, as coefficients approach +1 or –1, a difference in the absolute values of the coefficients becomes more important than the same numerical difference between lower correlations would be.

Second, a correlation does not necessarily imply a cause-and-effect relationship between two factors, as previously indicated. It should not therefore be interpreted as meaning that one factor is causing the scores on the other to be as they are. There are invariably other factors influencing both variables under consideration. Suspected cause-and-effect relationships would have to be confirmed by other kinds of study.

Third, a correlation coefficient is not to be interpreted in any absolute sense. A correlational value for a given sample of a population may not necessarily be the same as that found in another sample from the same

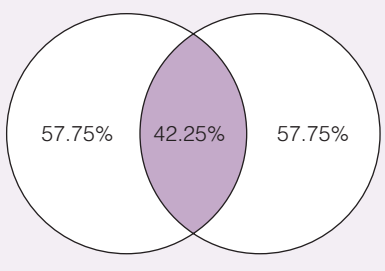

FIGURE 40.10 Visualization of correlation of 0.65 between reading grade and arithmetic grade

Source: Fox (1969)

population. Many factors influence the value of a given correlation coefficient and if researchers wish to extrapolate to the populations from which they drew their samples they will then have to consider testing the significance of the correlation or the sampling strategy used.

We now offer some general guidelines for interpreting correlation coefficients. They are based on Borg's (1963) analysis and assume that the correlations relate to 100 or more subjects.

Correlations ranging from 0.20 to 0.35

Correlations within this range show only very slight relationship between variables although they may be statistically significant. A correlation of 0.20 shows that only 4 per cent ($\{0.20 \times 0.20\} \times 100$) of the variance is common to the two measures. Whereas correlations at this level may have limited meaning in exploratory relationship research, they are of no value in either individual or group prediction studies.

Correlations ranging from 0.35 to 0.65

Within this range, correlations are statistically significant beyond the 1 per cent level. When correlations are around 0.40, crude group prediction may be possible. As Borg notes, correlations within this range are useful, however, when combined with other correlations in a multiple regression equation. Combining several correlations in this range in some cases can yield individual predictions that are correct within an acceptable margin of error. Correlations at this level used singly are of little use for individual prediction because they yield only a few more correct predictions than could be accomplished by guessing or by using some chance selection procedure.

Correlations ranging from 0.65 to 0.85

Correlations within this range make possible group predictions that are accurate enough for most purposes. Nearer the top of the range, group predictions can be made very accurately, usually predicting the proportion of successful candidates in selection problems within a very small margin of error. Near the top of this correlation range, individual predictions can be made that are considerably more accurate than would occur if no such selection procedures were used.

Correlations over 0.85

Correlations as high as this indicate a close relationship between the two variables correlated. A correlation of 0.85 indicates that the measure used for prediction has about 72 per cent variance in common with the performance being predicted. Prediction studies in education very rarely yield correlations this high. When correlations at this level are obtained, however, they are very useful for either individual or group prediction.

40.6 Partial correlations

Many researchers wish to control for the effects of other variables. As we discussed in Chapter 6, controlling for the effects of variables means holding them constant whilst manipulating other variables. Let us imagine that we examine the scores of 500 students on a mathematics test to see if there is any relationship between their test scores (marks out of 100) and how easy they find mathematics (scored out of 100). We conduct a Pearson correlation and find a large positive correlation (correlation coefficient of 0.738, indicated in Table 40.16), which is statistically significant $\rho = 0.000$.

However, we want to know if this positive correlation holds true when other variables are controlled, in this case the variable 'how interested are you in mathematics?' (Table 40.17), so we conduct a partial correlation. Partial correlations enable the researcher to control for a third variable, i.e. to see the correlation between two variables of interest once the effects of a third variable have been removed, hence rendering more accurate the relationship between the two variables of interest. Indeed SPSS will enable more than one control variable to be inserted. Partialling can rule out special or specific relationships that do not hold true when variables have been controlled. Using SPSS, partial correlations can be calculated straightforwardly at the touch of a key.

In our example we have 'mathematics test score', 'how easy do you find mathematics?', and, as the control variable, 'how interested are you in mathematics?'. This time we see that, from the SPSS output in Table 40.17, when we control for the third variable ('how interested are you in mathematics?'), the correlation coefficient between 'mathematics test score' and 'how easy do you find mathematics?' drops massively from 0.738 to 0.071, an extremely low correlation or no real correlation at all, which, this time, is not statistically significant ($\rho = 0.112$). In other words, when we control for the third variable, the degree of association between the two initial variables reduces; the third variable exerts a considerable effect on the strength of the relationship between the initial two variables.

Imagine, this time, that instead of controlling for 'how interested are you in mathematics?' we control for a different third variable: 'how much do you like mathematics?' (Table 40.18). This time the correlation coefficient between the original two variables 'mathematics test score' and 'how easy do you find

TABLE 40.16 CORRELATION BETWEEN SCORE ON MATHEMATICS TEST AND HOW EASY THE STUDENTS FIND MATHEMATICS (SPSS OUTPUT)

Correlations

		Mathematics test score	How easy do you find mathematics?
Mathematics test score	Pearson Correlation Sig. (2-tailed) N	1 500	0.738** 0.000 500
How easy do you find mathematics?	Pearson Correlation Sig. (2-tailed) N	0.738** 500	1 500

Note
** Correlation is significant at the 0.01 level (2-tailed).

	How easy do you find mathematics?	Correlation Significance (2-tailed) df	0.071 0.112 497	1.000 0

TABLE 40.18 CORRELATION BETWEEN SCORE ON MATHEMATICS TEST AND HOW EASY THE STUDENTS FIND MATHEMATICS, CONTROLLING FOR STUDENTS' LIKING OF MATHEMATICS (SPSS OUTPUT)

Correlations

Control variables			Mathematics test score	How easy do you find mathematics?
How much do you like mathematics?	Mathmatics test score	Correlation Significance (2-tailed) df	1.000 0	0.711 0.000 497
	How easy do you find mathematics?	Correlation Significance (2-tailed) df	0.711 0.000 497	1.000 0

mathematics?' has changed only a very small amount, from 0.738 to 0.711, and is still statistically significant ($\rho = 0.000$). Here the third variable has made almost no difference to the strength of the correlation between the two original variables, i.e. controlling for 'how much do you like mathematics?' has had very little effect on the strength of the relationship between the two original variables.

Partial correlation, then, enables relationships to be calculated after controlling for one or more variables.

In SPSS the command sequence for partial correlations is provided in Box 40.4.

40.7 Reliability

Correlation can be used in reliability testing. We need to know how reliable the items in our instrument are for data collection. Reliability in quantitative analysis takes two main forms, both of which are measures of internal consistency: the split-half technique and the alpha coefficient. Both calculate a coefficient of reliability that can lie between 0 and 1. The formula for calculating the Spearman-Brown split-half reliability (discussed in Chapter 14) is:

$$r = \frac{2r}{1+r}$$

where r = the actual correlation between the halves of the instrument (this requires the instrument to be able to be divided into two matched halves in terms of content and difficulty). So, for example, if the correlation coefficient between the two halves is 0.85 then the formula would be worked out thus:

$$r = \frac{2(0.85)}{1+0.85} = \frac{1.70}{1.85} = 0.919$$

Here the split-half reliability coefficient is 0.919, which is very high. SPSS automatically calculates split-half reliability at the click of a button.

An alternative calculation of reliability as internal consistency can be found in Cronbach's alpha, frequently referred to simply as the alpha coefficient of reliability. The Cronbach alpha provides a coefficient of inter-item correlations by calculating the average of all possible split-half reliability coefficients. It is a measure of the internal consistency among the *items* (not the people/cases) and is used for multi-item scales. SPSS calculates Cronbach's alpha at the click of a key. The formula for alpha is:

$$alpha = \frac{nr_{ii}}{1+(n-1)r_{ii}}$$

where n = the number of items in the test or survey (e.g. questionnaire) and r_{ii} = the average of all the inter-item correlations. Let us imagine that the number of items in the survey is 10, and that the average correlation is 0.738. The alpha correlation can be calculated thus:

$$alpha = \frac{nr_{ii}}{1+(n-1)r_{ii}} = \frac{10(0.738)}{1+(10-1)0.739} = \frac{7.38}{7.64} = 0.97$$

This yields an alpha coefficient of 0.97, which is very high. For the split-half coefficient and the alpha coefficient the following guidelines can be used:

>0.90 very highly reliable
0.80–0.90 highly reliable
0.70–0.79 reliable
0.60–0.69 marginally/minimally reliable
<0.60 unacceptably low reliability

Bryman and Cramer (1990, p. 71) suggest that the reliability level is acceptable at 0.8, though others suggest that it is acceptable if it is 0.67 or above.

If the researcher is using SPSS then there is a function which enables items to be discovered that might be exerting a negative influence on the Cronbach alpha. Table 40.19 provides an example of this, which indicates in the final column what the Cronbach alpha would be if any of the items were to be removed as being unreliable.

In the example, the overall alpha is given as 0.642, but it can be seen that if the item 'How much do you

BOX 40.4 SPSS COMMAND SEQUENCE FOR PARTIAL CORRELATIONS

In SPSS the command sequence for partial correlations is: 'Analyze' → 'Correlate' → 'Partial' → Send to the box marked 'Variables' the variables which you wish to correlate. Send to the box marked 'Controlling for' the control variable(s) that you wish to include. Check the radio button for the test of significance (one-tailed, two-tailed) → Click 'OK'.

feel that you treat colleagues as impersonal objects?' were removed, then the overall reliability would rise to 0.658. The researcher, then, may wish to remove that item; this is particularly true where the researcher is conducting a pilot to see which items are reliable and which are not.

In SPSS the command sequence for the Cronbach alpha is provided in Box 40.5.

TABLE 40.19 IDENTIFYING UNRELIABLE ITEMS IN CRONBACH'S ALPHA (SPSS OUTPUT)

Item-Total Statistics

	Scale Mean if Item Deleted	Scale Variance if Item Deleted	Corrected Item-Total Correlation	Cronbach's Alpha if Item Deleted
How hard do you feel you are working in your job?	17.71	51.379	.272	.642
How much do you feel exhausted by the end of the workday?	17.99	43.902	.472	.553
How much do you feel that you cannot cope with your job any longer?	21.02	38.863	.567	.495
How much do you feel that you treat colleagues as impersonal objects?	23.52	50.959	.242	.658
How much do you feel that working with colleagues all day is really a strain for you?	22.08	43.084	.436	.569

Overall alpha: .642

BOX 40.5 SPSS COMMAND SEQUENCE FOR RELIABILITY CALCULATION

In SPSS the command sequence for the Cronbach alpha is: 'Analyze' → 'Scale' → 'Reliability Analysis' → Send to the box marked 'Items' the variables which you wish to include → Click the box marked 'Statistics'. This opens a new window. In the area marked 'Descriptives for', check the box marked 'Scale if item deleted' → Click 'Continue' → Click 'OK'.

Companion Website

The companion website to the book provides additional material, data files and PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Inferential statistics

CHAPTER 41

Difference tests

The previous chapter introduced descriptive statistics. This chapter moves to inferential statistics, those statistics that enable researchers to make inferences about the wider population. Here we introduce difference tests and how they can be conducted. The chapter proceeds thus:

- measures of difference between groups
- the t-test (a test of difference for parametric data)
- Analysis of Variance (a test of difference for parametric data)
- the chi-square test for non-parametric data (a test of difference and a test of goodness of fit)
- degrees of freedom (a statistic that is used in calculating statistical significance in considering difference tests)
- the Mann-Whitney and Wilcoxon tests (tests of difference for non-parametric data)
- the Kruskal-Wallis and Friedman tests (tests of difference for non-parametric data)

These statistics constitute powerful tools in the arsenal of statistics for analysing numerical data. We give several worked examples for clarification, and take the novice reader by the hand through these.

41.1 Measures of difference between groups

Researchers will sometimes be interested to investigate whether there are differences between two or more groups of sub-samples, answering questions such as: 'Is there a statistically significant difference between the amount of homework done by boys and girls, and if so, how much?'; 'Is there a statistically significant difference between test scores from four similarly mixed-ability classes studying the same syllabus, and if so, how much?'; 'Does school A differ statistically significantly from school B in the stress level of its sixth form students, and if so, by how much?'. Such questions require measures of difference. This section introduces measures of difference and how to calculate difference. The process can commence with the null hypothesis, stating that 'there is no statistically significant difference between the two groups', or 'there is no statistically significant difference between the four groups', and, if this is not supported, then the alternative hypothesis is supported, namely, there is a statistically significant difference between the two (or more) groups'. Then it can proceed to tests of magnitude of difference (effect size). We discuss difference tests for parametric and non-parametric data. We discussed statistical significance and its limitations in Chapter 39, and we suggested very strongly that it should be accompanied by measures of effect size. Statistical significance suggests whether a result occurs by chance (though, as Chapter 39 suggests, this is, in fact, open to question), whilst effect size calculates how much of a difference there is.

Before going very far one has to ascertain:

- the kind of data with which one is working (parametric or non-parametric), as this affects the choice of statistic used;
- the number of groups being compared (e.g. two or more groups), to discover whether there is a difference between them;
- whether the groups are related or independent. Independent groups are entirely unrelated to each other, for example, males and females completing an examination; related groups might be the same group voting on two or more variables or the same group voting at two different points in time (e.g. a pre-test and a post-test).

Statistics are usually divided into those which work with parametric or non-parametric data, those which measure differences between two groups and those which measure differences between more than two groups, and whether the groups are related or independent. Decisions on these matters affect the choice of statistics used. Our discussion proceeds thus: *first* we look at a simple difference test for two groups using parametric data, which is the t-test (Section 41.2). *Second* we look at differences between three or more groups using parametric data: Analysis of Variance (ANOVA)

with *post hoc* tests (the Tukey test and the Games-Howell test) (Section 41.3). *Third* we look at a test of difference for categorical data (the chi-square test) (Section 41.4). *Fourth*, we introduce the 'degrees of freedom' (Section 41.5). *Fifth* we look at differences between two groups using non-parametric data (the Mann-Whitney and Wilcoxon tests) (Section 41.6); *sixth* we look at differences between three or more groups using non-parametric data (the Kruskal-Wallis and the Friedman tests) (Section 41.7). As in previous examples, we use SPSS to illustrate our points.

41.2 The t-test

The t-test is used to discover whether there are statistically significant differences between the means of two groups or for the same group under two conditions, drawn from random samples with a normal distribution and using parametric data in the dependent variable. It is used to compare the means of two groups randomly assigned, for example on a pre-test and a post-test in an experiment, or for the same group under two conditions. The t-test operates under certain assumptions, which we list here as 'safety checks', i.e. to see if it is safe to proceed with the use of the test.

Safety checks for using the t-test

The t-test requires several 'safety checks':

- parametric continuous data with the dependent variable at interval or ratio level;
- random sampling;
- normal distribution of the data (though large samples often overcome this);
- equality of variance (similarity/equality of variance in each group: 'homogeneity of variance'), though the Levene test can overcome problems here, and SPSS calculates this automatically.

If these safety requirements are not met then the researcher should use a non-parametric difference test (e.g. Mann-Whitney U test; the Wilcoxon test), even if the data are interval or ratio.

Conducting the-test

The t-test has two variants: the t-test for independent samples and the t-test for related (or 'paired') samples. The former assumes that the two groups are unrelated to each other; the latter assumes that it is the *same*, single group either voting on two variables or voting at two different points in time about the same variable or under two conditions. We will address the t-test for independent samples first. The t-test assumes that one variable is categorical (e.g. males and females) and one is a continuous variable (e.g. marks on a test). The formula calculates a statistic based on:

$$t = \frac{\text{Sample one mean} - \text{sample two mean}}{\text{Standard error of the difference in means}}$$

Let us imagine that we wish to discover whether, concerning how well learners are cared for, guided and supported, there is a statistically significant difference between (a) the leader/senior management team (SMT) of a group of randomly chosen schools and (b) the teachers. The data are ratio; the participants have awarded a mark out of ten for their response; and the higher the mark, the greater the care, guidance and support offered to the students. The t-test for two independent samples presents us with two tables in SPSS. First it provides the average (mean) of the voting for each group: 8.37 for the leaders/senior managers and 8.07 for the teachers, i.e. there is a difference of means between the two groups. Is this difference statistically significant, i.e. by chance or otherwise? Is the null hypothesis ('there is no statistically significant difference between the leaders/SMT and the teachers') supported or not supported? We commence with the null hypothesis ('there is no statistically significant difference between the two means') and then we set the level of significance (α) to use for supporting or not supporting the null hypotheses; for example we could say 'Let $\alpha = 0.05$'. Then the data are computed as in Table 41.1.

In running the t-test, SPSS gives us back what, at first glance, seems to be a morass of information in Table 41.1. Some of this is superfluous for our purposes here. We will concern ourselves with the most important pieces of data for introductory purposes here: the Levene test and the significance level for a two-tailed test (Sig. (2-tailed)) (Table 41.2).

The Levene test is a guide as to which row of the two to use ('equal variances assumed' and 'Equal variances not assumed'). Look at the column 'Sig.' in the Levene test (0.004). If the probability value is statistically significant (as in this case: 0.004) then variances are *unequal* and the researcher needs to use the second row of data ('Equal variances not assumed'); if the probability value is not significant ($\rho > 0.05$) then equal variances *are* assumed and she/he uses the first row of data ('Equal variances assumed'). Once she/he has decided which row to use then the Levene test has served its purpose and the researcher can move on. For our commentary here, the purpose of the Levene test is only there to determine which row to look at of the two presented.

Having discovered which row to follow, in our example it is the second row, we go along to the

TABLE 41.1 MEANS AND STANDARD DEVIATIONS FOR A t-TEST (SPSS OUTPUT)

Group Statistics

	who are you	N	Mean	Std. Deviation	Std. Error Mean
How well learners are cared for, guided and supported	leader/member of the SMT	347	8.37	2.085	.112
	teachers	653	8.07	2.462	.096

TABLE 41.2 THE LEVENE TEST FOR EQUALITY OF VARIANCES IN A t-TEST (SPSS OUTPUT)

Independent Samples Test

		Levene's Test for Equality of Variances		t-test for Equality of Means						
									95% Confidence Interval of the Difference	
		F	Sig.	t	df	Sig. (2-tailed)	Mean Difference	Std. Error Difference	Lower	Upper
How well learners are cared for, guided and supported	Equal variances assumed	8.344	.004	1.92	998	.055	.30	.155	-.006	.603
	Equal variances not assumed			2.02	811.922	.044	.30	.148	.009	.589

column 'Sig. (2-tailed)'. This tells us that there is a statistically significant difference between the two groups – leaders/SMT and the teachers – because the significance level is 0.044 (i.e. $\rho < 0.05$). Hence we can say that the null hypothesis is not supported, that there is a statistically significant difference between the means of the two groups ($\rho = 0.044$), and that the mean of the leaders/SMT is statistically significantly higher (8.37) than the mean of the teachers (8.07), i.e. the leaders/SMT of the schools think more highly than the teachers in the schools that the learners are well cared for, guided and supported, and that this difference is not by chance.

Look at Table 41.2 again, and at the column 'Sig. (2-tailed)'. Had equal variances been assumed (i.e. if the Levene test had indicated that we should remain on the top row of data rather than the second row of data) then we would *not* have found a statistically significant difference between the two means ($\rho = 0.055$, i.e. $\rho > 0.05$). Hence it is sometimes important to know whether equal variances are to be assumed or not to be assumed.

In the example here we find that there *is* a statistically significant difference between the means of the two groups, i.e. the leaders/SMT do not share the same perception as the teachers that the learners are well cared for, guided and supported. Typically the leaders/SMT are more generous than the teachers, and this difference is not by chance. This is of research interest, for example, to discover the reasons for, and impact of, the differences of perception. It could be, for example, that the leaders/SMT have a much rosier picture of the situation than the teachers, and that the teachers – the ones who have to work with the students on a close daily basis – are more in touch with the students and know that there are problems, a matter to which the senior managers may be turning a blind eye.

In reporting the t-test here the following form of words can be used:

> The mean score of the leaders/SMT on the variable 'How well learners are cared for, guided and supported' ($M = 8.37$, $SD = 2.02$) is statistically significantly higher ($t = 1.92$, $df = 811.922$, two-tailed $\rho = 0.044$) than those of teachers on the same variable ($M = 8.07$, $SD = 2.462$).

In this example, significance testing suggests to the researcher whether or not the difference found is by chance alone; that's all. This may be of limited use to

the researcher who wants to know *how much* difference there is, and here we refer the reader to the tests of effect size addressed in Chapter 39, for example, Cohen's *d*. Effect size can be calculated straightforwardly with online calculators, and we indicate these in Chapter 39, alongside how to perform hand calculations of effect size.

Let us take a second example. Here the leaders/SMT and teachers are voting on 'the attention given to teaching and learning in the school', again awarding a mark out of ten, i.e. ratio data. The mean for the leaders/SMT is 5.53 and for the teachers it is 5.46. Are these means statistically significantly different (Tables 41.3 and 41.4) or is there a difference that is not due to chance alone?

If we examine the Levene test (Sig.) in Table 41.4 we find that equal variances *are* assumed ($\rho = 0.728$), i.e. we remain on the top row of the data output. Running along to the column headed 'Sig. (2-tailed)' we find that $\rho = 0.610$, i.e. there is no statistically significant difference between the means of the two groups, therefore the null hypothesis (there is no statistically significant difference between the means of the two groups) is supported. In other words, the difference between the means is by chance alone. This should not dismay the researcher; finding or *not* finding a statistically significant difference is of equal value in research: a win–win situation. Here, for example, one can say that there is a shared perception between the leaders/managers and the teachers on the attention given to teaching and learning in the school, even though the attention given is poor (means of 5.53 and 5.46 respectively). The fact that there is a shared perception – that both parties see the same problem in the same way – offers a positive prospect for development and a shared vision, i.e. even though the picture is poor, nevertheless it is perhaps more positive than if there were very widely different perceptions.

In reporting the t-test here the following form of words can be used:

> The mean score for the leaders/SMT on the variable 'the attention given to teaching and learning at the school' ($M = 5.53$, $SD = 2.114$) did not differ statistically significantly ($t = 0.510$, $df = 998$, two-tailed $\rho = 0.610$) from that of the teachers ($M = 5.46$, $SD = 2.145$).

In this example, too, significance testing suggests to the researcher whether or not the difference found is by

TABLE 41.3 A t-TEST FOR LEADERS AND TEACHERS (SPSS OUTPUT)

Group Statistics

	who are you	N	Mean	Std. Deviation	Std. Error Mean
The attention given to teaching and learning at the school	leader/member of the SMT	347	5.53	2.114	.113
	teachers	653	5.46	2.145	.084

TABLE 41.4 THE LEVENE TEST FOR EQUALITY OF VARIANCES BETWEEN LEADERS AND TEACHERS (SPSS OUTPUT)

Independent Samples Test

		Levene's Test for Equality of Variances		t-test for Equality of Means						
									95% Confidence Interval of the Difference	
		F	Sig.	t	df	Sig. (2-tailed)	Mean Difference	Std. Error Difference	Lower	Upper
The attention given to teaching and learning at the school	Equal variances assumed	.121	.728	.510	998	.610	.07	.142	-.206	.351
	Equal variances not assumed			.513	714.630	.608	.07	.141	-.205	.350

chance alone; that's all. This may be of limited use to the researcher who wants to know *how much* difference there is, and, as before, we refer the reader to the tests of effect size and how to calculate it, set out in Chapter 39.

The t-test for independent examples is a very widely used statistic, and we support its correct use very strongly.

The t-test can also be used for a paired (related) sample, i.e. where the same group votes on two variables (e.g. liking for mathematics and music), or the same *group* is measured on two occasions (e.g. the pre-test and the post-test) or under two conditions (e.g. morning and evening), or the same *variable* is measured at two points in time (pre-test and post-test). Here two variables are paired, with marks awarded by the same group (Table 41.5).

One can look to see if the mean of the 1,000 respondents who voted on 'the attention given to teaching and learning in the school' (mean = 5.48) is statistically significantly different from the mean of the same group voting on the variable 'the quality of the lesson preparation' (mean = 7.17) (Table 41.6).

In Table 41.6 we can move directly to the final column ('Sig. (2-tailed)') where we find that $\rho = 0.000$, i.e. $\rho < 0.001$, telling us that the null hypothesis is not supported, and that there is a statistically significant difference between the two means (i.e. the result is not by chance alone), even though it is the same group that is awarding the marks.

The issue of testing the difference between two proportions is set out on the accompanying website.

Box 41.1 provides the SPSS command sequence for the t-test for independent samples.

Box 41.2 provides the SPSS command sequence for the t-test for related (paired) samples.

To complement statistical significance in difference measurement, calculating effect size can be conducted using 'partial eta squared' and Cohen's *d*. (In SPSS the command sequence is: 'Analyze' → 'General Linear Model' → 'Univariate' → 'Estimates of effect size'.) Eta squared is also used, and is the proportion of the

TABLE 41.5 MEANS AND STANDARD DEVIATIONS IN A PAIRED SAMPLES t-TEST (SPSS OUTPUT)

BOX 41.1 SPSS COMMAND SEQUENCE FOR INDEPENDENT SAMPLES T-TEST

To run the t-test for independent samples in SPSS the command sequence is: 'Analyze' → 'Compare means' → 'Independent samples T Test' → Send the dependent variable to box 'Test variable' and the independent variable to the 'Grouping variable' box → Click 'Define groups' (which is activated when the 'Grouping variable' box contains the independent variable) and then type the number that you assigned to each of the two groups in the SPSS file (e.g. males '1' and females '2') → Click 'Continue' (which returns you to the original screen) → Click 'OK'.

BOX 41.2 SPSS COMMAND SEQUENCE FOR T-TEST FOR RELATED (PAIRED) SAMPLES

To run the t-test for related (paired) samples in SPSS it is important, first, for the researcher to define the single group to be observed under the two conditions. The single group might be, for example, only the males from a total sample of males and females. Here SPSS requires you to use the Select Cases function (the command sequence in SPSS is: 'Data' → 'Select Cases'). Then decide which radio button you wish to activate ('If the condition is satisfied'; 'random sample of cases'; 'Based on time or case range'; 'Use filter variable'); each of these open another box for further selection and instructions (cf. Pallant, 2016). Once you have selected the cases (NB if you do not use this function then the entire sample is used), the SPSS command sequence for the t-test is: 'Analyze' → 'Compare means' → 'Paired samples T Test' → Click the first variable in which you are interested and send it to the 'Variable 1' box, and then click the second variable in which you are interested and send it to the 'Variable '2 box → Click 'OK'.

total variance that can be attributed to a particular effect; partial eta squared is the proportion of the effect plus error variance that can be attributed to a particular effect. Partial eta squared and Cohen's *d* are the preferred measures here.

41.3 Analysis of Variance

The t-test is useful for examining differences between *two* groups of respondents, or the same group on either two variables or two occasions, using parametric data from a random sample and assuming that each datum value is independent of the others. However, in much educational research we may wish to investigate differences between *more than two* groups. For example, we may wish to look at the examination results of four regions or four kinds of schools. In this case the t-test will not suit our purposes, and we must turn to Analysis of Variance. Analysis of Variance (ANOVA) can be used with three or more groups and is premised on the same assumptions as t-tests, and the research should conduct these 'safety checks' to ensure that it is appropriate to use ANOVA.

Safety checks for using ANOVA

Analysis of Variance (ANOVA) requires:

- continuous parametric data;
- random sampling;
- normal distribution of the data (though large samples often overcome this);
- homogeneity (equality) of variances (though the Levene test can identify problems here, and SPSS can offer the Brown-Forsythe and Welch tests to overcome the problem here, discussed below).

There are several kinds of Analysis of Variance; here we introduce only the three most widely used versions: the one-way Analysis of Variance, the two-way Analysis of Variance and Multiple Analysis of Variance (MANOVA). Analysis of Variance, like the t-test, assumes that the independent variable(s) is/are categorical (e.g. teachers, students, parents, governors) and one is a continuous variable (e.g. marks on a test). It calculates the F ratio, given as:

$$\text{F ratio} = \frac{\text{Between-groups variance}}{\text{Within-groups variance}}$$

ANOVA calculates the means for all the groups and then it calculates the average of these means. For each group separately it calculates the total deviation of each individual's score from the mean of the group (within-groups variation). Finally it calculates the deviation of each group mean from the grand mean (between-groups variation).

One-way Analysis of Variance

Let us imagine that we have four types of school:

- rural primary
- rural secondary
- urban primary
- urban secondary.

Let us imagine further that all of the schools in these categories have taken the same standardized test of mathematics, and the results have been given as a percentage thus, as shown in Table 41.7.

Table 41.7 gives us the means, standard deviations, standard error, confidence intervals, and the minimum and maximum marks for each group. At this stage we are only interested in the means:

rural primary: mean = 59.85%
rural secondary: mean = 60.44%
urban primary: mean = 50.64%
urban secondary: mean = 51.70%

Are these means statistically significantly different, i.e. real differences or by chance alone? Analysis of Variance (ANOVA) calculates statistical significance. We commence with the null hypothesis ('there is no statistically significant difference between the four means') and then we set the level of significance (α) to use for supporting or not supporting the null hypothesis; for example, we could say 'Let $\alpha = 0.05$'. SPSS performs the calculation (Table 41.8).

Table 41.8 tells us that, for three degrees of freedom (df), the F-ratio is 8.976. The F-ratio is the *between*-group mean square (variance) divided by the *within*-group mean square (variance), i.e.:

$$F = \frac{\text{Between-group variance}}{\text{Within-group variance}} = \frac{3981.040}{443.514} = 8.976$$

Looking at the final column ('Sig.'), ANOVA tell us that there is a statistically significant difference between the means ($\rho = 0.000$). This does *not* mean that all the means are statistically significantly different from each other, but that some are. For example, it may be that the means

TABLE 41.7 DESCRIPTIVE STATISTICS FOR ANALYSIS OF VARIANCE (SPSS OUTPUT)

for the rural primary and rural secondary schools (59.85 per cent and 60.44 per cent respectively) are not statistically significantly different, and that the means for the urban primary schools and urban secondary schools (50.64 per cent and 51.70 per cent respectively) are not statistically significantly different. However, it could be that there is a statistically significant difference between the scores of the rural (primary and secondary) and the urban (primary and secondary) schools. How can we find out which groups are statistically significantly different from each other? The purpose of a *post hoc* test is to find out exactly where those differences are.

There are several tests that can be employed here, though we will only concern ourselves with two commonly used tests: the Tukey honestly significant difference test, sometimes called the 'Tukey hsd' test, or simply (as in SPSS) the Tukey test, and the Games-Howell test. Others include the Bonferroni and Scheffé test; they are more rigorous than the Tukey test and tend to be used less frequently. The Scheffé test is very similar to the Tukey hsd test, but it is more stringent than the Tukey test in respect of reducing the risk of a Type I error, though this comes with some loss of statistical power (see Chapter 39 on statistical power): one may be less likely to find a difference between groups in the Scheffé test. The Tukey test assumes equality of variances ('homogeneity of variance') in the scores of the groups and equal sub-sample sizes, whilst the Games-Howell test is used if homogeneity of variance is not present or if sub-sample sizes differ.

The Tukey test groups together sub-samples whose means are *not* statistically significantly different from each other and places them in a different group from a group whose means *are* statistically significantly different from the first group. Let us see what this means in our example of the mathematics results of four types of school (Table 41.9).

Table 41.9 takes each type of school and compares it with the other three types, in order to see where there may be statistically significant differences between them. Here the rural primary school is first compared with the rural secondary school (row one of the left-hand column cell named 'Rural primary'), and no statistically significant difference is found between them (Sig. = 0.996, i.e. $\rho > 0.05$). The rural primary school is then compared with the urban primary school and a statistically significant difference is found between them (Sig. = 0.002, i.e. $\rho < 0.05$). The rural primary school is then compared with the urban secondary school, and, again, a statistically significant difference is found between them (Sig. = 0.003, i.e. $\rho < 0.05$). The next cell of the left hand column commences with the

*. The mean difference is significant at the .05 level.

rural secondary school, and this is compared with the rural primary school, and no statistically significant difference is found (Sig. = 0.996, i.e. $\rho > 0.05$). The rural secondary school is then compared to the urban primary school and a statistically significant difference is found between them (Sig. = 0.001, i.e. $\rho < 0.05$). The rural secondary school is then compared with the urban secondary school, and, again, a statistically significant difference is found between them (Sig. = 0.001, i.e. $\rho < 0.05$). The analysis is continued for the urban primary and the urban secondary school. One can see that the two types of rural school do *not* differ statistically significantly from each other, that the two types of urban school do *not* differ statistically significantly from each other, but that the rural and urban schools *do* differ statistically significantly from each other. We can see where the null hypothesis *is* supported and where it is *not* supported.

In fact the Tukey test in SPSS presents this very clearly, as shown in Table 41.10. (If the Games-Howell test is used then a similar output is provided by SPSS.) In Table 41.10, one group of similar means (i.e. those not statistically significantly different from each other: the urban primary and urban secondary) is placed together (the column labelled '1') and the other group of similar means (i.e. those not statistically significantly different from each other: the rural primary and rural secondary) is placed together (the column labelled '2'). SPSS automatically groups these and places them in ascending order (the group with the lowest means appears in the first column, and the group with the highest means is in the second column). So, one can see clearly that the difference between the school lies *not* in the fact that some are primary and some are secondary, but that some are rural and some are urban, i.e. the differences relate to geographical location rather than age group in the school. The Tukey test helps us to locate exactly where the similarities and differences between groups lie. It places the means into homogeneous sub-groups, so that we can see which means are close together but different from other groups of means.

TABLE 41.10 HOMOGENEOUS GROUPINGS IN THE TUKEY TEST (SPSS OUTPUT)

Standardised Mathematics scores (percentages)

Tukey HSD[a,b]

Grouping of school	N	Subset for alpha = .05	
		1	2
Urban primary	141	50.64	
Urban secondary	194	51.70	
Rural primary	134		59.85
Rural secondary	136		60.44
Sig.		.973	.995

Means for groups in homogeneous subsets are displayed.

a. Uses Harmonic Mean Sample Size = 147.806.

b. The group sizes are unequal. The harmonic mean of the group sizes is used. Type I error levels are not guaranteed.

Analysis of Variance here tells us that there are or are not statistically significant differences between groups; the Tukey test indicates where these differences lie, if they exist. We advise using the two tests together. Of course, as with the t-test, it is sometimes just as important if we do *not* find a difference between groups as if we *do* find a difference. For example, if we were to find that there was no statistically significant difference between four groups (parents, teachers, students and school governors/leaders) on a particular issue, say, the move towards increased science teaching, then this would give us greater grounds for thinking that a proposed innovation – the introduction of increased science teaching – would stand a greater chance of success than if there had been statistically significant differences between the groups. Finding no difference can be as important as finding a difference.

In reporting Analysis of Variance and the Tukey test one could use a form of words thus:

> Analysis of Variance found that there was a statistically significant difference between rural and urban schools ($F_{14} = 8.975$, $\rho < 0.001$). The Tukey test found that the means for rural primary schools and rural secondary schools (59.85 and 60.44 respectively) were not statistically significantly different from each other, and that the means for urban primary schools and urban secondary schools (50.64 and 51.70 respectively) were not statistically significantly different from each other. The homogeneous subsets calculated by the Tukey test reveal two subsets in respect of the variable 'Standardized mathematics scores': (a) urban primary and urban secondary schools; (b) rural primary and rural secondary schools. The two subsets reveal that these two groups were distinctly and statistically significantly different from each other in respect of this variable. The means of the rural schools were statistically significantly higher than the means of the urban schools.

Box 41.3 provides the SPSS command sequence for one-way ANOVA with the Tukey test.

Box 41.4 provides the SPSS command sequence for repeated measures in ANOVA with the Tukey test.

BOX 41.3 SPSS COMMAND SEQUENCE FOR ONE-WAY ANOVA WITH THE TUKEY TEST

To run one-way ANOVA in SPSS, checking for homogeneity of variance, with the Tukey and Games-Howell tests, the command sequence is: 'Analyze' → 'Compare means' → 'One-Way ANOVA' → Send the independent variable to the 'Factor' box → Send the dependent variable to the 'Dependent' box → Click the 'Post Hoc' box → Check the 'Tukey' box and the 'Games-Howell' box → Click 'Continue' → Click the 'Options' box → Check the boxes marked 'Homogeneity of variance test', 'Brown-Forsythe' and 'Welch' → Click 'Continue' (which returns you to the original screen) → Click 'OK'. The Homogeneity of variance test is the test of equality of variance (which informs the researcher whether to proceed with the Tukey or the Games-Howell test), and if the homogeneity of variance is violated (i.e. $\rho > 0.05$) then the Brown-Forsythe test and the Welch tests are more robust than the ANOVA, and SPSS provides the significance levels for these two tests here.

BOX 41.4 SPSS COMMAND SEQUENCE FOR REPEATED MEASURE ANOVA WITH THE TUKEY TEST

For repeated measures in ANOVA using SPSS (i.e. the same groups under three or more conditions), with the Tukey test and a measure of effect size, the SPSS command sequence is: 'Analyze' → 'General Linear Model' → 'Repeated Measures' → In the box 'Within-Subject Factor Name' name a new variable → In the box 'Number of Levels' insert the number of dependent variables that you wish to include→ Click 'Add'→ Click 'Define' → Send over the dependent variables that you wish to include (the number of variables must be the same as the 'Number of Levels') into the box 'Within-Subjects Variables' → Send over the independent variable into the box 'Between-Subjects Factors'→ Click 'Options' → Click 'Estimates of effect size' → Click 'Continue' → Click 'Post Hoc' → Send over the factor from the 'Factor(s)' box to the 'Post Hoc Tests for' box → Click 'Tukey' → Click 'Continue' (which returns you to the original screen) → Click 'OK'. This will give you several boxes in the output. Go to the box called 'Multivariate Tests'; the furthest right-hand column has the partial eta squared. Go to the row that contains the last box, and look at the partial eta squared (e.g. 'Pillai's Trace' and 'Wilk's Lambda'); this gives the partial eta squared.

Statistical significance in one-way ANOVA is an indication of whether the results occur by chance alone. To find how much difference there is (i.e. effect size), the researcher can calculate eta squared, and we refer the reader to Chapter 39, which indicates exactly how this can be calculated. Chapter 39 also reports other tests of effect size, together with how to conduct and interpret them.

Two-way Analysis of Variance

The example of ANOVA above illustrates one-way Analysis of Variance, i.e. the difference between the means of three or more groups on a *single* independent variable. Additionally, ANOVA can take account of more than one independent variable. Two-way Analysis of Variance is used to estimate the effect of two independent variables on a single variable (Cohen and Holliday, 1996, p. 277). Let us take the example of how examination performance in science is affected by both age group and sex. Two-way ANOVA enables the researcher to examine not only the effect of each independent variable but also the interaction effects on each other of these two independent variables, i.e. how sex effects are influenced or modified when combined with age group effects. We may discover, for example, that age group has a differential effect on examination performance according to whether one is male or female, i.e. there is an interaction effect.

For two-way Analysis of Variance the researcher requires two independent categorical (nominal) variables, for example, sex, age group and one continuous dependent variable (e.g. performance on examinations). Two-way ANOVA enables the researcher to calculate three effects. In this example they are:

- differences in examination performance by sex;
- difference in examination performance by age group;
- the interaction of sex and age group on examination, for example, is there a difference in the effects of age group on examination performance for males and females?

We will use SPSS to provide an example of this. SPSS firstly presents descriptive statistics, as shown in Table 41.11. This table simply presents the data, with means and standard deviations. Next SPSS calculates the

TABLE 41.11 MEANS AND STANDARD DEVIATIONS IN A TWO-WAY ANALYSIS OF VARIANCE (SPSS OUTPUT)

Levene test for equality of error variances, degrees of freedom and significance levels (Table 41.12).

The Levene test in Table 41.12 enables the researcher to know whether there is equality across the variances. The researcher needs to see if the significance level is greater than 0.05, looking for a significance level *greater than* 0.05, i.e. *not* statistically significant, which supports the null hypothesis which states that there is no statistically significant difference between the variances across the groups (i.e. to support the assumptions of ANOVA). In our example this is the case as the significance level is 0.156. The researcher is safe, therefore, to proceed with the analysis. SPSS provides here with important information, as shown in Table 41.13.

TABLE 41.12 THE LEVENE TEST OF EQUALITY OF VARIANCES IN A TWO-WAY ANALYSIS OF VARIANCE (SPSS OUTPUT)

Levene's Test of Equality of Error Variances [a]

Dependent Variable: SCIENCE

F	df1	df2	Sig.
3.463	7	992	.001

Tests the null hypothesis that the error variance of the dependent variable is equal across groups.

a. Design: Intercept+SEX+AGE GROUP +SEX * AGE GROUP

In this table, there are three sets of independent variables listed (SEX, AGE GROUP, SEX*AGE GROUP). The column headed 'Sig.' shows that the significance levels for the three sets are, respectively: 0.956, 0.004 and 0.244. Sex does not have a statistically significant effect on science examination performance ($\rho = 0.956$). Age group does have a statistically significant effect on the performance in the science examination ($\rho = 0.004$). The interaction effect of sex and age group does not have a statistically significant effect on performance ($\rho = 0.244$). SPSS also computes the effect size (Partial Eta squared). For the important variable AGE GROUP this is given as 0.014, which shows that the effect size is very small indeed, suggesting that even though statistical significance has been found, the actual difference in the mean values is very small. This latter is a neat illustration of

TABLE 41.13 BETWEEN-SUBJECT EFFECTS IN TWO-WAY ANALYSIS OF VARIANCE (SPSS OUTPUT)

b. R Squared = .018 (Adjusted R Squared = .011)

the point made in Chapter 39, that relying on statistical significance alone is dangerous, and that effect sizes are often more useful and, indeed, tell us *how much* of a difference there is, which is something that significance testing alone cannot do.

As with one-way ANOVA, the Tukey and/or the Games-Howell tests can be applied here to present the homogeneous groupings of the sub-sample means. SPSS can also present a graphic plot of the two sets of scores, which gives the researcher a ready understanding of the effects of the males and females across the four age groups in their science examination (Figure 41.1).

In reporting the results of the two-way Analysis of Variance one can use the following form of words:

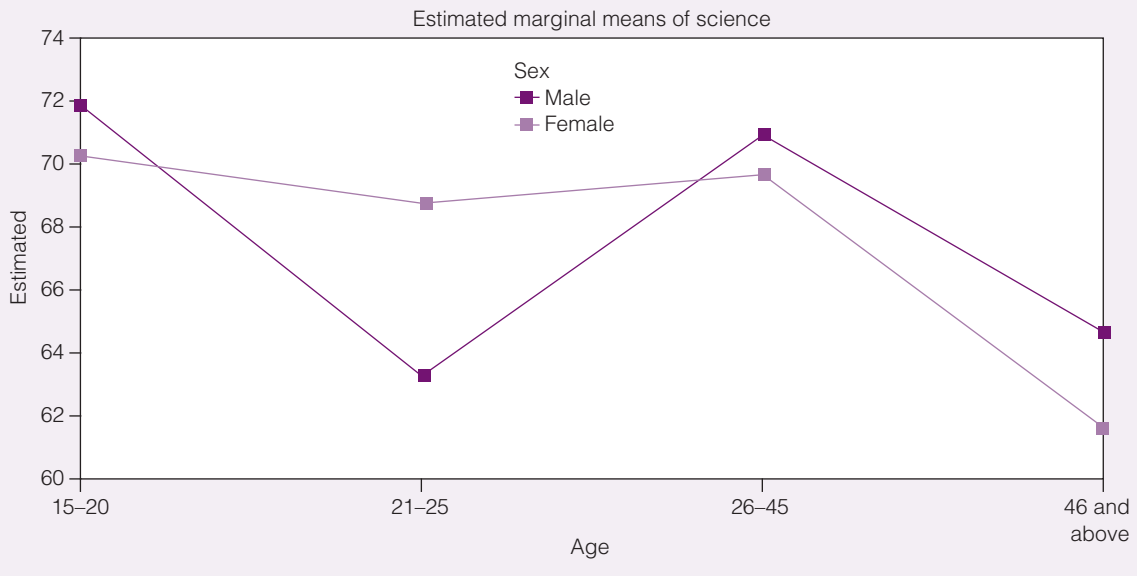

FIGURE 41.1 Graphic plots of two sets of scores on a dependent variable

A two-way between-groups Analysis of Variance was conducted to discover the impact of sex and age group on performance in a science examination. Subjects were divided into four groups by age: Group 1: 15–20 years; Group 2: 21–25 years; Group 3: 26–45 years; and Group 4: 46 years and above. There was a statistically significant main effect for age group ($F=4.554$, $\rho=0.004$); however, the effect size was small (partial eta squared=0.014). The main effect for sex ($F=0.003$, $\rho=0.956$) and the interaction effect ($F=1029.877$, $\rho=0.244$) were not statistically significant.

Box 41.5 provides the SPSS command sequence for two-way ANOVA.

Multiple Analysis of Variance

Multiple Analysis of Variance (MANOVA) is designed to see the effects of one categorical independent variable on two or more continuous variables (e.g. 'do males score more highly than females in terms of how hard they work and their IQ'). We mention it here by way of introduction, but we refer readers to more advanced texts (e.g. Tabachnick and Fidell, 2013; Pallant, 2016), for a fuller analysis of how to conduct this.

Safety checks for using MANOVA

MANOVA is very sensitive to the assumptions that are made about the data, and researchers should conduct 'safety checks' to ensure that the data are suitable for this statistic to be calculated:

- continuous parametric data for dependent variables;
- independent variables are categorical, with two or more values;
- groups are independent of each other;
- random sampling;
- adequate sample size (more cases in each cell than the number of dependent variables being studied, e.g. a minimum of twenty cases in each cell);
- normal distribution of the data (though large samples often overcome this);
- no outliers;
- a linear relationship between each pair of dependent variables;
- no multicollinearity (dependent variables are independent of each other but moderately correlated);
- homogeneity (equality) of variances (though the Levene test can identify problems here, and SPSS can offer the Brown-Forsythe and Welch tests to overcome the problem here, discussed below).

Box 41.6 provides the SPSS command sequence for MANOVA.

BOX 41.5 SPSS COMMAND SEQUENCE FOR TWO-WAY ANOVA

To run two-way ANOVA in SPSS the command sequence is: 'Analyze' → Click 'General Linear Model' → Click 'Univariate' → Send the dependent variable to the box 'Dependent Variable' → Send the independent variables to the box 'Fixed Factors' → Click the 'Options' box; in the 'Display' area, check the boxes 'Descriptive Statistics' and 'Estimates of effect size' → Click 'Continue' → Click the 'Post Hoc' box, and send over from the 'Factors' box to the 'Post Hoc tests for' box those factors that you wish to investigate in the post hoc tests → Click the post hoc test that you wish to use (e.g. Tukey') → Click 'Continue' → Click the 'Plots' box → Move to the 'Horizontal' box the factor that has the most groups → Move to the 'Separate lines' box the factor the other independent variable → Click 'Add' → Click 'Continue' → Click 'OK'.

BOX 41.6 SPSS COMMAND SEQUENCE FOR MANOVA

To run MANOVA, the SPSS command sequence is: 'Analyze' → Click 'General Linear Model' → Click on 'Multivariate' → Send to the box 'Dependent Variables' the dependent variables that you wish to include → Send to the 'Fixed Factors' box the independent variable that you wish to use → Click 'Model' and ensure that the 'Full factorial' (in the 'Specify Model' box) and the 'Type III' (in the 'Sum of Squares') boxes are selected → Click 'Continue' → Click the 'Options' box and send to the 'Display Means for' box the independent variable that you wish to include → In the 'Display' section, click 'Descriptive Statistics', 'Estimates of effect size' and 'Homogeneity tests' → Click 'Continue' → If you want a post hoc test click 'Post Hoc' → Send over the independent variable from the 'Factor(s)' box to the 'Post Hoc tests for' box (if you want a post hoc test and if your independent variable has three or more values) → Click 'Tukey' and 'Games-Howell' → Click 'Continue' → Click 'OK'.

For further guidance on running SPSS for these matters and interpreting the SPSS output, we refer readers to Tabachnick and Fidell (2013) and Pallant (2016).

41.4 The chi-square test

Difference testing is an important feature in educational research. We can conduct a chi-square test (χ^2) (pronounced 'kigh', as in 'high') to investigate difference. The chi-square test is a test of difference that can be conducted for a univariate analysis (one categorical variable), and between two categorical variables. The chi-square test measures the difference between a statistically generated expected result and an actual (observed) result to see if there is a statistically significant difference between them, i.e. to see if the frequencies observed are statistically significantly different or by chance alone; it is a measure of 'goodness of fit' between an expected and an actual, observed result or set of results. The expected result is based on a statistical process discussed below. Here is not the place to go into the mathematics of the test, not least because computer packages automatically calculate the results, though the formula for calculating chi-square is:

$$\chi^2 = \sum \frac{(O-E)^2}{E}$$

where
O = observed frequencies
E = expected frequencies
$\sum$ = the sum of

For *univariate data* (one variable) let us take the example of 120 students who were asked which of four teachers they preferred. We start with the null hypothesis that states that there is no statistically significant difference in their preferences for four teachers, i.e. that the 120 scores are spread evenly across the four teachers (30 votes for each teacher), thus:

Frequencies	*Teacher A*	*Teacher B*	*Teacher C*	*Teacher D*
Observed	20	70	10	20
Expected	30	30	30	30
Residual (difference between observed and expected frequencies)	–10	40	–20	–10

The results indicate that the assumed equal distribution of preferences (30 for each teacher) in reality is not evenly distributed; there are 20 for teacher A, 70 for teacher B, 10 for teacher C and 20 for teacher D. Is this by chance or are these differences statistically significant? Using the formula above we compute the chi-square value thus:

$$\chi^2 = \sum \frac{(O-E)^2}{E}$$
$$= \sum \frac{(-10)^2}{30} + \frac{(40)^2}{30} + \frac{(-20)^2}{30} + \frac{(-10)^2}{30}$$
$$= \frac{100+1600+400+100}{30} = \frac{2200}{30} = 73.3$$

The chi-square value here is 73.3, with three degrees of freedom (explained below). In a table of critical values for chi-square distributions (in the appendices of most statistics books and freely available on the Internet), we look up the level of statistical significance for three degrees of freedom:

Degrees of freedom	*Level of significance*	
	0.05	*0.01*
2	5.99	9.21
3	7.81	11.34
4	9.49	13.28
5	11.07	15.09
6	12.59	16.81

We find that, at 73.3, the chi-square value is considerably larger than the 11.34 given in the table, i.e. it has a probability level which is more than by chance, being stronger than 0.01, i.e. there is a statistically significant difference between the observed and expected frequencies, i.e. not all teachers are equally preferred (more people preferred Teacher B, and this was statistically significant, i.e. not by chance).

Box 41.7 provides the SPSS command sequence for univariate chi-square.

For *bivariate data* (two variables) the chi-square test is a test of independence, to see whether there is a relationship or association between two categorical variables. Let us say that we have a crosstabulation of males and females and their liking for maths (like/dislike). We start with the null hypothesis that states that there is *no* statistically significant difference between the males and females (variable 1) in their (dis)liking for mathematics (variable 2), and we seek to discover if the null hypothesis is supported.

BOX 41.7 SPSS COMMAND SEQUENCE FOR UNIVARIATE CHI-SQUARE

In SPSS the command sequence for univariate chi-square is: 'Analyze' → 'Nonparametric tests' → 'Legacy dialogs' → 'Chi-square' → Send over the variable of interest to the 'Test variable' box → Click 'OK'. Note that the 'expected values' default setting is 'All categories equal'. If the researcher expects that not all the categories will be equal then she/he can set the expected distribution proportions in the 'expected values' window by setting the values as a decimal fraction, for example, 0.6, 0.3, 0.1 for three categories (which must not exceed 1.0 in total).

We set the level of significance (α) that we wish to use for supporting or not supporting the null hypothesis; for example we could say 'Let $\alpha=0.05$'. Having found out the true voting we set out a 2×2 crosstabulation thus, with the observed frequencies in the cells:

	Male	*Female*	*Total*
Like mathematics	60	25	85
Dislike mathematics	35	75	110
Total	95	100	195

These are the observed frequencies. To find out the expected frequencies for each cell we use the formula:

$$\text{Expected value of a cell} = \frac{\text{row total} \times \text{column total}}{\text{Overall total}}$$

Using the row totals, the column totals and the overall total, we can calculate the expected frequencies for each thus (figures rounded):

	Male	*Female*	*Total*
Like mathematics	(85 × 95)/ 195=41.4	(85 × 100)/ 195=43.6	85
Dislike mathematics	(110 × 95)/ 195=53.6	(110 × 100)/ 195=56.4	110
Total	95	100	195

The chi-square value, using the formula above is:

$$\chi^2 = \sum \frac{(O-E)^2}{E}$$

$$= \sum \frac{(60-41.4=18.6)^2}{41.4} + \frac{(25-43.6=18.6)^2}{53.6} + \frac{(35-53.6=18.6)^2}{43.6} + \frac{(75-56.4=18.6)^2}{56.4}$$

$$= \frac{345.96}{41.4} + \frac{345.96}{53.6} + \frac{345.96}{43.6} + \frac{345.96}{56.4}$$

$$= 8.36 + 6.45 + 7.93 + 6.13$$

$$= 28.87$$

When we look up the chi-square value of 28.87 in the table of critical values of the chi-square distribution earlier, with two degrees of freedom, we observe that the figure of 28.87 is larger than the figure of 9.21 given in that table and required for statistical significance at the 0.01 level. Hence we conclude that the distribution of likes and dislikes for mathematics by males and females is not simply by chance but that there is a statistically significant difference between the voting of males and females here. Hence the null hypothesis is not supported and the alternative hypothesis, that there is a statistically significant difference between the voting of the two groups, is supported.

We do not need to perform these calculations by hand. Computer software such as SPSS will do all of the calculations with a few keystrokes.

We recall that the conventionally accepted minimum level of statistical significance is usually 0.05, and we used this level in the example; the significance level of our data here is smaller than either the 0.05 and 0.01 levels, i.e. it is highly statistically significant.

One can report the results of the chi-square test thus:

> When the chi-square statistic was calculated for the distribution of males and females on their liking for mathematics, a statistically significant difference was found between the males and the females ($\chi^2=28.87$, $df=2$, $\rho=0.000$).

We use Yates's correction (a continuity correction) to compensate for the over-estimate of the chi-square in a 2×2 table, and this can be activated by simple keystrokes in SPSS or other software.

The chi-square statistic is normally used with nominal (categorical) data, and our example illustrated this. We provide a further example of the chi-square statistic, with data that are set into a contingency table, this time in a 2×3 contingency table, i.e. two horizontal rows and three columns (contingency tables may contain more than this number of variables). The example this time presents data concerning sixty students' entry into science, arts and humanities, in a college, and whether the students are male or female.

The lower of the two figures in each cell is the number of actual students who have opted for the particular subjects (sciences, arts, humanities). The upper of the two figures in each cell is what might be expected purely by chance to be the number of students opting for each of the particular subjects. The figure is arrived at by statistical computation, hence the decimal fractions for the figures. What is of interest to the researcher is whether the actual distribution of subject choice by males and females differs significantly from that which could occur by chance variation in the population of college entrants (Table 41.14).

The researcher begins with the null hypothesis that there is no statistically significant difference between the actual results noted and what might be expected to occur by chance in the wider population. When the chi-square statistic is calculated, if the observed, actual distribution differs from that which might be expected to occur by chance alone, then the researcher has to determine whether that difference is statistically significant, i.e. not to support the null hypothesis.

In our example of sixty students' choices, the chi-square formula yields a final chi-square value of 14.64. This we refer to the tables of the critical values of the chi-square distribution (an extract from which is set out for the first example above) to determine whether the derived chi-square value indicates a statistically significant difference from that occurring by chance.

TABLE 41.14 A 2 × 3 CONTINGENCY TABLE FOR CHI-SQUARE

	Science subjects	*Arts subjects*	*Humanities subjects*	
Males	7.6 14	8 4	8.4 6	24
Females	11.4 5	12 16	12.6 15	36
	19	20	21	60

The researcher sees that the 'degrees of freedom' (a mathematical construct that is related to the number of restrictions that have been placed on the data) has to be identified. In many cases, to establish the degrees of freedom, one simply takes 1 away from the total number of rows of the contingency table and 1 away from the total number of columns and adds them; in this case it is (2–1)+(3–1)=3 degrees of freedom. Degrees of freedom are discussed in the next section. (Other formulae for ascertaining degrees of freedom hold that the number is the total number of cells minus 1.) The researcher looks along the table from the entry for the three degrees of freedom and notes that the derived chi-square value calculated (14.64) is statistically significant at the 0.01 level, i.e. is higher than the required 11.34, indicating that the results obtained – the distributions of the actual data – could not have occurred simply by chance. The null hypothesis is not supported at the 0.01 level of statistical significance. Interpreting the specific numbers of the contingency table (Table 41.14) in educational rather than statistical terms, noting (a) the low incidence of females in the science subjects and the high incidence of females in the arts and humanities subjects, and (b) the high incidence of males in the science subjects and low incidence of males in the arts and humanities subjects, the researcher would say that this distribution is statistically significant – suggesting, perhaps, that the college needs to consider action possibly to encourage females into science subjects and males into arts and humanities.

The chi-square test is one of the most widely used tests, and is applicable to nominal data in particular. More powerful tests are available for ordinal, interval and ratio data, and we discuss these separately. However, one has to be cautious of the limitations of the chi-square test. Look at the example shown in Table 41.15.

TABLE 41.15 A 2 × 5 CONTINGENCY TABLE FOR CHI-SQUARE

	Music	*Physics*	*Maths*	*German*	*Spanish*	
Males	7 14.0%	11 22.0%	25 50%	4 8.0%	3 6%	50 100%
Females	17 12.1%	38 27.0%	73 52%	12 8.5%	1 0.7%	141 100%
Total	24 12.6%	49 25.7%	98 51%	16 8.4%	4 2.1%	191 100%

If one were to perform the chi-square test on Table 41.15 then one would have to be very cautious. The chi-square statistic assumes that no more than 20 per cent of the total number of cells contain fewer than five cases. In the example here we have one cell with four cases, another with three, and another with only one case, i.e. three cells out of the ten (two rows – males and females – with five cells in each for each of the rating categories). This means that 30 per cent of the cells contain fewer than five cases; even though a computer will calculate a chi-square statistic, it means that the result is unreliable. This highlights the point made in Chapter 12 about sampling, namely. that the subsample size has to be large. For example, if each category here were to contain five cases then it would mean that the minimum sample size would be fifty (10×5), assuming that the data are evenly spread. In the example here, even though the sample size is much larger (191) it still does not guarantee that the 20 per cent rule will be observed, as the data are unevenly spread. When calculating the chi-square statistic, the researcher can use the Fisher's Exact Probability Test if more than 25 per cent of the cells have fewer than five cases, and this is automatically calculated and printed as part of the normal output in the chi-square calculation in SPSS.

Because of the need to ensure that at least 80 per cent of the cells of a chi-square contingency table contain more than five cases if confidence is to be placed in the results, it may not be feasible to calculate the chi-square statistic if only a small sample is being used. Hence the researcher would tend to use this statistic for larger-scale survey data. Other tests could be used if the problem of low cell frequencies obtains, for example, the binomial test and, more widely used, the Fisher Exact Probability Test (Cohen and Holliday, 1996, pp. 218–20). The required minimum number of cases in each cell renders the chi-square statistic problematical, and, apart from with nominal data, there are alternative statistics that can be calculated and which overcome this problem (e.g. the Mann-Whitney, Wilcoxon, Kruskal-Wallis and Friedman tests for non-parametric – ordinal – data, and the t-test and Analysis of Variance test for parametric – interval and ratio – data).

With statistical significance being increasingly questioned and being replaced with measures of effect size (see Chapter 39), calculations of effect size for categorical tables (crosstabulations) use two main statistics (see Chapter 39):

- the *phi* coefficient for 2×2 tables (in which Cohen's d indicates small effect for 0.10, a medium effect for 0.30 and a large effect for 0.50).
- Cramer's V for contingency tables larger than 2×2, which takes account of degrees of freedom.

Two significance tests for very small samples are given in the accompanying website.

Box 41.8 provides the SPSS command sequence for bivariate chi-square with crosstabulations for simple frequencies, i.e. in which each case has its own row in the SPSS file. However, sometimes the data that researchers collect do not come in a case-by-case form but are already aggregated, i.e. with totals rather than individual cases, and Box 41.9 indicates how to work with this in SPSS.

41.5 Degrees of freedom

The chi-square statistic introduces the term *degrees of freedom*. Gorard (2001b, p. 233) suggests that 'the degrees of freedom is the number of scores we need to know before we can calculate the rest'. Cohen and Holliday (1996) explain the term clearly:

> Suppose we have to select any five numbers. We have complete freedom of choice as to what the numbers are. So, we have five degrees of freedom. Suppose however we are then told that the five

BOX 41.8 SPSS COMMAND SEQUENCE FOR BIVARIATE CHI-SQUARE WITH CROSSTABULATIONS

The SPSS command sequence for bivariate chi-square works with the 'Crosstabs' command; it is: 'Analyze' → 'Descriptive Statistics' → 'Crosstabs' → Send over the row variable to the 'Rows' box and send over the column variables to the 'Columns' box → Click the 'Statistics' box, which opens a new window → Check the 'Chi-square' and the 'Phi and Cramer's V' boxes → Click 'Continue' → Click the 'Cells' box, which opens a new window → In the 'Percentages' area of the new window check the 'Total' box → Click 'Continue' → Click 'OK'. Note that SPSS automatically applies Yates's correction ('Continuity Correction') for 2×2 tables in chi-square and SPSS automatically uses the Fisher Exact Probability test if more than 25 per cent of the cells have fewer than five cases.

BOX 41.9 SPSS COMMAND SEQUENCE FOR BIVARIATE CHI-SQUARE WITH AGGREGATED DATA

Sometimes the researcher only has already-aggregated data. For example, imagine that the researcher is given only a table of aggregated totals of subject choices by 200 students (100 males and 100 females) at age 15, thus:

	Subject choices			
	Physical sciences	*Arts and humanities*	*Social sciences*	*Business studies*
Males	27	12	18	43
Females	10	29	28	33

Here each row contains aggregated cases rather than single cases. SPSS can handle this but the data have to be entered differently in SPSS and a preliminary command sequence for weighting cases has to take place before the command sequence in Box 41.8 can be followed. Here there are eight cells of numbers, with one variable for 'Gender' (males and females) and one variable for 'subject choices'. SPSS creates a variable for 'Gender', with values in the SPSS file as: 1='Males', 2='Females'. SPSS creates a variable for 'Subject choices', with values in the SPSS files as: 1='Physical Sciences', 2='Arts and Humanities', 3='Social Sciences' and 4='Business Studies'. SPSS creates a new variable of 'Frequencies' to contain the numbers in each cell; this is a scale variable in SPSS. Having created the SPSS file the 'Data View' window in SPSS takes each of the pieces of data for the eight cells in the first table above and reforms it for SPSS, to appear thus:

Gender	*Subject choices*	*Frequencies*
1	1	27
1	2	12
1	3	18
1	4	43
2	1	10
2	2	29
2	3	28
2	4	33

Data row one is for males choosing Physical Sciences, with 27 students.
Data row two is for males choosing Arts and Humanities, with 12 students.
Data row three is for males choosing Social Sciences, with 18 students.
Data row four is for males choosing Business Studies, with 43 students.
Data row one is for females choosing Physical Sciences, with 10 students.
Data row two is for females choosing Arts and Humanities, with 29 students.
Data row three is for females choosing Social Sciences, with 28 students.
Data row four is for females choosing Business Studies, with 33 students.

To run a chi-square in SPSS here, the researcher constructs this data file and then runs the 'Weight Cases' command sequence: 'Data' → 'Weight Cases' → Click the radio button 'Weight cases by' and send the variable 'Frequencies' to the box marked 'Frequency variable' → Click 'OK'. Having done this, the SPSS command sequence in Box 41.8 can be followed.

numbers must have a total value of 25. We will have complete freedom of choice to select four numbers but the fifth will be dependent on the other four. Let's say that the first four numbers we select are 7, 8, 9, and 10, which total 34, then if the total value of the five numbers is to be 25, the fifth number must be –9.

$$7+8+9+10-9=25$$

A restriction has been placed on one of the observations; only four are free to vary; the fifth has lost its freedom. In our example then d.f. = 4, that is $N-1=5-1=4$.

Suppose now that we are told to select any five numbers, the first two of which have to total 9, and the total value of all five has to be 25. Our restriction is apparent when we wish the total of the first two numbers to be 9. Another restriction is apparent in the requirement that all five numbers must total 25. In other words we have lost two degrees of freedom in our example. It leaves us with d.f. = 3, that is, $N-2=5-2=3$.'

(Cohen and Holliday, 1996, p. 113)

For a crosstabulation (a contingency table), degrees of freedom refer to the freedom with which the researcher is able to assign values to the cells, given fixed marginal totals, usually given as (number of rows – 1)+ (number of columns – 1). There are many variants of this, and readers will need to consult more detailed texts to explore this issue. We do not dwell on degrees of freedom here, as it is automatically calculated and addressed in calculations by most statistical software packages such as SPSS.

41.6 The Mann-Whitney and Wilcoxon tests

The non-parametric equivalents of the t-test are the Mann-Whitney U test for two independent samples and the Wilcoxon test for two related samples, both used with one categorical variable and a minimum of one ordinal variable. These enable us to see, for example, whether there are statistically significant differences between males and females on a rating scale.

The Mann-Whitney U test is based on ranks – how many times a score from one group is ranked higher than a score from another group (Bryman and Cramer, 1990, p. 129), thereby overcoming the problem of low cell frequencies in the chi-square statistic. Let us take an example. Imagine that we have conducted a course evaluation, using five-point rating scales ('very little'; 'a little'; 'a moderate amount'; 'quite a lot'; 'a very great deal'), and we wish to find if there is a statistically significant difference between the voting of males and females on the variable 'The course gave you opportunities to learn at your own pace', i.e. whether any differences between males and females are by chance alone. We commence with the null hypothesis ('there is no statistically significant difference between the two rankings') and then we set the level of significance (α) for supporting or not supporting the null hypothesis; for example we could say 'Let $\alpha = 0.05$'. A crosstabulation is shown in Table 41.16.

Are the differences between the two groups statistically significant? Using SPSS, the Mann-Whitney statistic is given in Tables 41.17 and 41.18.

Mann-Whitney using ranks (as in Table 41.17) yields a U-value of 2,732.500 (Table 41.18) from the formula it uses for the calculation (SPSS does this automatically). The important information in Table 41.18 is the 'Asymp. Sig. (2-tailed)', i.e. the statistical significance level of

a. Grouping Variable: sex

any difference found between the two groups (males and females). Here the significance level ($\rho = 0.019$, i.e. $\rho < 0.05$) indicates that the voting by males and females is statistically significantly different and that the null hypothesis is not supported, in other words the differences were not simply by chance. In the t-test and the Tukey test, researchers could immediately find exactly where differences might lie between the groups (by looking at the means and the homogeneous sub-groups respectively). Unfortunately the Mann-Whitney U test does not enable the researcher to identify clearly where the differences lie between the two groups, so the researcher would need to go back to the crosstabulation to identify where differences lie. In the example above, it appears that the males feel more strongly than the females that the course in question has afforded them the opportunity to learn at their own pace.

In reporting the Mann-Whitney U test one could use a form of words such as the following:

> When the Mann-Whitney statistic was calculated to determine whether there was any statistically significant difference in the voting of the two groups ($U = 2{,}732.500$, $\rho = 0.019$), a statistically significant difference was found between the males and females. A crosstabulation found that males felt more strongly than the females that the course in question had afforded them the opportunity to learn at their own pace.

Box 41.10 provides the SPSS command sequence for the Mann-Whitney statistic.

For two *related* samples (e.g. the same group voting for more than one item, or the same grouping voting at

BOX 41.10 SPSS COMMAND SEQUENCE FOR THE MANN-WHITNEY STATISTIC

The SPSS command sequence for the Mann-Whitney statistic is: 'Analyze' → 'Nonparametric statistics' → 'Legacy Dialogs' → '2 Independent Samples' → Send the dependent variable to box 'Test variable list' and the independent variable to the 'Grouping variable' box → Click 'Define groups' (which is activated when the 'Grouping variable' box contains the independent variable) and then type the number that you assigned to each of the two groups in the SPSS file (e.g. males '1' and females '2') → Click 'Continue' (which returns you to the original screen) → Click 'OK'.

two points in time), the Wilcoxon test is applied, and the data are presented and analysed in the same way as the Mann-Whitney U test. For example, in Tables 41.19 and 41.20 there are two variables ('The course was just right' and 'The lecturer was well prepared'), voted on by the same group. The frequencies are given. Is there a statistically significant difference in the voting for these two variables?

As it is the *single, same group* voting on two variables, the sample is not independent, hence the Wilcoxon test is used. Using SPSS output, the data analysis shows that the voting of the group on the two variables is statistically significantly different (see Tables 41.21 and 41.22).

The reporting of the results of the Wilcoxon test can be as follows:

> When the Wilcoxon statistic was calculated to determine whether there was any statistically significant difference in the voting of the group on the two variables ($\rho = 0.000$), a statistically significant difference was found. The group was more

positive about the variable 'The lecturer was well prepared' than for the variable 'The course was just right'.

Box 41.11 provides the SPSS command sequence for running the Wilcoxon test.

For both the Mann-Whitney and Wilcoxon tests, *not* finding a statistically significant difference between groups can be just as important as finding a statistically significant difference between them, as the former suggests that nominal characteristics of the sample make no statistically significant difference to the voting, i.e. the voting is consistent, regardless of particular features of the sample. Both of these tests yield statistical significance alone, not effect size; they are simply measures of chance.

41.7 The Kruskal-Wallis and Friedman tests

The non-parametric equivalents of Analysis of Variance are the Kruskal-Wallis test for three or more independent samples and the Friedman test for three or more related samples, both of them for use with one categorical variable and one ordinal variable. These enable us to see, for example, whether there are differences between three or more groups (e.g. classes, schools, groups of teachers) on a rating scale.

These tests operate in a very similar way to the Mann-Whitney test, being based on rankings. Let us take an example. Teachers in four different groups, according to the number of years that they have been teaching, have been asked to evaluate one aspect of a particular course that they have attended ('The teaching and learning tasks and activities consolidate learning through application'). One of the results is the crosstabulation shown in Table 41.23. Are the groups of teachers statistically significantly different from each other in respect of their voting? We commence with the null hypothesis ('there is no statistically significant difference between the four groups') and then we set the level of significance (α) to use for supporting or not supporting the null hypotheses; for example we could say 'Let $\alpha = 0.05$'.

The Kruskal-Wallis test calculates and presents the results in SPSS as shown in Tables 41.24 and 41.25.

BOX 41.11 SPSS COMMAND SEQUENCE FOR THE WILCOXON TEST

To run the Wilcoxon test for related (paired) samples in SPSS it is important, first, for the researcher to define the single group to be observed under the two conditions. The single group might be, for example, only the males from a total sample of males and females. Here SPSS requires you to use the Select Cases function (the command sequence in SPSS is: 'Data' → 'Select Cases' → Then decide which radio button you wish to activate ('If the condition is satisfied'; 'random sample of cases'; 'Based on time or case range'; 'Use filter variable'), and each of these open another box for further selection and instructions (cf. Pallant, 2016). Once you have selected the cases (NB if you do not use this function then the entire sample is used) the SPSS command sequence for the Wilcoxon test is: 'Analyze' → 'Nonparametric statistics' → 'Legacy Dialogs' → '2 Related Samples' → Click the first variable in which you are interested and send it to the 'Variable 1' box, and then click the second variable in which you are interested and send it to the 'Variable 2' box → Ensure that the box marked 'Wilcoxon' has been checked → Click 'OK'.

TABLE 41.23 CROSSTABULATION FOR THE KRUSKAL-WALLIS TEST (SPSS OUTPUT)

	16-18	95	106.53
	19-21	87	82.02
	>21	2	123.00
	Total	189	

The important figure to note here is the 0.009 ('Asymp.Sig.) in Table 41.25: the significance level. Because this is less than 0.05 we can conclude that the null hypothesis ('there is no statistically significant difference between the voting by the different groups of years in teaching') is not supported, i.e. that the difference in the voting according to the number of years in teaching by the voters is not simply by chance. As with the Mann-Whitney test, the Kruskal-Wallis test tells us only that there *is* or *is not* a statistically significant difference, not *where* the difference lies. To find out where the difference lies, one has to return to the crosstabulation (Table 41.23) and examine it. In the example here it appears that those teachers in the group which had been teaching for 16–18 years are the most positive about the aspect of the course in question.

In reporting the Kruskal-Wallis test one could use a form of words such as the following:

TABLE 41.25 SIGNIFICANCE LEVELS IN A KRUSKAL-WALLIS TEST (SPSS OUTPUT)

Test Statistics [a,b]

	the teaching and learning tasks and activities consolidate learning through application
Chi-Square	11.595
df	3
Asymp. Sig.	.009

a. Kruskal Wallis Test

b. Grouping Variable: number of years teaching

When the Kruskal-Wallis statistic was calculated to determine whether there was any statistically significant difference in the voting of the four groups ($\chi^2 = 11.595$, $\rho = 0.009$), a statistically significant difference was found between the groups which had different years of teaching experience. A crosstabulation found that those teachers in the group who had been teaching for 16–18 years were the most positive about the variable 'The teaching and learning tasks and activities consolidate learning through application'.

The k-sample slippage test from Conover (1971), as an alternative to the Kruskal-Wallis test, is set out in the accompanying website.

Box 41.12 provides the SPSS command sequence to the Kruskal-Wallis statistic.

For more than two *related* samples (e.g. the same group voting for three or more items, or the same grouping voting at three points in time), the Friedman test is applied. For example, in Tables 41.26 to 41.28 there are three variables ('The course encouraged and stimulated your motivation and willingness to learn'; 'The course encouraged you to take responsibility for your own learning'; and 'The teaching and learning tasks and activities consolidate learning through application'), all of which are voted on by the same group. The frequencies are given. Is there a statistically significant difference between the groups in their voting?

The Friedman test reports the mean rank and then the significance level; in the examples here the SPSS output has been reproduced in Tables 41.29 and 41.30.

One can see in Table 41.30 that, with a significance level of 0.838 (greater than 0.05), the voting by the same group on the three variables is not statistically significantly different, i.e. the null hypothesis is supported. The reporting of the results of the Friedman test can follow that of the Kruskal-Wallis test.

When the Friedman statistic was calculated to determine whether there was any statistically significant difference in the voting of the group on the three variables 'The course encouraged and stimulated your motivation and willingness to learn', 'The course encouraged you to take responsibility for your own learning', and 'The teaching and learning tasks and activities consolidate learning through application', no statistically significant difference was found between the group on the three variables in question ($\chi^2 = 0.353$, $\rho = 0.838$).

Box 41.13 provides the SPSS command sequence for the Friedman test.

For both the Kruskal-Wallis and the Friedman tests, as with the Mann-Whitney and Wilcoxon tests, *not* finding a statistically significant difference between groups can be just as important as finding a statistically significant difference between them, as the former suggests that nominal characteristics of the sample make no statistically significant difference to the voting, i.e. the voting is consistent, regardless of particular features of the sample. Similarly, as with the Mann-Whitney and the Wilcoxon tests, the Kruskal-Wallis and Friedman tests yield only statistical significance and not effect size.

BOX 41.12 SPSS COMMAND SEQUENCE FOR THE KRUSKAL-WALLIS STATISTIC

The SPSS command sequence for the Kruskal-Wallis statistic is: 'Analyze' → 'Nonparametric statistics' → 'Legacy Dialogs' → 'K Independent Samples' → Send the dependent variable to box 'Test variable list' and the independent variable to the 'Grouping variable' box → Click 'Define range' (which is activated when the 'Grouping variable' box contains the independent variable) and then type the number that you assigned to the first and last groups in the range in the SPSS file (e.g. School A: '1', School B: '2', School C: '3'). Ensure that the 'Kruskal-Wallis' box has been checked → Click 'OK'.

41.8 Conclusion

This chapter has introduced several inferential statistics and their related concepts:

- measures of difference for parametric data (t-test and ANOVA (one-way, two-way, Multiple Analysis of Variance) and post hoc tests of difference);
- measures of difference for non-parametric data (Mann-Whitney U test, Wilcoxon test, Kruskal-Wallis, Friedman);
- the chi-square test of independence and goodness of fit for univariate and bivariate categorical and ordinal variables, as a measure of difference between observed and expected values and as a test of association/difference;
- degrees of freedom.

It has indicated that, even with interval and ratio data, if the 'safety checks' indicate that they are unsuitable for parametric statistics, then non-parametric statistics should be used. The chapter has also included SPSS command sequences to run these statistics. The next chapter introduces more inferential statistics: regression analysis and standardization.

Companion Website

The companion website to the book provides additional material, data files and PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Inferential statistics

CHAPTER 42

Regression analysis and standardization

This chapter introduces regression and multiple regression, and, arising from these, the need for standardized scores and how they can be calculated. The chapter proceeds thus:

- regression analysis (prediction tests for parametric data)
- simple linear regression (predicting the value of one variable from the known value of another variable)
- multiple regression (calculating the different weightings of independent variables on a dependent variable)
- standardized scores (used in calculating regressions and comparing sets of data with different means and standard deviations)

These statistics are powerful tools for analysing numerical data. We give several worked examples for clarification, and take the novice reader by the hand through these.

42.1 Regression analysis

Regression analysis enables the researcher to predict 'the specific value of one variable when we know or assume values of the other variable(s)' (Cohen and Holliday, 1996, p. 88). It is a way of modelling the relationship between variables. We concern ourselves here with simple linear regression and simple multiple regression, though we also reference stepwise multiple regression and logistic regression.

In using regression techniques, one has to be faithful to the assumptions underpinning them. Pallant (2016, chapters 13 and 14) and Tabachnick and Fidell (2013) set these out as follows, and they are 'safety checks' to ensure that the data are suitable for this set of statistical procedures.

Safety checks

For regression to be used safely there are several requirements:

- sample size: the larger, the better. Pallant (2016) suggests that fifteen cases for each independent variable are required, and that a formula can be applied to determine the minimum sample size required thus: sample size $\geq 50 + (8 \times$ number of independent variables), i.e. for ten independent variables one would require a minimum sample size of 130, i.e. $50 + (8 \times 10)$. Tabachnick and Fidell (2013) also suggest samples of $>50 + 8$ times the number of independent variables), and for stepwise regression (discussed below) there should be a minimum of forty cases for each independent variable;
- avoidance of multicollinearity, i.e. avoiding strong correlation ($r = 0.9$ or higher) between independent variables so that no independent variable is a perfect linear combination of another (avoid perfect 'multicollinearity');
- avoidance of singularity (where one variable is a combination of independent variables);
- avoidance of outliers (remove outliers);
- the measurements are from a random sample (or at least a probability-based one);
- all variables are real numbers (ratio data) (or at least the dependent variable must be);
- all variables are measured without error;
- there is an approximate linear (straight line) relationship between the dependent variable and the independent variable(s) (both individually and grouped);
- normal distribution of the variables;
- the residuals (explained below) for the dependent variable are approximately normally distributed and each value of the independent variables has equal and constant variance;
- homoscedasticity (the variance of the residuals for the dependent variable is the same); each residual is consistent across the range of values for all other variables;
- the residuals are not strongly correlated with the independent variables;
- for any two cases the correlation between the residuals should be zero (each case is independent of the others).
- interaction effects of independent variables are measured.

These safety checks should be applied prudently, as perfection is impossible. However, some of these are essential: random sampling; large sample; no multicollinearity or singularity; assumption of straight line linearity (rather than a curvilinear relationship); removal of outliers; ratio data; normal distributions of the residuals about the predicted dependent variable scores; homoscedasticity. SPSS easily runs tests for these, and we address this below.

42.2 Simple linear regression

In simple linear regression, the model includes one explanatory variable (the independent variable) and one explained variable (the dependent variable). For example, we may wish to see the effect of hours of study on levels of achievement in an examination, to see how much improvement can be predicted to be made to an examination mark from a given number of hours of study. 'Hours of study' is the independent variable and 'level of achievement' is the dependent variable. Conventionally, as in the example shown in Figure 42.1, one places the independent variable in the vertical axis and the dependent variable in the horizontal axis. In this example we have taken fifty cases of hours of study and student performance, and have constructed a scatterplot to show the distributions (SPSS performs this function at the click of two or three keys). We have also constructed a line of best fit (SPSS does this easily) to indicate the relationship between the two variables. The line of best fit is the closest straight line that can be constructed to take account of variance in the scores, and strives to have the same number of cases above it and below it and to make each point as close to the line as possible; for example, one can see that some scores are very close to the line and others are some distance away.

One can observe that the greater the number of hours spent in studying, generally the greater the level of achievement. This is akin to correlation. The line of

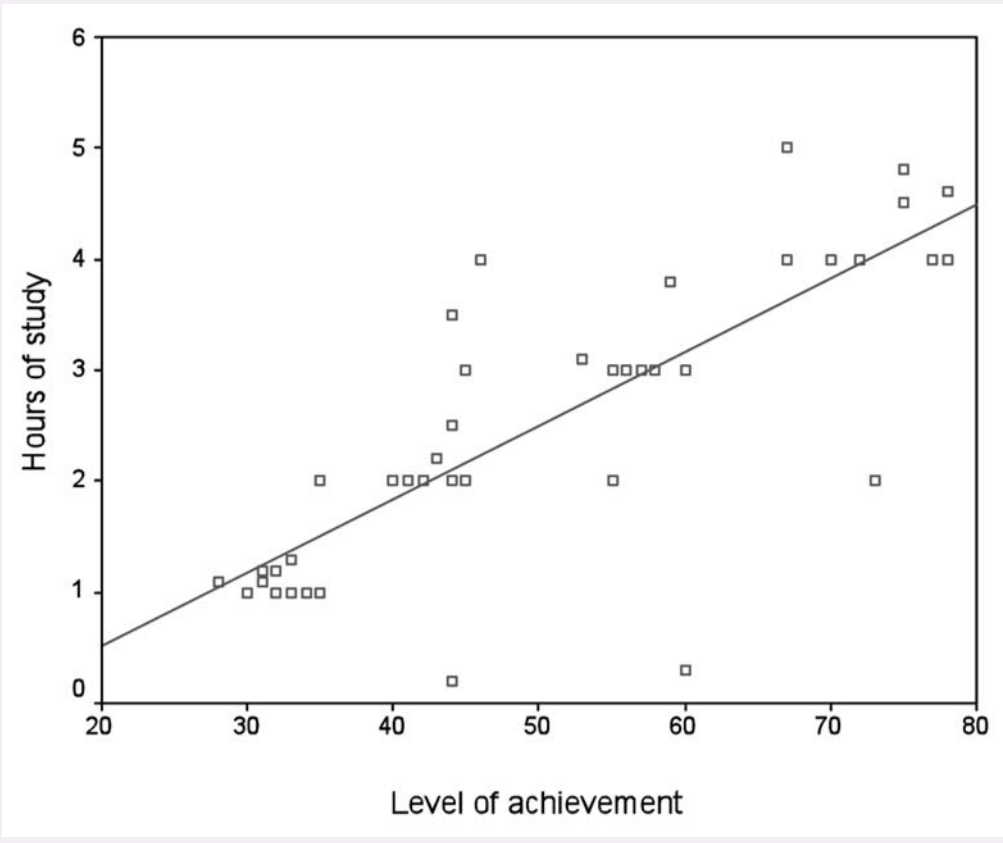

FIGURE 42.1 A scatterplot with the regression line (SPSS output)

best fit indicates not only that there is a positive relationship but that the slope of the line is quite steep. However, where regression departs from correlation is that regression provides an exact prediction of the value – the amount – of one variable when one knows the value of the other. One can read off the level of achievement, for example, if one were to study for two hours (43 marks out of 80) or for four hours (72 marks out of 80), of course, taking no account of variance. To help here, scatterplots (e.g. in SPSS) can insert grid lines.

It is dangerous to predict *outside* the limits of the line; simple regression is only used to calculate values *within* the limits of the actual line, and not beyond it. One can observe also that, though it is possible to construct a straight line of best fit (SPSS does this automatically), some of the data points lie close to the line and some lie a long way from the line; the distance of the data points from the line is termed the residuals, and this would have to be commented on in any analysis. A residual is the difference between the predicted and the actual score on the dependent variable (the distance from an actual score to the line of best fit). Ideally the residuals should be small, i.e. all the data points (values) on the graph should be close to the line of best fit (homoscedasticity), with few, if any, large exceptions (outliers or exceptional cases).

Where the line of best fit strikes the vertical axis is named the *intercept*. We return to this later, but at this stage we note that the line does not go through the origin (the 'zero') but starts a little way up the vertical line. In fact this is all calculated automatically by SPSS.

Let us look at a typical SPSS output shown in Table 42.1. This table provides the R square. The R square tells us how much variance in the dependent variable is explained by the independent variable in the calculation. First it gives us an R square value of 0.632, which indicates that 63.2 per cent of the variance is accounted for in the model, which is high. The 'Adjusted R square' is more accurate, and we advocate its use, as it automatically takes account of the number of independent variables. The Adjusted R square is usually smaller than the unadjusted R square, as it also takes account of the fact that one is looking at a sample rather than the whole population. Here the Adjusted R square is 0.625, and this shows that in the regression model that we have constructed, the independent variable accounts for 62.5 per cent of the variance in the dependent variable, which is high, i.e. our regression model is robust. Muijs (2004, p. 165) suggests that, for a goodness of fit from an Adjusted R square:

<0.1: poor fit
0.11–0.3: modest fit
0.31–0.5: moderate fit
>0.5: strong fit

SPSS then calculates the Analysis of Variance (ANOVA) (see Table 42.2). At this stage we will not go into all of the calculations here (typically SPSS prints out far more than researchers may need; for a discussion of df (degrees of freedom) we refer readers to Chapter 41). We go to the final column here, marked 'Sig.'; this is the significance level, and, because the significance is 0.000, we have a statistically significant relationship (stronger than 0.001) between the independent variable (hours of study) and the dependent variable (level of achievement), i.e. the relationship is not simply by chance.

All of this tells us that it is useful to proceed with the analysis. SPSS then gives us a table of coefficients, both unstandardized and standardized (Table 42.3). Here we advise researchers to opt for the standardized coefficients, the Beta weightings, as this gives greater precision, comparability and accuracy. The Beta weight (β) is the amount of standard deviation unit of change in the dependent variable for each standard deviation unit of change in the independent variable. In Table 42.3, the Beta weighting is 0.795; this tell us that, for every standard deviation unit change in the independent

TABLE 42.1 A SUMMARY OF THE R, R SQUARE AND ADJUSTED R SQUARE IN REGRESSION ANALYSIS (SPSS OUTPUT)

	Total	11050.500	49			

a. Predictors: (Constant), Hours of study

b. Dependent Variable: Level of achievement

variable (hours of study), the dependent variable (level of achievement) will rise by 0.795 (79.5 per cent) of one standard deviation unit, i.e. in layperson's terms, for every one unit rise in the independent variable there is just over three-quarters of a unit rise in the dependent variable. This also explains why the slope of the line of best fit is steep but not quite 45 degrees – each unit of one is worth only 79.5 per cent of a unit of the other (Table 42.3).

Table 42.3 also indicates that the results are highly statistically significant (the 'Sig.' column (0.000) reports a significance level stronger than 0.001). Table 42.3 also includes a 'constant'; this is an indication of the vertical scale point where the line of best fit strikes the vertical axis, the intercept; the constant is sometimes taken out of subsequent analyses.

In reporting the example of regression, one could use a form of words thus:

> A scattergraph of the regression of hours of study on levels of achievement indicates a linear positive relationship between the two variables, with an Adjusted R square of 0.625. A standardized beta coefficient (β) of 0.795 is found for the variable 'hours of study', which is statistically significant ($\rho < 0.001$).

In simple regression the Beta (β) is the measure of effect size, as it is a correlation coefficient. The three main pieces of information to look for in a simple regression are (i) the Adjusted R square; (ii) the ANOVA significance level; and (iii) the Beta (β) value.

Box 42.1 presents the SPSS command sequence for simple regression.

42.3 Multiple regression

In linear regression we are able to calculate the effect of one independent variable on one dependent variable. However, it is often useful to be able to calculate the effects of two or more independent variables on a dependent variable. Multiple regression enables researchers to predict and weight the relationship between two or more *explanatory* – independent – variables and an *explained* – dependent – variable. We know from the previous example that the Beta (β) weighting gives an indication of how many standard deviation units will be changed in the dependent variable for each standard deviation unit of change in each of the independent variables. The Beta, as before, is the measure of effect size here.

TABLE 42.3 THE BETA COEFFICIENT IN A REGRESSION ANALYSIS (SPSS OUTPUT)

Coefficients[a]

a. Dependent Variable: Level of achievement

BOX 42.1 SPSS COMMAND SEQUENCE FOR SIMPLE REGRESSION

The SPSS commands for simple regression are in two stages. The first stage is to create a scatterplot, using these commands: 'Graphs' → 'Legacy Dialogs' → 'Scatter/Dot' → 'Simple Scatter' → 'Define' → Send over the dependent variable to the 'Y Axis' box and the independent variable to the 'X Axis' box → Click 'OK'. Edit the content by placing the cursor inside the scattergraph and right-clicking to create the SPSS command: 'Edit Content in separate window' → Click 'Add Fit line at Total' → Close the 'Edit' window. This creates the scattergraph. Then run the regression: 'Analyze' → 'Regression' → 'Linear' → Send the dependent variable to the 'Dependent' box and the independent variable to the 'Independent' box → Click 'Statistics' → Check the boxes 'Confidence Intervals', 'Select Descriptives', 'Part and Partial Correlations' and deselect 'Model Fit' → Click 'Continue' → Click 'OK'.

Let us take a worked example. An examination mark may be the outcome of study time and intelligence (Figure 42.2), and the formula here is:

Examination mark = β hours of study + β intelligence

Let us say that the β for hours of study is calculated by SPSS to be 0.65, and the β for intelligence is calculated to be 0.30. These are the relative weightings of the two independent variables. We wish to see how many marks in the examination a student will obtain who has an intelligence score of 110 and who studies for thirty hours per week. The formula becomes:

Examination mark
$= (0.65 \times 30) + (0.30 \times 110) = 19.5 + 33 = 52.5$

If the same student studies for forty hours then the examination mark could be predicted to be:

Examination mark
$= (0.65 \times 40) + (0.30 \times 110) = 26 + 33 = 59$

This enables the researcher to see the exact predicted effects of a particular independent variable on a dependent variable, when other independent variables are also present. In SPSS the constant is also calculated and this can be included in the analysis, to give the following, for example:

Examination mark = β hours of study + β intelligence + constant

Let us give an example with SPSS with more than two independent variables. Imagine that we wish to see how much improvement will be made to an examination mark from a given number of hours of study together with measured intelligence (e.g. IQ) and level of interest in the subject studied. We know from the previous example that the Beta weighting (β) gives us an indication of how many standard deviation units will be changed in the dependent variable for each standard deviation unit of change in each of the independent variables. The equation is:

Level of achievement in the examination = β hours of study + β IQ + β level of interest in the subject + constant

The constant is calculated automatically by SPSS. Each of the three independent variables – hours of study, IQ and level of interest in the subject – has its own Beta (β) weighting in relation to the dependent variable: level of achievement.

If we calculate the multiple regression using SPSS we obtain several tables of results (using fictitious data on fifty students) which we address here.

First, for Table 42.4, the Adjusted R square is very high indeed (0.975), indicating that 97.5 per cent of the variance in the dependent variable is explained by the independent variables, which is extremely high. Table 42.5 indicates that the Analysis of Variance is highly statistically significant (0.000), indicating that the relationship between the independent and dependent variables is very strong, i.e. not by chance.

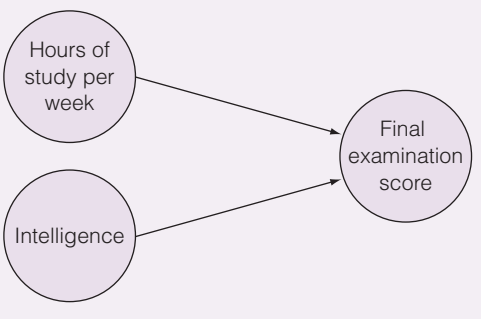

FIGURE 42.2 Multiple regression to determine relative weightings

TABLE 42.4 A SUMMARY OF THE R, R SQUARE AND ADJUSTED R SQUARE IN MULTIPLE REGRESSION ANALYSIS (SPSS OUTPUT)

Model Summary

Model	R	R Square	Adjusted R Square	Std. Error of the Estimate
1	.988[a]	.977	.975	2.032

a. Predictors: (Constant), Level of interest in the subject, Intelligence, Hours of study

TABLE 42.5 SIGNIFICANCE LEVEL IN MULTIPLE REGRESSION ANALYSIS (SPSS OUTPUT)

ANOVA[b]

Model		Sum of Squares	df	Mean Square	F	Sig.
1	Regression	7969.607	3	2656.536	643.116	.000[a]
	Residual	190.013	46	4.131		
	Total	8159.620	49			

a. Predictors: (Constant), Level of interest in the subject, Intelligence, Hours of study

b. Dependent Variable: Level of achievement

The Beta (β) weighting of the three independent variables is given in the 'Standardized Coefficients' column of Table 42.6. The constant is given as 1.996.

It is important to note here that the Beta weightings for the three independent variables are calculated *relative to* each other rather than independent of each other. Hence we can say that, relative to each other:

- the independent variable 'hours of study' has the strongest positive effect on ($\beta = 0.920$) on the level of achievement, and this is statistically significant (the column 'Sig.' indicates that the level of significance, at 0.000, is stronger than 0.001);
- the independent variable 'intelligence' has a negative effect on the level of achievement ($\beta = -0.062$) but this is not statistically significant (at 0.644, $\rho > 0.05$);

TABLE 42.6 THE BETA COEFFICIENTS IN A MULTIPLE REGRESSION ANALYSIS (SPSS OUTPUT)

Coefficients[a]

Model		Unstandardized Coefficients		Standardized Coefficients	t	Sig.
		B	Std. Error	Beta		
1	(Constant)	21.304	10.675		1.996	.052
	Hours of study	9.637	1.863	.920	5.173	.000
	Intelligence	-6.20E-02	.133	-.062	-.466	.644
	Level of interest in the subject	.116	.135	.131	.858	.395

a. Dependent Variable: Level of achievement

- the independent variable 'level of interest in the subject' has a positive effect on the level of achievement $\beta = 0.131$), but this is not statistically significant (at 0.395, $\rho > 0.05$);
- the only independent variable that has a statistically significant effect (i.e. not by chance) on the level of achievement is 'hours of study'.

So, for example, with this knowledge, if we knew the hours of study, the IQ and the level of measured interest of a student, we could predict his or her expected level of achievement in the examination.

Box 42.2 provides the command sequence for multiple regression in SPSS.

Running the safety checks in multiple regression in SPSS

Safety checks here include checks for:

- sample size, random sampling and parametric data (can be checked before deciding whether to embark on multiple regression);
- collinearity;
- normality, linearity and homoscedasticity;
- outliers and distributions;
- residual scatterplot analysis.

We address below those areas which can only be conducted once the initial multiple analysis has been run (the last four bullet points above).

In the SPSS output that results from the command sequence, check for collinearity: (a) look at the table called 'Correlations', where the correlation coefficients between each independent variable and the dependent variable should be between 0.3 and 0.7; (b) look at the table called 'Coefficients' where the figures in the column labelled 'Tolerance' should be higher than 0.10 and the figures in the column labelled the 'Variance Inflation Factor' ('VIF') should be lower than 10. An example of this is given in Table 42.7, where the dependent variable 'Mathematics test score' is correlated with two independent variables 'How hard do you work for mathematics' and 'How many hours a week do you spend on your mathematics homework'. Here the Tolerance is 0.991 and the VIF is 1.009, both of which are 'safe'.

In the SPSS output, check for normality, linearity and homoscedasticity: (a) the points in the 'normal probability plot' (automatically produced by SPSS) should lie in a reasonably straight line running from the bottom left to the top right (linearity) and they should be close to the line of best fit (normality) and evenly distributed above and below the line (homoscedasticity) (Figure 42.3 gives an example of this).

In the output from SPSS, look at the scatterplot (automatically produced by SPSS). An example of this is given in Figure 42.4. Here the residuals are approximately rectangularly distributed with the centre of the box being in a straight line with the horizontal axis centre-point and the vertical axis centre point both going through zero.

In the SPSS output, check for outliers. Go to the table 'Residuals Statistics' (see Table 42.8 for an example of this). Go to the Mahalanobis Distance ('Mahal. Distance') (to identify outliers) to see if the figure is lower than the critical value; a table of critical values of chi-square is necessary here, and is available in most statistics textbooks or online. In the SPSS data file a new variable has been created in the data file (MAH_1). Go to the table of critical values of chi-square (provided in soft copy on the companion website), and use $\rho = 0.001$ as a significance level. In this instance there are two independent variables, for $\rho = 0.001$ the value is 13.82. But the 'Mahal. Distance' maximum here is 15.639, i.e. higher than the chi-square critical value; this is a problem. To solve this problem, go back to the Data Editor in SPSS, then Sort Cases, then sort by the new variable at the bottom of the data file (Mahalanobis Distance, MAH-1) in 'Descending' order. In the Data View window, the case with the

BOX 42.2 SPSS COMMAND SEQUENCE FOR MULTIPLE REGRESSION

To run multiple regression in SPSS, the command sequence is: 'Analyze' → 'Regression' → 'Linear'. Send over dependent variable to the 'Dependent' box. Send over independent variables to the 'Independent' box → Click 'Statistics'. Tick the boxes 'Estimates', 'Confidence Intervals', 'Model fit', 'Descriptives', 'Part and partial correlations', 'Collinearity diagnostics', 'Casewise diagnostics' and 'Outliers outside 3 standard deviations' → Click 'Continue' → Click 'Options' → Click 'Exclude cases pairwise' → Click 'Continue' → Click 'Plots'. Send over *ZRESID to the 'Y' box. Send over *ZPRED to the 'X' box → Click 'Normal probability plots' → Click 'Continue' → Click 'Save' → Click the 'Mahalanobis' box and the 'Cook's' box → Click 'Continue' → Click 'OK'. For further discussion of the SPSS commands and analysis of output we refer the reader to Pallant (2016, chapter 13) and Tabachnick and Fidell (2013, chapter 5).

largest Mahalanobis Distance value will be at the top of the data file. If there are only a few then this is not a problem, but if there are many, or if the Mahalanobis Distance greatly exceeds the critical values, then consider removing those cases (there are only six cases here, so it is probably safe).

In the SPSS output, check for distributions and outliers in respect of the standardized residuals values: Table 42.9 provides the 'Casewise Diagnostics', i.e. the cases which are outside the normal range. Here cases number 9, 15, 22, 28, 133 and 350 in the SPSS file are outside the range and should be considered for removal. You can check to see if these outliers are exerting an undue influence on the results by going to the 'Cook's Distance' (Table 42.8); here the Cook's distance is 0.107, i.e. it is 'safe', as it should not exceed 1. If there is a problem then, as with the Mahalanobis Distance, go back to the SPSS data file and then sort cases in descending order, and then remove the 'offenders'.

In working with multiple regression then, using SPSS, there are six stages:

Stage 1: Conduct those 'safety checks' which can be conducted before the calculations proceed (e.g. random sampling, sample size).
Stage 2: Run the multiple regression.
Stage 3: Conduct the 'safety checks' once you have data (e.g. SPSS output): collinearity (correlation, Tolerance and VIF); normality; linearity; homoscedasticity; residuals scatterplot analysis (rectangular shape with centres of the rectangles on the

TABLE 42.9 CASEWISE DIAGNOSTICS (OUTLIER CASES) (SPSS OUTPUT)

centre-points of the vertical and horizontal axes); outliers (remove them if necessary), with the Mahalanobis Distance and the Cook's Distance; standardized residuals values (Casewise diagnostics).

Stage 4: Note the Adjusted R square (to see the amount of explained variance that the independent variables have on the dependent variable). The R square is the multiple correlation coefficient squared. The Adjusted R square is the R square adjusted to take account of the sample size and the number of independent variables (it usually reduces the R square a little).

Stage 5: Check ANOVA and its significance level (to see if the model is statistically significant).

Stage 6: Note the Standardized Beta coefficients (β) and their statistical significance levels. The Standardized Beta Coefficient is the standardized regression coefficient. This tells you the amount of relative weight of each of the independent variables on the dependent variable so researchers can see which independent variable exerts more or less weight than the others. The standardized beta values indicate the number of standard deviations that scores in the dependent variable would change if there was one standard deviation unit change in the independent variable.

Multiple regression is useful in that it can take in a range of variables and enable researchers to calculate their relative weightings on a dependent variable. However, one has to be cautious: adding or removing variables affects their Beta coefficients. Morrison (2009, pp. 40–1) gives the example of Beta coefficients concerning the relative effects of independent variables on teacher stress (Table 42.10).

In Table 42.10 one can see the relative strengths (i.e. when one factor is considered in relation to the others included) of the possible causes of stress. It appears that 'teacher voice and support' exert the strongest influence on the outcome ('levels of stress') (beta of 0.323), followed by 'benefits and rewards' of teaching (beta of 0.205), then 'stress reproducing stress' (beta of 0.164) (i.e. the feeling of stress causes yet more stress), followed by 'burnout' (beta of 0.157), 'managing students' (beta of 0.116) and so on down the list. However, if we remove those variables connected with family ('family

TABLE 42.10 RELATIVE BETA WEIGHTINGS OF INDEPENDENT VARIABLES ON TEACHER STRESS (SPSS OUTPUT)

Beta Coefficients

	Standardized Coefficients	Significance level
	Beta	
Teacher voice and support	.323	.000
Workload	.080	.000
Benefits and rewards of teaching	.205	.000
Managing students	.116	.000
Challenge and debate	.087	.000
Family pressures	.076	.000
Considering leaving teaching	.067	.000
Emotions and coping	.044	.000
Burnout	.157	.000
Balancing work, family and cultural expectations	.100	.000
Local culture	.071	.000
Stress from family	.058	.000
Stress reproducing stress	.164	.000
Control and relationships	.092	.000

pressures', 'balancing work, family and cultural expectations' and 'stress from family') then the relative strengths of the remaining factors alter (see Table 42.11). In this revised situation (Table 42.11), the factor 'teacher voice and support' has slightly less weight, 'benefits and rewards of teaching' have added strength, and 'control and relationships' take on much greater strength.

On the other hand, if one adds in new independent variables ('principal behaviour' and 'clarity of jobs and goals') then the relative strengths of the variables alter again, as shown in Table 42.12. In this table the variable 'principal behaviour' greatly over-rides the other factors, and the order of the relative strengths of the other factors alters.

The point here is that the Beta coefficient (weightings) vary according to the independent variables included.

Further, variables may interact with each other and may be intercorrelated (the issue of multicollinearity), for example, Gorard (2001b, p. 172) suggests that poverty and ethnicity are likely to be correlated. If collinearity is discovered (e.g. if correlation coefficients between variables are higher than 0.80) then the researcher should consider removing one of the highly correlated variables, though caution has to be exercised here: the variable might be too important to remove, in which case Gorard advises researchers to create a single new variable that combines both previously intercorrelated variables.

SPSS automatically removes variables where there is strong covariance (collinearity). Muijs (2004) indicates that, in SPSS, one can find multicollinearity by looking at 'Collinearity Diagnostics' in the 'Statistics' command box of SPSS, and in the collinearity statistics, one should look at the 'Tolerance' column on the output. He indicates that values will vary from 0 to 1, and the higher the value the less is the collinearity, whereas a value close to 0 indicates that nearly all the variance in the variable is explained by the other variables in the model. For further discussion of collinearity, collinearity diagnostics and tolerance of collinearity, we refer the reader to Pallant (2016, chapter 13).

In reporting multiple regression, in addition to presenting tables (often of SPSS output), one can use a form of words thus, for example:

> Multiple regression was used, and the results include the adjusted R square (0.975), ANOVA ($\rho < 0.001$) and the standardized β coefficient of each component variable. Relative to each other, 'hours of study' exerted the greatest influence on level of achievement ($\beta = 0.920$, $\rho < 0.001$), 'level of interest' exerted a small and statistically insignificant influence on level of achievement ($\beta = 0.131$, $\rho = 0.395$), and 'intelligence' exerted a negative but statistically insignificant influence on level of achievement ($\beta = -0.062$, $\rho = 0.644$).

Control and relationships	.086	.000

One variant of multiple regression is stepwise multiple regression. Here the computer enters variables one at a time, in a sequence, to see which adds to the explanatory power of a model, by looking at its impact on the R-squared – whether it increases the R-square value. This alternative way of entering variables and running the SPSS analysis in a 'stepwise' sequence is the same as above, except that in the 'Method' box the word 'Enter' should be replaced, in the drop-down box, with 'Stepwise'. In stepwise multiple regression the computer, not the researcher decides the order in which the independent variables are entered on the basis of significance testing and statistical computation (and this attracts criticism from some authors, e.g. Tabachnick and Fidell (2013) and Pallant (2016)). For working with stepwise regression we refer readers to these two sources.

Another type of multiple regression is logistic regression. It enables the researcher to work with categorical variables in a multiple regression where the dependent variable is a categorical variable with two or more values. Here the independent variables may be categorical, discrete or continuous. Logistic regression uses a Maximum Likelihood Estimation to produce a value between 0.0 and 1.0 which indicates the probability of the outcome. It does not require normality of distributions, but it is sensitive to outliers and collinearity.

Box 42.3 provides the command sequence for logistic regression in SPSS.

For more on logistic regression we refer the reader to Pallant (2016, chapter 14) and Tabachnick and Fidell (2013).

42.4 Standardized scores

Many forms of difference tests (see Chapter 41) and regression analysis with parametric data prefer to work with standardized scores, and we introduce these here. Imagine the following scenes:

1 Student (1) comes home from school and tells his parents that he scored a mark of 75 for a mathematics test; his parents berate him.

BOX 42.3 SPSS COMMAND SEQUENCE FOR LOGISTIC REGRESSION

To run logistic regression in SPSS, the command sequence is: 'Analyze' → 'Regression' → 'Binary Logistic' → Insert dependent variable in the 'Dependent' box → Insert independent variables into the 'Covariates' box → Click on 'Categorical' → Move your first categorical variable into the 'Categorical Covariates' box → Click the radio button 'First' → Click the 'Change' button → Repeat this for every categorical variable → Click 'Continue' to return to the first screen → Click 'Options' → Click the boxes 'Classification plots', 'Hosmer-Lemeshow goodness of fit', 'Casewise listing of residuals' and 'CI for Exp(B) → Click 'Continue' to return to the first screen → Click 'OK'.

2 Student (2) comes home from school and tells his parents that he scored a mark of 8 for a history test; his parents praise him.
3 Student (3) comes home from school and tells his parents that he scored a mark of 25 for an English test and a mark of 60 for a physics test; his parents praise him for both.
4 Student (4) comes home from school and tells his parents that he scored a mark of 80 for a geography test and a mark of 120 for a chemistry test; his parents berate him for both.

How can we explain these apparently discrepant behaviours? In the examples here we do not know the scales used, the range of scores, the means and the distributions around the means. For example, the student (1) scored 75 for his maths test and was berated because the mean score was 144 and the range was from 75 to 200, i.e. he scored very low on the test. On the other hand, student (2) scored 8 for his history test and was praised because that was the highest mark in the test, with an average mark of 4 out of a possible 10, and a range of 1 to 8. In the case of student (3) who was praised for scoring two very different marks (25 and 60), this was because the scales and range for the two tests varied, whereas student (4) who scored 80 for geography and 120 for chemistry was berated because both tests were marked out of 300 and the average mark for both was 220.

These examples show the need for researchers to compare like with like in using numerical data and scores. We need to know how to judge whether a mark is high or low and how to compare marks between one test and another. Therefore we need to know the *scale* of the marks, the *range* of the marks, the *mean* of the marks and the *distribution* of the marks either side of the mean. We need to know how to compare marks from a test which:

- uses one *scale* with marks from a test which uses another scale;
- has one *range* of marks with marks from a test that has another range of marks;
- has a *mean* which is different from the mean of another test;
- has a *distribution* around the mean which is different from the distribution of another test.

This is addressed by converting scores into standardized scores. Standardizing scores enables the researcher to judge whether a mark is high or low; it enables the researcher to compare marks between one test and another when two different tests have different scales, range, means and distributions around the mean. To standardize scores is to convert them into z-scores; z-scores have the same mean and standard deviation, even though the original sets of scores had different means and standard deviations, i.e. z-scores let researchers compare scores fairly. A z-score tells us how many standard deviations someone's scores lies above or below the mean. By standardizing different sets of scores (usually either a mean of zero and a standard deviation of one), this enables the researcher to compare like with like, to compare scores fairly.

To calculate the z-score we subtract the mean from the raw score and divide that answer by the standard deviation. The formula is thus:

$$z = \frac{\text{the actual score} - \text{the mean of the sample}}{\text{standard deviation of the sample}}$$

$$= \frac{x_i - \bar{x}}{s}$$

For example, if the raw (unadjusted) score is 15, the mean is 10 and the standard deviation is 4, then the standardized score is (15–10)/4=(5 ÷ 4)=1.25. Here the z-score tells us that the person's score is +1.25 standard deviations above the mean. However, we do not know whether this is a good score, a bad score, or, indeed, what it means. We need to see how this compares with other scores on the same distribution. Figure 42.5 plots the standardized scores on the normal curve of distribution, with the mean score of 0 (zero) and the standard deviation of 1, and marks the score of +1.25 on that diagram.

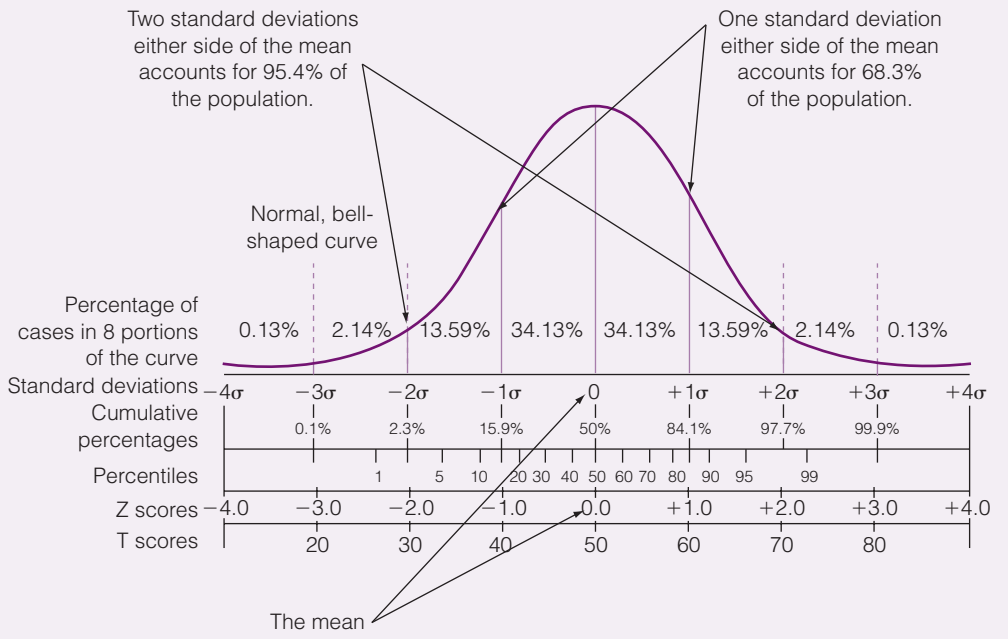

FIGURE 42.5 Standardizing scores

Looking at Figure 42.5, in our example, the person who scores +1.25 has scored very well. Had she scored 1 then she would have been better than 84.12 per cent of the population (34.13+34.13+13.59+2.14+0.13= 84.12): the percentage of people below her (see the lines marked 'Percentages of cases in 8 portions of the curve', 'Cumulative percentages' and 'Percentiles' in Figure 42.5). We know that she is higher than one standard deviation above the mean (she has scored 1.25, not 1), so we need to find where her score places her in terms of the rest of the population. For an exact indication of where she stands in relation to the rest of the population we can turn to statistical tables concerning 'areas under the normal curve' (on the Internet and in the appendices of most statistics books). Then we can simply read off the results (see Table 42.13 for an extract from such a table).

Referring to Table 42.13, she has a z-score of 1.25, so we go to the left-hand column, to the row marked '1.2'. Then we go to the column marked '0.05', as this gives us the second decimal place of the '1.25'. Then we see the value 0.3944 (emboldened and shaded), i.e. the person is 39.44 per cent above the mean of zero. We know from Figure 36.5 that 49.99 per cent of people are below zero (34.13+13.59+2.14+0.13=49.99, usually rounded to 50 per cent); now we add to that the 39.44 per cent above zero, giving a total of 89.44 per cent (from the rounded figure of 50 per cent). This tells us that, for the person with the z-score of 1.25, only 10.56 per cent (100 per cent minus 89.44 per cent) of the population is above her, so her score is very high.

Using the same table for another example, if a person receives a z-score of 1.56 then the table gives us a

TABLE 42.13 EXTRACT FROM AREA UNDER THE NORMAL CURVE OF DISTRIBUTION

z	0.00	0.01	0.02	0.03	0.04	0.05	0.06	0.07	0.08	0.09
1.0	0.3413	0.3438	0.3461	0.3485	0.3508	0.3531	0.3554	0.3577	0.3599	0.3621
1.1	0.3643	0.3665	0.3686	0.3708	0.3729	0.3749	0.3770	0.3790	0.3810	0.3830
1.2	0.3849	0.3869	0.3888	0.3907	0.3925	**0.3944**	0.3962	0.3980	0.3997	0.4015
1.3	0.4032	0.4049	0.4066	0.4082	0.4099	0.4115	0.4131	0.4147	0.4162	0.4177
1.4	0.4192	0.4207	0.4222	0.4236	0.4251	0.4265	0.4279	0.4292	0.4306	0.4319
1.5	0.4332	0.4345	0.4357	0.4370	0.4382	0.4394	0.4406	0.4418	0.4429	0.4441

reading of 0.4406, i.e. 44.06 per cent. We know from Figure 42.5 that 49.99 per cent of people are below zero (34.13+13.59+2.14+0.13=49.99, usually rounded to 50 per cent); now we add to that the 44.06 per cent above zero, giving a total of 94.06 per cent from the rounded figure of 50 per cent. This tells us that for the person with the z-score of 1.56 only 5.94 per cent (100 per cent minus 94.06 per cent) of the population is above that score, so the score is extremely high.

An online calculator of this is at:

- www.danielsoper.com/statcalc/calculator.aspx?id=2.

This calculator gives the cumulative area under the curve (a figure as a decimal fraction that is less than 1 (let us call it *X*). To find the area under the curve beyond that one point simply subtract this figure from 1 (the formula, then, is *1–X*) and, for a percentage, multiply it by 100. Another equally straightforward free online calculator of the area under the curve, and the position of a given z-score in that curve is given at:

- http://stattrek.com/online-calculator/normal.aspx.

Box 42.4 provides the SPSS command sequence for calculating standardized scores (z-scores).

Some people are uncomfortable with z-scores, as they do not like negative scores nor do they like an average being 0 (zero). To overcome this, z-scores can be converted to T-scores. To convert a z-score to a T-score, multiply the z-score by 10 and add 50 to the result. For example a z-score of 0.5, multiplied by 10 gives 5, and then, with 50 added, gives 55. The T-score is 55. Many IQ tests and standardized tests convert z-scores. For example, a common conversion in IQ tests is to multiply the z-score by 15 and add 100. So a z-score on an IQ test might be 0.5, multiplied by 15 gives 7.5, with 100 added gives 107.5, i.e. the IQ z-score converts to a T-score of 107.5.

Standardized scores are widely used in simple regression, as they enable researchers to compare different sets of scores on a fair basis.

42.5 Conclusion

This chapter has introduced several inferential statistics and their related concepts:

- simple regression and multiple regression (typical usage, stepwise regression and logistic regression);
- standardized scores and T-scores.

It has also included SPSS command sequences to run these statistics. Regression in all its forms is widely used in data analysis, and we commend it strongly to researchers. However, we also caution researchers to pay close attention to the several 'safety checks' before proceeding with regression analysis, together with confirmation that the assumptions underlying regression have been met. A widely used text on regression is Tabachnick and Fidell (2013).

BOX 42.4 SPSS COMMAND SEQUENCE FOR CALCULATING Z-SCORES

To calculate z-scores with SPSS, the command sequence is: 'Analyze' → 'Descriptive Statistics' → 'Descriptives' → 'Variables' → Click the box 'Save standardized values as variables' → Click 'OK'→ Two new variables will be created of the standardized scores.

Companion Website

The companion website to the book provides data files and PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.

Factor analysis, cluster analysis and structural equation modelling

CHAPTER 43

This chapter addresses statistics and procedures for:

- conducting factor analysis
- what to look for in factor analysis output
- cluster analysis
- a note on structural equation modelling
- a note on multilevel modelling

Some of these items have significant coverage (e.g. factor analysis and cluster analysis), whilst others are more by way of introduction (e.g. structural equation modelling and multilevel modelling).

Techniques for grouping several research variables into factors are many and various: one of the best-known grouping techniques is factor analysis. Factor analysis is a widely used statistical technique in data analysis, and we introduce it in this chapter. We move to a note on cluster analysis as a way of organizing people/groups rather than variables, and then close with some introductory remarks on structural equation modelling and multilevel modelling.

43.1 Conducting factor analysis

Factor analysis is a method of grouping together variables which have something in common. It is a process which enables the researcher to take a set of variables and reduce them to a smaller number of underlying (latent) factors which account for as many variables as possible. It detects structures and commonalities in the relationships between variables. Thus it enables researchers to identify where different variables in fact are addressing the same underlying concept. For example, one variable could measure somebody's height in centimetres; another variable could measure the same person's height in inches; the underlying factor that unites both variables is height; it is a latent factor that is indicated by the two variables.

Factor analysis can take two main forms: *exploratory factor analysis* and *confirmatory factor analysis*. The former refers to the use of factor analysis (principal components analysis in particular) to explore previously unknown groupings of variables, to seek underlying patterns, clustering and groups. By contrast *confirmatory factor analysis* is more stringent, testing a found set of factors against a hypothesized model of groupings and relationships. Such a model derives from pre-established theory which informs the generation of the model, and the confirmatory factor analysis tests a theory of the latent processes and relationships. This section introduces a widely used kind of factor analysis: principal components analysis.

The analysis here uses SPSS output, as it is commonly used by educational researchers in undertaking principal components analysis.

As an example of factor analysis, one could have the following variables in a piece of educational research:

1. Student demotivation.
2. Poor student concentration.
3. Undue pressure on students.
4. Narrowing effect on curriculum.
5. Punishing the weaker students.
6. Overemphasis on memorization.
7. Testing only textbook knowledge.

These seven variables can be grouped together under the single overarching factor of 'negative effects of examinations'. Factor analysis, working through multiple correlations, is a method for grouping together several variables under one or more common factor(s).

To address factor analysis in more detail we provide a worked example. Consider the following variables concerning school effectiveness:

1. The clarity of the direction that is set by the school leadership.
2. The ability of the leader to motivate and inspire the educators.
3. The drive and confidence of the leader.
4. The consultation abilities/activities of the leader.
5. The example set by the leader.
6. The commitment of the leader to the school.
7. The versatility of the leader's styles.
8. The ability of the leader to communicate clear, individualized expectations.

9 The respect in which the leader is held by staff.
10 The staff's confidence in the Senior Management Team.
11 The effectiveness of the teamwork of the Senior Management Team.
12 The extent to which the vision for the school impacts on practice.
13 Educators given opportunities to take on leadership roles.
14 The creativity of the Senior Management Team.
15 Problem-posing, problem-identifying and problem-solving capacity of the Senior Management Team.
16 The use of data to inform planning and school development.
17 Valuing of professional development in the school.
18 Staff consulted about key decisions.
19 The encouragement and support for innovativeness and creativity.
20 Everybody is free to make suggestions to inform decision-making.
21 The school works in partnership with parents.
22 People take positive risks for the good of the school and its development.
23 Staff voluntarily taking on coordination roles.
24 Teamwork among school staff.

Here we have twenty-four different variables and the question which might concern researchers here is 'are there any underlying groups of factors' ('latent variables') that can embrace several of these variables, or of which the several variables are elements or indicators? Factor analysis indicates whether there are. In what follows we distinguish *factors* from *variables*; a *factor* is an underlying or latent feature in which groups of variables are included; a *variable* is one of the elements that can be a member of an underlying factor. In our example here we have twenty-four variables and, as we shall see, five factors.

Let us imagine that we have gathered data from 1,000 teachers in several different schools, and we wish to see how the twenty-four variables above can be grouped, based on the teachers' voting (using ratio data by awarding marks out of ten for each of the variables). (This follows the rule that there should be more subjects in the sample than there are variables.)

In what follows we set out a five-stage model in conducting factor analysis:

Stage 1: safety checks;
Stage 2: data processing and initial analysis;
Stage 3: constructing the factors from the variables;
Stage 4: naming the factors;
Stage 5: reporting the factor analysis.

This takes researchers from setting up the factor analysis to conducting the processing and analysis, to reporting the results. We also provide readers with the SPSS command sequence for Principal Components Analysis (PCA).

Factor analysis (sometimes termed 'principal axis factoring') is not the same as PCA, even though the terms are frequently used interchangeably. A major difference between the two is that in PCA all the variance in the data is analysed whereas in factor analysis only the shared variance is analysed, thereby excluding unique variance (Dancey and Reidy, 2011, p. 457). Further, PCA is used for reducing a large set of variables into factors, whereas factor analysis is used in causal modelling, particularly in confirmatory factor analysis where a hypothesized model or theory of relationships is tested (p. 457). In this chapter we focus on PCA.

Stage 1: safety checks

The first stage in factor analysis is to conduct 'safety checks' to see if the data are suitable for factor analysis, and to check whether the assumptions underpinning factor analysis have been met. There are several assumptions that factor analysis makes, and these must be addressed fairly in deciding whether, in fact, it is safe to proceed with factor analysis (cf. Tabachnick and Fidell, 2013). Factor analysis uses correlations, and several of the comments below concern correlations (see Chapter 40 for a discussion of correlations).

- *Sample size.* The suggested sample size varies in the literature, from a minimum of 30 to a minimum of 300. Tabachnick and Fidell (2013) suggest that a sample size of 50 is very poor, 100 is poor, 200 is fair, 300 is good, 500 is very good and 1,000 is excellent; they suggest that 300 should be regarded as a general minimum, and if the sample size is small then the factor loadings (discussed later) should be high. Some authors suggest a minimum of 10 cases per variable, whilst others suggest a minimum of between 150 and 200 cases in total, regardless of the number of variables. Bryman and Cramer (1990, p. 255) suggest no fewer than 100 subjects in the total sample.
- *Number of variables.* It is important to have neither too few nor too many variables: too few and the extraction of the factors may only extract one or two variables per factor, and this gives very little 'added value'. Too many and the number of factors extracted could be so many as to be unhelpful in identifying underlying latent factors.

- *Ratio of sample size to number of variables.* Different ratios are given in literature, from 5:1 to 30:1.
- *Interval and ratio data*. Ordinal data may also be used if this does not distort the underlying metric scaling.
- *Sampling adequacy.* The Kaiser-Mayer-Olkin (KMO) measure of sampling adequacy, which correlates pairs of variables and the magnitude of partial correlations among variables and which requires many pairs of variables to be statistically significantly correlated, should yield an overall measure of 0.6 or higher (maximum is 1). If the KMO index is high (1.0) then Principal Components Analysis can be conducted; if it is low (around 0.0) then PCA is not relevant.
- *Intercorrelations between variables.* Correlation coefficients (see Chapter 40) between variables should be no less than 0.3, as below this the data may not be suitable for finding latent, underlying factors, as the variables are not sufficiently closely related. Factor analysis with only low intercorrelations between variables (indicated in a correlation matrix, discussed below) is likely to generate as many factors as there are original variables, and this defeats the original purpose of factor analysis which is to reduce data and to generate clusters containing several variables each. Above 0.6 and there may be problems of multicollinearity (see Chapter 41), and this can be identified in a correlation matrix, which SPSS automatically calculates, and variables removed before conducting the factor analysis. The Tolerance and Variation Inflation Factor (VIF) (see Chapter 42) screen for collinearity, though typically the KMO statistic, which conducts a series of partial correlations, can also be used here, and SPSS can run this automatically; this enables the distinctiveness (unrelatedness) of each factor to be assured. The Bartlett test of sphericity, which investigates the correlations between variables, should show statistical significance ($\rho < 0.05$) (mainly used where the number of cases per variable is five or fewer).
- *Intercorrelations between factors.* The factors should not be highly correlated with each other (the principle of orthogonality).
- *Normal distributions.* Factor analysis assumes a normal distribution (measured by kurtosis and skewness). It is particularly important to screen the data for normality if the sample is small.
- *Linearity.* Principal Components Analysis (PCA) assumes linear (straight line) relationships between variables rather than, for example, curvilinearity (see Chapter 40). It is important to screen the data for linearity, particularly if the sample size is small.
- *Outliers.* The presence of outliers can distort calculations in factor analysis. Researchers can use the Mahalanobis Distance calculation (see Chapter 42) to identify cases which are outliers and then remove them before conducting the factor analysis.
- *Selection bias/proper specification.* Excluding relevant variables and including irrelevant variables can affect the nature of the factors extracted. Researchers must decide carefully which variables to include and exclude in conducting factor analysis.
- *Theoretical underpinning of factors.* Factor analysis assumes that there are underlying dimensions which are shared by clusters of variables in order to extract a factor. This refers to the need for there to be a strong theoretical underpinning of the factors. Factor analysis cannot create valid factors if none exist in the original data; even though factor analysis can create factors, if they have little or no theoretical substance then they are likely to be worthless. Factors and their labels must have face validity and strong theoretical grounding.

If the data are suitable for factor analysis then the researcher can proceed.

Stage 2: data processing and initial analysis

The analysis in the example here assumes that the data are suitable for factor analysis to proceed and the material discussed below is based on SPSS processing and output. At first SPSS produces a correlation matrix so that the researcher can check the intercorrelations mentioned above. Then it produces a table of extracted factors (Table 43.1).

Though Table 43.1 seems to contain a lot of complicated data, in fact most of this need not trouble us at all. SPSS has automatically found and reported five factors for us through correlational analysis, and it presents data on these five factors (the first five rows of the chart, marked 'Component'). Table 43.1 takes the twenty-four variables (listed in order on the left hand column (Component)) and then it provides three sets of readings: Eigenvalues, Extraction Sums of Squared Loadings, and Rotation Sums of Squared Loadings. Eigenvalues are measures of the variance between factors, and are the sum of the squared loadings for a factor, representing the amount of variance accounted for by that factor. We are only interested in those Eigenvalues that are greater than 1, since those that are smaller than 1 generally are not of interest to researchers as they account for less than the variation explained by a single variable. Indeed SPSS automatically filters out for us the Eigenvalues that are greater than 1, using

TABLE 43.1 INITIAL SPSS OUTPUT FOR PRINCIPAL COMPONENTS ANALYSIS (SPSS OUTPUT)

Total Variance Explained

Component	Initial Eigenvalues			Extraction Sums of Squared Loadings			Rotation Sums of Squared Loadings		
	Total	% of Variance	Cumulative %	Total	% of Variance	Cumulative %	Total	% of Variance	Cumulative %
1	9.343	38.930	38.930	9.343	38.930	38.930	4.037	16.820	16.820
2	1.424	5.931	44.862	1.424	5.931	44.862	2.810	11.706	28.527
3	1.339	5.580	50.442	1.339	5.580	50.442	2.779	11.578	40.105
4	1.220	5.085	55.526	1.220	5.085	55.526	2.733	11.386	51.491
5	1.085	4.520	60.047	1.085	4.520	60.047	2.053	8.556	60.047

24	.207	.862	100.000						

Extraction Method: Principal Component Analysis.

the Kaiser criterion (in SPSS this is termed the Kaiser Normalization).

A scree plot can also be used at this stage, to identify and comment on factors (this is available at a keystroke in SPSS). A scree plot shows each factor on a chart, in descending order of magnitude of amount of variance explained. For researchers, the scree plot becomes interesting where it flattens out (like the rubble that collects at the foot of a scree), as this indicates very clearly which factors account for a lot of the variance, and which account for little. In the scree plot here shown in Figure 43.1 one can see that the scree flattens out considerably after the first factor, and then it levels out a little for the next four factors, tailing downwards all the time. This suggests that the first factor is the significant factor in explaining the greatest amount of variance.

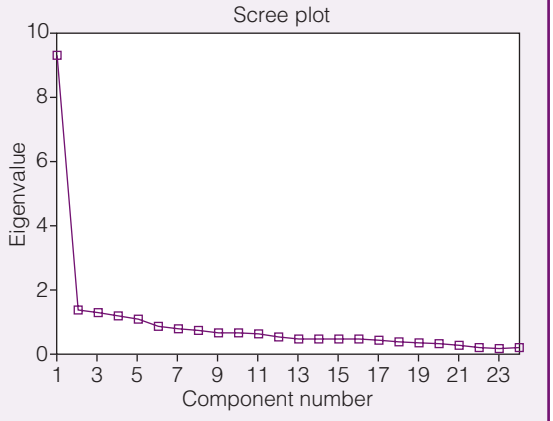

FIGURE 43.1 A scree plot (SPSS output)

In using the scree plot one can look for the 'bend in the elbow' of the data (after factor one), and then regard those factors above the bend in the elbow as being worthy of inclusion, and those below the bend in the elbow as being relatively unimportant. However, this is draconian, as it risks placing too much importance on those items above the bend in the elbow and too little importance on those below it. The scree plot adds little to the variance table presented above in Table 43.1, though it does enable one to see at a glance which are the significant and less important factors, or, indeed which factors to focus on (the ones before the scree levels off) and which to ignore.

Next we turn to the columns labelled 'Extraction Sums of Squared Loadings'. The Extraction Sums of Squared Loadings contain two important pieces of information. First, in the column marked '% of Variance' SPSS tells us how much variance is explained by each of the factors identified, in order from the greatest amount of variance to the least amount of variance. So, here the first factor accounts for 38.930% of the variance in the total scenario – a very large amount – whilst the second factor identified accounts for only 5.931 per cent of the total variance, a much lower amount of explanatory power. By showing us how much variance in the total picture is explained by each factor we can see which factors possess the most and least explanatory power – the power to explain the total scenario of twenty-four factors. Secondly, SPSS keeps a score of the cumulative amount of explanatory power of the five factors identified. In the column 'Cumulative' it tells us that in total 60.047 per cent of the total picture (of the twenty-four variables) is accounted for – explained – by the five factors identified. This is a moderate amount of explanatory power, and researchers would be happy with this.

The three columns under 'Extraction Sums of Squared Loadings' give us the initial, rather crude, unadjusted percentage of variance of the total picture explained by the five factors found. These are crude in the sense that the full potential of factor analysis has not been caught. What SPSS has done here is to plot the factors on a two-dimensional chart (which it does not present in the data output) to identify groupings of variables, the two dimensions being vertical and horizontal axes as in a conventional graph such as a scattergraph. On such a two-dimensional chart some of the factors and variables could be plotted quite close to each other, such that discrimination between the factors would not be very clear. However, if we were to plot the factors and variables on a three-dimensional chart that includes not only horizontal and vertical axes but also *depth* by *rotating* the plotted points through ninety degrees, then the effect of this would be to bring closer together those variables that are similar to each other and to separate them more fully – in distance – from those variables that have no similarity to them, i.e. to render each group of variables (factors) more homogeneous and to separate more clearly one group of variables (factor) from another group of variables (factor). The process of rotation keeps together those variables that are closely interrelated and keeps them apart from those variables that are not closely related. This is represented in Figure 43.2.

This distinguishes more clearly one factor from another than that undertaken in the Extraction Sums of Squared Loadings.

Rotation can be conducted in many ways (Tabachnick and Fidell, 2013), of which there are two main forms:

- Direct Oblimin: which is used if the researcher believes that there may be correlations between the *factors* (an oblique, correlated) rotation;
- Varimax rotation: which is used if the researcher believes that the *factors* may be uncorrelated (orthogonal).

Pallant (2016) argues for the importance of researchers giving strong consideration to the Direct Oblimin rotation. Even though it is more difficult to interpret, it is often actually more faithful to the correlated nature of the data and factors. The default setting in SPSS is the orthogonal, Varimax rotation, and this may misrepresent existing correlations between the factors, even though it is easier to analyse. Indeed Pallant (2016) suggests starting with Direct Oblimin rotation.

Rotation in the example here is undertaken by *Varimax rotation*. This maximizes the variance between factors and hence helps to distinguish them from each other. In SPSS the rotation is called *orthogonal* because

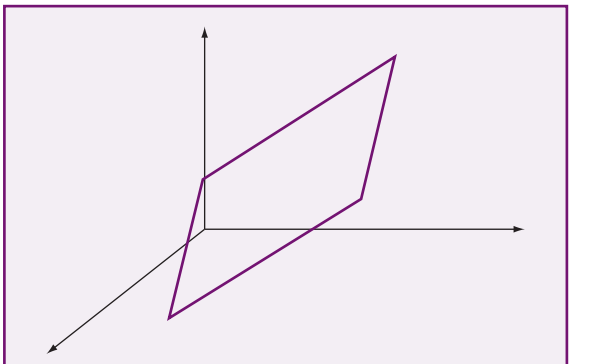

FIGURE 43.2 Three dimensional rotation

the factors are unrelated to, and independent of, each other.

In the column 'Rotation Sums of Squared Loadings' the fuller power of factor analysis is tapped, in that the rotation of the variables from a two-dimensional to a three-dimensional chart has been undertaken, thereby identifying more clearly the groupings of variables into factors, and separating each factor from the other much more clearly. We advise researchers to use the Rotation Sums of Squared Loadings rather than the Extraction Sums of Squared Loadings. With the Rotation Sums of Squared Loadings the percentage of variance explained by each factor is altered, even though the total cumulative percentage (60.047 per cent) remains the same. For example, the first factor in the rotated solution no longer accounts for 38.930 per cent as in the Extraction Sums of Squared Loadings, but only 16.820 per cent of the variance; factors 2, 3 and 4, which each only accounted for just over 5 per cent of the variance in the Extraction Sums of Squared Loadings now each account for over 11 per cent of the variance; and factor 5, which accounted for 4.520 per cent of the variance in the Extraction Sums of Squared Loadings now accounts for 8.556 per cent of the variance in the Rotation Sums of Squared Loadings.

By the end of this second stage we can see that:

1. factor analysis brings variables together into homogeneous and distinct groups, each of which is a factor and each of which has an Eigenvalue of greater than 1;
2. factor analysis in SPSS indicates the amount of variance in the total scenario explained by each individual factor and all the factors together (the cumulative percentage);
3. the Rotation Sums of Squared Loadings is preferable to the Extraction Sums of Squared Loadings.

We are ready to proceed to the third stage.

Stage 3: constructing the factors from the variables

Stage 3 consists of presenting a matrix of all of the relevant data and variables for the researcher to identify which variables belong to which factor (Table 43.2). SPSS presents what at first sight is a bewildering set of data, but the reader is advised to keep cool and to look at the data slowly, as, in fact, they are not complicated. SPSS often presents researchers with more data than they need, overwhelming the researcher with data. In fact the data in Table 43.2 are comparatively straightforward.

Across the top of the matrix in Table 43.2 we have a column for each of the five factors (1–5) that SPSS has found for us. The left-hand column prints the names of each of the twenty-four variables with which we are working. We can ignore those pieces of data which contain the letter 'E' (exponential), as these contain figures that are so small as to be able to be discarded. Look at the column labelled '1' (factor 1). Here we have a range of numbers, from 0.114 (for the variable 'Teamwork amongst school staff') to 0.758 (for the variable 'The drive and confidence of the leader'). The researcher now has to use her professional judgement to decide what the 'cut-off' points should be for inclusion in the factor. Not all twenty-four variables will appear in factor 1, only those with high values (factor loadings – the amount that each variable contributes to the factor in question). The decision on which variables to include in factor 1 is not a statistical matter but a matter of professional judgement, informed by theory and judgements about whether the variables 'hang together' – cluster – in a single factor. Factor analysis is an art as well as a science. The researcher has to find those variables with the highest values (factor loadings) and include those in the factor. The variables chosen should not only have high values but also have values that are conceptually and numerically close to each other (homogeneous) and which are some numerical distance away from the other variables. In the column labelled '1' we can see that there are seven such variables, and we set these out in the example below. Other variables from the list are some numerical distance away from the variables selected (see below) and also seem to be conceptually unrelated to the seven variables identified for inclusion in the factor. The variables selected are high, close to each other both numerically and conceptually, and distant from the other variables. The lowest of these seven values (factor loadings) is 0.513; hence the researcher would report that seven variables had been selected for inclusion in factor 1, and that the cut-off point was 0.51 (i.e. the lowest point, above which the variables have been selected). Having such a high cut-off point gives considerable power to the factor. Hence we have factor 1, which contains seven variables.

Let us look at a second example, that of factor 2 (the column labelled '2' in Table 43.2). Here we can identify four variables that have high values that are close to each other and yet are some numerical distance away from the other variables. These four variables constitute factor 2, with a reported cut-off point of 0.445. At first glance it may seem that 0.445 is low; however, recalling that the data in the example were derived from 1,000 teachers, 0.445 is still highly statistically significant, statistical significance being a combination of the coefficient *and* the sample size.

TABLE 43.2 THE ROTATED COMPONENTS MATRIX IN PRINCIPAL COMPONENTS ANALYSIS (SPSS OUTPUT)

Rotated Component Matrix[a]

	Component				
	1	2	3	4	5
The clarity of the direction that is set by the school leadership	.559	.133	7.552E-02	.248	.212
The ability of the leader to motivate and inspire the educators	.743	.142	.176	9.058E-02	.160
The drive and confidence of the leader	.758	2.151E-02	.122	2.796E-02	.222
The consultation abilities/activities of the leader	.548	.342	.208	.278	.160
The example set by the leader	.572	.239	.126	.319	.209
The commitment of the leader to the school	.513	.290	.252	.329	.137
The versatility of the leader's styles	.284	.332	.377	.285	5.668E-02
The ability of the leader to communicate clear, individualized expectations	.449	.246	.303	.351	.205
The respect in which the leader is held by staff	.184	7.988E-02	.154	.810	.240
The staff's confidence in the SMT	.180	.121	7.859E-02	.809	.279
The effectiveness of the teamwork of the SMT	.385	.445	.249	.443	8.104E-02
The extent to which the vision for the school impacts on practice	.413	.341	.305	.379	.113
Educators given opportunities to take on leadership roles	.247	.225	.494	.339	-2.66E-02
The creativity of the SMT	.212	7.188E-02	.822	-2.97E-03	.189
Problem-posing, problem-identifying and problem-solving capacity of SMT	.459	.351	.262	.361	-3.21E-02
The use of data to inform planning and school development	.690	.167	.188	5.158E-02	-3.79E-02
Valuing of professional development in the school	.187	.249	.551	.260	7.013E-02
Staff consulted about key decisions	.148	6.670E-02	.854	7.531E-02	.167
The encouragement and support for innovativeness and creativity	.143	5.187E-02	.189	.269	.661
Everybody is free to make suggestions to inform decision-making	.165	.150	.172	.264	.642
The school works in partnership with parents	.222	.804	8.173E-02	.143	.199
People take positive risks for the good of the school and its development	.206	.778	8.998E-02	.181	2.635E-02
Staff voluntarily taking on coordination roles	.195	.210	2.681E-02	3.660E-02	.779
Teamwork amongst school staff	.114	.642	.220	-3.41E-02	.277

Extraction Method: Principal Component Analysis.
Rotation Method: Varimax with Kaiser Normalization.

a. Rotation converged in 6 iterations.

We repeat this analysis for all five factors, deciding the cut-off point and which variables to include, looking for homogeneous high values and numerical and conceptual distance from other variables in the list.

Stage 4: naming the factors

By this time we have identified five factors. However, neither SPSS nor any other software package tells us what to name each factor. The researcher has to devise a name that describes the factor in question. This can be challenging, as it has to catch the issue that is addressed by all the variables that are included in the factor. We have done this for all five factors, and we report this below, with the factor loadings for each variable reported in brackets.

Factor 1: Leadership skills in school management
Cut-off point: 0.51
Variables included:

- The drive and confidence of the leader (factor loading 0.758).
- The ability of the leader to motivate and inspire the educators (factor loading 0.743).
- The use of data to inform planning and school development (factor loading 0.690).
- The example set by the leader (factor loading 0.572).
- The clarity of the direction set by the school leadership (factor loading 0.559).

- The consultation abilities/activities of the leader (factor loading 0.548).
- The commitment of the leader to the school (factor loading 0.513).

Factor 2: Parent and teacher partnerships in school development
Cut-off point: 0.44
Variables included:

- The school works in partnership with parents (factor loading 0.804);
- People take positive risks for the good of the school and its development (factor loading 0.778);
- Teamwork amongst school staff (factor loading 0.642);
- The effectiveness of the teamwork of the SMT (factor loading 0.445).

Factor 3: Promoting staff development by creativity and consultation
Cut-off point: 0.55
Variables included:

- Staff consulted about key decisions (factor loading 0.854).
- The creativity of the smt (senior management team) (factor loading 0.822).
- Valuing of professional development in the school (factor loading 0.551).

Factor 4: Respect for, and confidence in, the senior management
Cut-off point: 0.44
Variables included:

- The respect in which the leader is held by staff (factor loading 0.810).
- The staff's confidence in the SMT (factor loading 0.809).
- The effectiveness of the teamwork of the SMT (factor loading 0.443).

Factor 5: Encouraging staff development through participation in decision making
Cut-off point 0.64
Variables included:

- Staff voluntarily taking on coordination roles (factor loading 0.779).
- The encouragement and support for innovativeness and creativity (factor loading 0.661).
- Everybody is free to make suggestions to inform decision making (factor loading 0.642).

Each factor should usually contain a minimum of three variables, though this is a rule of thumb rather than a statistical necessity. Further, in the example here, though some of the variables included have considerably lower factor loadings than others in that factor (e.g. in factor 2 the variable 'the effectiveness of the teamwork of the SMT' (0.445)), nevertheless the conceptual similarity of this to the other variables in that factor, coupled with the fact that, with 1,000 teachers in the study, 0.445 is still highly statistically significant, combine to suggest that this still merits inclusion. As mentioned earlier, factor analysis is an art as well as a science.

If one wished to suggest a more stringent level of exactitude then a higher cut-off point could be taken. In the example above, factor 1 could have a cut-off point of 0.74, thereby including only two variables in the factor; factor 2 could have a cut-off point of 0.77, thereby including only two variables in the factor; factor 3 could have a cut-off point of 0.82, thereby including only two variables in the factor; factor 4 could have a cut-off point of 0.80, thereby including only two variables in the factor; and factor 5 could have a cut-off point of 0.77, thereby including only one variable in the factor. The decision on where to place the cut-off point is a matter of professional judgement when reviewing the data, but it makes little sense to have a factor containing only one or two variables.

Stage 5: reporting the factor analysis

In reporting factor analysis the following points should be included, for example:

- the kind of extraction method used (e.g. Principal Components Analysis) and why;
- the kind of rotation used (e.g. Varimax) and why;
- the use of Eigenvalues, KMO and Bartlett tests and what they show;
- the total amount of variance explained and whether this is high, medium or low;
- the amount of explained variance of each factor and whether it is high, medium or low;
- the cut-off points in the factor loadings for each variable and why;
- the titles given to each factor;
- which factors have the highest and lowest explained variance, and what this shows.

The reporting should also draw attention to specific points in relevant tables of data. It might also include indications of which variables were included in each factor and why, their factor loadings (though a table would normally include these), and which variables were excluded from

all/any of the factors and why. A short introductory commentary could be provided, for example:

> In order to obtain conceptually similar and significant clusters of issues of the variables, principal components analysis with Varimax rotation and Kaiser Normalization were conducted as the factors were deemed to be orthogonal. Eigenvalues equal to or greater than 1.00 were extracted and the Kaiser-Meyer-Olkin (0.845) and Bartlett tests of sphericity ($\rho = 0.000$) indicated that the data were suitable for factorization. From the twenty-four variables included, orthogonal rotation of the variables yielded five factors, accounting for 16.82, 11.71, 11.58, 11.39 and 8.56 per cent of the total variance respectively, a total of 60.05 per cent of the total variance explained, i.e. a high degree of total explained variance. The factor loadings are presented in Table XXX [give the table a number]. To enhance the interpretability of the factors, only variables with factor loadings as follows were selected for inclusion in their respective factors: >0.51 (factor 1), >0.44 (factor 2), >0.55 (factor 3), >0.44 (factor 4), and >0.64 (factor 5). The factors are named, respectively: (i) Leadership skills in school management; (ii) Parent and teacher partnerships in school development; (iii) Promoting staff development by creativity and consultation; (iv) Respect for, and confidence in, the senior management; and (v) Encouraging staff development through participation in decision making.

So far this reports only the process and the outcome of the data analysis. This would then have to be accompanied by a subsequent commentary on what the results *mean*, what they *show* and what are the *educational* aspects of the results: what the results show, suggest and what can be concluded from them. This would relate to, for example, the purposes of the research and the research questions, the main findings of the research, the theoretical and conceptual contributions of the results to the research, what can safely be concluded from the results and what alternative interpretations there are of the results. In other words, having presented the data for the factor analysis, the researcher then fits the results into the overall context and purposes of the research, interpreting and explaining the findings.

Box 43.1 provides the SPSS command sequence for conducting Principal Components Analysis.

43.2 What to look for in factor analysis output

SPSS typically produces many sets of data in factor analysis. The researcher must first conduct the 'safety checks', i.e. checking that the data are suitable for factor analysis, for example:

- sample size;
- number of variables;
- ratio of sample size to number of variables;
- interval and ratio data;
- normal distributions;
- linearity;
- outliers;
- selection bias/proper specification;
- theoretical underpinning of factors;
- intercorrelations between variables and intercorrelations between factors;
- strength of intercorrelations: most should be no less than 0.3 and no more than 0.6 (see the correlation matrix);

BOX 43.1 SPSS COMMAND SEQUENCE FOR PRINCIPAL COMPONENTS ANALYSIS

The SPSS command sequence for Principal Components Analysis is: 'Analyze' → 'Dimension Reduction' → 'Factor'. Send over to the 'Variables' box the variables which are to be included → Click the box marked 'Descriptives' (which opens another window) → In the area marked 'Correlation Matrix, check the boxes marked 'KMO and Bartlett's test of sphericity' and 'Coefficients' → Click 'Continue' → Click 'Extraction' (which opens another window) → Check that 'Principal components' is the setting in the area marked 'Method'. Ensure that the radio buttons are set for 'Correlation matrix' and 'Based on Eigenvalue' of 1. In the 'Display' check the boxes marked 'Unrotated factor solution' and 'Scree plot' → Click 'Continue' → Click 'Rotation' (which opens another window) → in the 'Method' area check either the 'Direct Oblimin' or 'Varimax' (depending on whether you wish to select the oblique rotation (Direct Oblimin) or the orthogonal rotation (Varimax)). In the 'Display' area, ensure that the 'Rotated Solution' box has been checked → Click 'Continue' → Click 'Options' (which opens a new window). In the 'Missing values' area, click the radio button 'Exclude cases pairwise', and in the 'Coefficient Display format' area check the box marked 'Sorted by size' → Click 'Continue' → Click 'OK'.

- Bartlett's test of sphericity should be statistically significant ($\rho < 0.05$);
- Kaiser-Mayer-Olkin measure of sampling adequacy should be 0.6 or higher.

If the safety checks indicate that it is safe to continue then what follows below is a set of pointers for what to look at in the different tables that SPSS typically produces. The example uses a Direct Oblimin rotation, taking an example of research on factors that affect teacher stress. In some cases the SPSS tables are too large to reproduce in their entirety, so extracts are included that illustrate the main points being made.

Imagine that we have given SPSS all the instructions indicated above, to run the SPSS analysis, and to check for the suitability of the data for factorization. In Table 43.3 the researcher checks that most of the correlation coefficients in the cells are greater than 0.3.

In Table 43.4 the researcher checks the suitability of the data for factor analysis by examining the output concerning the Kaiser-Meyer-Olkin (KMO) and the Bartlett test. Here the KMO measure is greater than 0.6 (0.845) and the Bartlett test is statistically significant (0.000), so the researcher is safe to continue, knowing that the data are suitable for factorization.

Table 43.5 indicates the amount of variance explained by each item (if it is lower than 0.3 then the item is a poor fit).

Table 43.6 indicates that two factors have been extracted (two components), i.e. those with Eigenvalues over 1: factor 1 explains 45.985 per cent of the total variance; factor 2 explains 18.852 per cent of the total

variance. The total variance explained is 64.836 per cent (Cumulative percentage), i.e. very high.

If a scree plot has been produced then the researcher can look to see the 'bend in the elbow', i.e. the change in the shape of the plot, where the line flattens out and where the Eigenvalues are above and below 1.

Table 43.7 provides the pattern matrix, from which the researcher can identify which variables load onto the factors. The left-hand column prints the names of each variable and each column under the title 'Component' is a factor. Here we have emboldened and circled the variables that load onto each factor, for ease of identification.

Guidelines for which variables to select to include in each factor are:

- include the highest-scoring variables (those with the highest factor loadings);
- omit the low-scoring variables;
- look for where there is a clear scoring distance between those included and those excluded;
- review your selection to check that no lower-scoring variables have been excluded which are conceptually close to those included;
- review your selection to check whether some higher-scoring variables should be excluded if they are not sufficiently conceptually close to the others that have been included;
- review your final selection to see that the variables included in the factor are conceptually similar;
- each factor should include a minimum of three or four variables if possible (in the example in Table 43.7 it is clear that only two variables should be included).

Deciding on inclusions and exclusions is an art, not a science; there is no simple formula, so the researcher has to use his/her judgement.

In reporting the factor analysis the researcher should consider:

- reporting the method of factor analysis used (Principal Components; Direct Oblimin; KMO and Bartlett test of sphericity; Eigenvalues greater than 1; scree test; rotated solution);
- reporting how many factors were extracted with Eigenvalues greater than 1;
- reporting how many factors were included as a result of the scree test;
- giving a name/title to each of the factors;
- reporting how much of the total variance was explained by each factor;
- reporting the cut-off point for the variables included in each factor;
- reporting the factor loadings of each variable in the factor;
- reporting what the results show.

43.3 Cluster analysis

Whereas factor analysis enables the researcher to group *variables* into factors, cluster analysis enables the researcher to group together similar and homogeneous sub-samples of *people* (also termed 'cases'). In educational research this can be used, for example, to identify students with particular needs or abilities, regions with outstanding performance, high-achieving students, teachers with particular interests etc. Cluster analysis is often used in combination with factor analysis.

How much frustration do you feel in your job?	1.000	.595

Extraction Method: Principal Component Analysis.

Cluster analysis is based on the measured proximity, distance and similarity between cases or variables. Distance/similarity, for example, is measured by Euclidean distance and Squared Euclidean distance (and SPSS constructs a proximity matrix from data), and clusters are formed by repeatedly combining the two or more cases with the greatest similarity. Cluster analysis has two main forms: hierarchical and non-hierarchical analysis (and, indeed, the two may be used in combination). Typically researchers can use K-means cluster

(non-hierarchical cluster analysis), hierarchical cluster and two-step cluster, of which hierarchical cluster analysis is the most widely used. Cluster analysis can work with interval, ratio, ordinal and nominal data, using different statistics for each kind of data. Here we comment on hierarchical cluster analysis, a commonly used method.

In hierarchical cluster analysis, homogeneous clusters of similar cases are formed at increasingly high levels of generality, and these are shown on a dendrogram. A dendrogram is a tree diagram that shows how cases are combined and linked at increasingly hierarchical and general levels until they become a single cluster, and it separates and indicates the several levels of combination. The dendrogram is an important feature of cluster analysis because it includes and lists all the cases, it indicates the level of similarity at which any two or more clusters are joined and the distance at which they are joined (the position of the line on the scale). Further, given its diagrammatic nature, it shows the clusters and their linkages at a glance and is easily understood.

Cluster analysis is best approached through software packages such as SPSS, and we illustrate this here. SPSS creates a dendrogram of results, grouping and regrouping groups until all the variables are embraced.

For example, here is a simple cluster analysis based on twenty cases (people). Imagine that their scores have been collected on an item concerning the variable 'your confidence in handling new situations'. Figure 43.3 presents the dendrogram of the clusters. Here one can see that, at the most general level there are two clusters: cluster one = persons 19, 20, 10, 11, 2, 4, 9, 3, 17, 18, 1, 16, 14, 15, 12, 13; cluster two = persons 7, 8, 5, 6. If one wished to have more detailed, specific clusters then three groupings can be found: cluster one: persons 19, 20, 10, 11, 2, 4, 9, 3, 17, 18, 1, 16; cluster two: persons 14, 15, 12, 13; cluster three: persons 7, 8, 5, 6. If one wishes to have a yet more specific, discriminating specification of groups then five groupings can be found: cluster one: persons 19, 20; cluster two: persons 10, 11, 2, 4, 9, 13; cluster three: persons 17, 18, 1, 16; cluster four: persons 14, 15, 12, 13; cluster five: persons 7, 8, 5, 6. In Figure 43.3, the final level in the hierarchy, bringing all the clusters into a single group, is not advised, not only because it defeats the purpose of identifying separate clusters but because the distance (shown in the horizontal axis as the distance from point

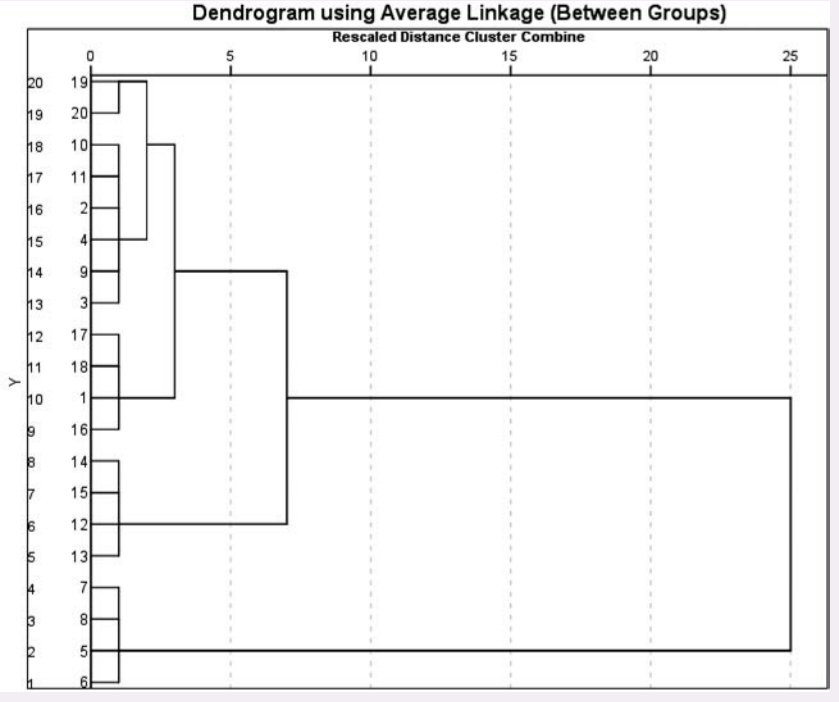

FIGURE 43.3 Cluster analysis using average linkage (SPSS output)

7 to point 25) is so great as to suggest gross dissimilarity, therefore the researcher here would be advised not to proceed beyond the two-cluster level (the second level) of the hierarchy, and in fact a strong case could be made for remaining at the first level of five clusters.

Before conducting cluster analysis the same 'safety checks' have to be performed as for factor analysis, with particular attention paid to the removal of outliers. If scales are different or if their standard deviations are large then standardized scores should be used.

Using cluster analysis enables the researcher to identify important groupings of people in a *post hoc* analysis, i.e. not setting up the groupings and sub-groupings at the stage of sample design, but *after* the data have been gathered. In the example of the two-group cluster here one could examine the characteristics of those participants who were clustered into groups one and two, and, for the three-group cluster, one could examine the characteristics of those participants who were clustered into groups one, two and three for the variable 'your confidence in handling new situations'. For example, in the two-group cluster it may be that group one comprises generally confident people whilst group two comprises generally less-confident people. For the three-group cluster it may be that one group comprises people below the age of twenty-one, the second group comprises people from ages twenty-two to forty, and the third group comprises people between the ages of forty-one and sixty-five.

There are several ways of conducting hierarchical cluster analysis; each way can produce a different clustering. For example, Figure 43.3 is the dendrogram that uses the default settings on SPSS, whilst Figure 43.4 uses a 'nearest neighbor' ('single linkage') setting.

As we can see, the two figures (43.3 and 43.4) are very different in the make-up of the groups (which people are in which groups), the linkages between groups and the number of 'layers' of groupings (three layers in Figure 43.3 and five layers in Figure 43.4). This means that researchers need to choose the most appropriate method of cluster analysis to use. This is beyond the scope of the present volume. Field (2000) and Yim and Ramdeen (2015) provide a straightforward introduction to key features of cluster analysis, showing clearly the steps to be used in SPSS, whilst Liew (2013) provides further introductory material on this. A useful introduction is provided at www.slideshare.net/jewelmrefran/cluster-analysis-15529464, with clear instructions for running cluster analysis with SPSS, and YouTube contains many short guides on working with cluster analysis.

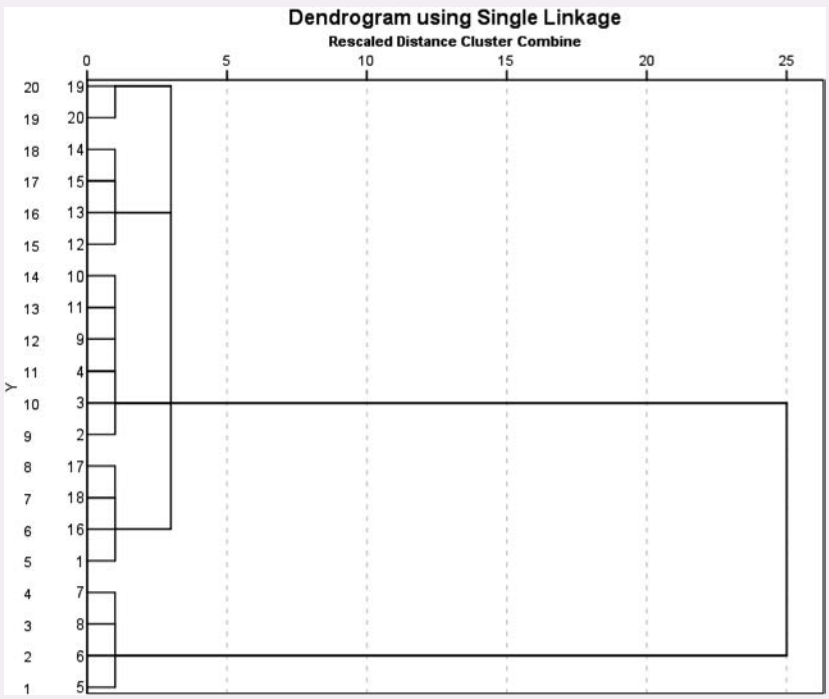

FIGURE 43.4 Cluster analysis using 'nearest neighbour' single linkage (SPSS output)

Box 43.2 provides the SPSS command sequence for hierarchical cluster analysis.

In reporting the results of cluster analysis, researchers must indicate the method of cluster analysis used and why, and what the results of the dendrogram show. It is important for researchers to indicate:

- what is the similarity criterion that combines individual cases into a single cluster (e.g. all females);
- how many cases (and who) are in each cluster;
- how similar the cases are within each cluster. The proximity matrix in SPSS indicates the measured degree of closeness or distance between cases, and this is useful in enabling the researcher to comment on just how similar the cases are within the cluster;
- what differentiates that cluster from another (e.g. high achievers in one cluster and low achievers in another), and, as clusters are combined further up the hierarchy of the dendrogram, what is the criterion or characteristic that combines them (this is based on the judgement of the researcher rather than a statistical procedure);
- how similar/dissimilar are the clusters. Again, the proximity matrix in SPSS indicates the measured degree of closeness or distance between clusters, and this is useful in enabling the researcher to comment on how different one cluster is from another;
- what is the most suitable 'cut-off' point in a dendrogram and why, i.e. at what level in the hierarchy it is most advisable to cease combining clusters. This requires the researcher to make an educational rather than statistical judgement, though the distance criterion (shown on the horizontal distance on an SPSS dendrogram) is a useful guide here.

Cluster analysis has been criticized for being atheoretical, non-generalizable, descriptive rather than inferential, its assumption that real structures exist (i.e. clusters are based on statistical rather than actual similarity), and for being more suited to small rather than large samples (the latter being particularly a problem in constructing a dendrogram). Nevertheless it is a frequently used technique for grouping cases, and working with hierarchical cluster analysis in SPSS is a useful tool for researchers. For further guidance we refer readers to Field (2000), Landau and Chis Ster (2010); Everitt *et al*. (2011), Liew (2013) and Yim and Ramdeen (2015).

43.4 A note on structural equation modelling

Structural equation modelling (SEM) is a further method in statistics-based research using interval and ratio data. We provide an introduction to it here; for further in-depth discussion researchers should go sources referenced below. Structural equation modelling is the name given to a group of techniques that enable researchers to construct models of putative causal relations, and to test those models against data. It is designed to enable researchers to confirm, modify and test their models of causal relations between variables. It is based on multiple regression, but advances beyond this to create and test models of relationships, often causal, to see how well the models fit the data, and in this respect it is often also used for confirmatory factor analysis. Though SPSS does not have a function to handle this, the Analysis of Moment Structures (AMOS) is a software package that enables the researcher to import and work with SPSS files.

As mentioned earlier, factor analysis can be both *exploratory* and *confirmatory*. Structural equation modelling is used in confirmatory factor analysis. Whilst the earlier discussion concerned exploratory factor analysis, confirmatory factor analysis is a feature of the group of latent variable models (models of factors

BOX 43.2 SPSS COMMAND SEQUENCE FOR HIERARCHICAL CLUSTER ANALYSIS

The SPSS command sequence for hierarchical cluster analysis is: 'Analyze' → 'Classify' → 'Hierarchical cluster' → Send over the variable(s) of interest to the box marked 'Variable(s)' → Click the box marked 'Statistics', which this opens a new window, and check the box marked 'Proximity matrix' → Click 'Continue' → Click the box marked 'Plots', which opens a new window, and check the box marked 'Dendrogram' → Click 'Continue' → Click the box marked 'Method', which opens a new window, and decide, from the drop-down menus, which 'Cluster Method' you wish to use (the default setting is 'Between groups linkage', which is widely used, but many researchers also suggest using the advocate the 'Nearest neighbor' setting. Decide which 'Measure' you wish to use (for scale data – the 'Interval' radio button – a widely used measure is the default setting of 'Square Euclidian Distance'; for ordinal data (the ('Counts' radio button) the chi-square setting is often used; and for binary nominal data (the 'Binary' radio button) the 'Squared Euclidian Distance' is often used) → Click 'Continue' → Click 'OK'.

rather than observed variables) which includes factor analysis, path analysis and structural equation analysis. Confirmatory factor analysis seeks to verify (to confirm or refute) the researcher's predictions about factors and their factor loadings in data and data structures. As mentioned earlier, factors are latent, they cannot be observed as they underlie variables.

By contrast, path analysis – an extension of multiple regression – only works with observed variables, and it attempts to estimate and test the magnitude and significance of relationships, often putatively causal, between sets of observed variables. Path analysis is a statistical method that enables a researcher to determine how well a multivariate set of data fits with a particular (causal) model that has been set up in advance by the researcher (i.e. an *a priori* model). It is a particular kind of multiple regression analysis that enables the researcher to see the relative weightings of observed independent variables on each other and on a dependent variable, to establish pathways of causation, and to determine the direct and indirect effects of independent variables on a dependent variable (Morrison, 2009, p. 96). The researcher constructs what she or he thinks will be a suitable model of the causal pathway between independent variables and between independent and dependent variables, often based on literature and theory, and then tests this to see how well it fits with the data.

In constructing path analysis, computer software is virtually essential. Programs such as AMOS (in SPSS) and LISREL are two commonly used examples.

Morrison (2009, pp. 96–8) gives an example of path analysis in degree classification, with three independent variables and their relationship to the dependent variable of degree classification:

- socio-economic status
- part-time working
- level of motivation for academic study

These three variables are purported to have an effect on the class of degree that a student gains (the dependent variable). Figure 43.5 is constructed from the AMOS software.

The researcher believes that this can be modelled in a nonrecursive model (a model in which the direction of causality is not solely one-way – see the direction of the causal arrows joining 'part-time work' and 'level of motivation for academic study' in Figure 43.5, which go to and from each other. This is in contrast to a recursive model, in which the direction of putative causality is one-way only). In the nonrecursive model here, socio-economic status determines part-time working, level of motivation for academic study and the dependent variable 'class of degree'. The variable 'socio-economic status' is deemed to be an exogenous variable (a variable caused by variables that are *not* included in the causal model), whilst the variables 'part-time working' and 'level of motivation for academic study' are deemed to be endogenous variables (those caused by variables that *are* included in the model) as well as being affected by exogenous variables.

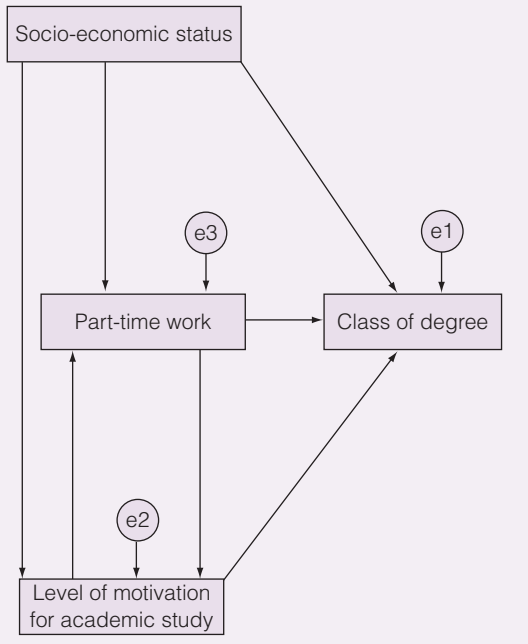

FIGURE 43.5 Path analysis modelling with AMOS (AMOS output)

In the model (Figure 43.5), the dependent variable is 'class of degree' and there are directional causal arrows leading both to this dependent variable and to and from the three independent variables. The model assumes that the variables 'part-time work' and 'level of motivation for academic study' influence each other and that socio-economic status precedes the other independent variables rather than being caused by them. In the model there are also three variables in circles, termed 'e1', 'e2' and 'e3'; these three additional variables are 'error factors', i.e. additional extraneous/exogenous factors which may also be influencing the three variables in question, and AMOS adjusts the results for these factors. (AMOS also enables the researcher to draw the model and manipulate its layout.)

AMOS then calculates the regression coefficient of each relationship and places each coefficient on the model. An example of the model generated by AMOS

is presented in Figure 43.6 (using the 'standardized estimates' in AMOS).

From Figure 43.6 one can see that:

- 'socio-economic' status exerts a direct influence on class of degree (0.18), and that this is higher than the direct influence of either 'part-time work' (–.01) or 'level of motivation for academic study' (0.04);
- 'socio-economic status' exerts a powerful direct influence on 'level of motivation for academic study' (0.52), and this is higher than the influence of 'socio-economic status' on 'class of degree' (0.18);
- 'socio-economic status' exerts a direct and negative influence on 'part-time work' (–0.21), i.e. the higher the socio-economic status, the lesser is the amount of part-time work undertaken;
- 'part-time work' exerts a powerful direct influence on 'level of motivation for academic study' (1.37), and this is higher than the influence of 'socio-economic status' on 'level of motivation for academic study' (0.52);
- 'level of motivation for academic study' exerts a powerful negative direct influence on 'part-time work' (–1.45), i.e. the higher is the level of motivation for academic study, the lesser is the amount of part-time work undertaken;

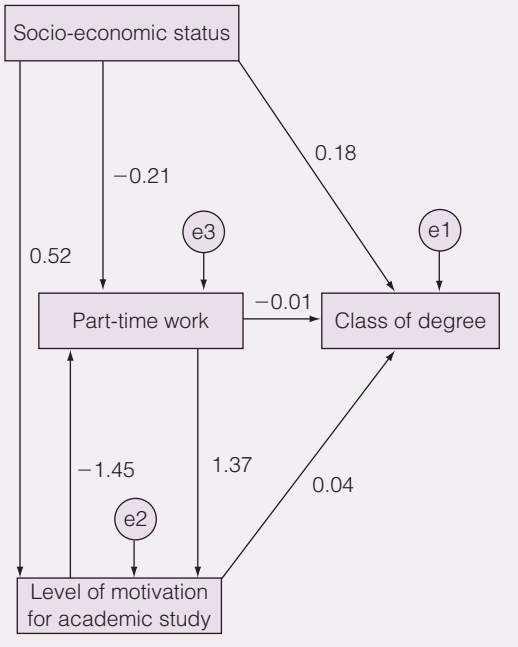

FIGURE 43.6 Path analysis with calculations added (AMOS output)

- 'level of motivation for academic study' exerts slightly more influence on 'class of degree' (0.04) than does 'part-time work' (–0.01);
- 'part-time work' exerts a negative influence on the class of degree (–0.01), i.e. the more one works part-time, the lower is the class of degree obtained.

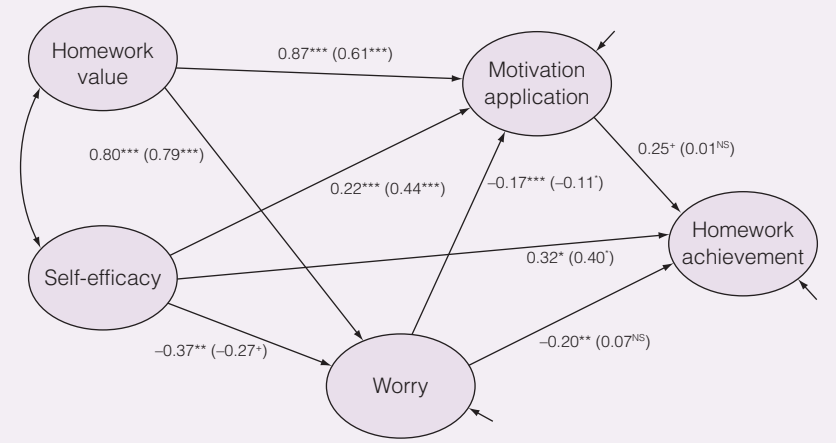
AMOS also yields a battery of statistics about the 'goodness of fit' of the model to the data, most of which are beyond the scope of this book. Kline (2015a, pp. 268–80) suggests three main tests of goodness of fit here: the chi-square statistic, the Comparative Fit Index (CFI) and the Root Mean Square Error of Approximation (RMSEA). Suffice it to say here that the chi-square statistic must *not* be statistically significant (i.e. $\rho > 0.05$), i.e. to indicate that the model does not differ statistically significantly from the data, in other words that the model is faithful to the data, the Comparative Fit Index (CFI) should be 0.9 or higher and the Root Mean Square Error of Approximation (RMSEA) should be below 0.10, and ideally should be smaller than 0.05.

Hong *et al*. (2015) provide a clear example of a structural equation model of the causal effects of homework motivation and worry anxiety on homework achievement in mathematics and English (Figure 43.7). The model in Figure 43.7 derived from theories of social-cognitive and expectancy-value theories of motivation, and included antecedent variables (perceived homework value and self-efficacy), mediating effects and direct effects (worry and motivation application).

The authors constructed a causal model, then tested its goodness of fit and then considered the findings. They report an acceptable goodness of fit: for mathematics the chi-square was not statistically significant ($\rho = 0.011$), the CFI was 0.997 and the RMSEA was 0.048; for English the chi-square was not such a good fit, being statistically significant ($\rho = 0.0005$), whereas the CFI was 0.990 and the RMSEA was 0.073, both of these being a good fit.

Having conducted a goodness of fit test, the authors then report the findings. In Figure 43.7 the figures outside the brackets are the beta weightings for mathematics and those inside the brackets are for English. Here the strongest direct effect on homework achievement was from self-efficacy (0.32 for mathematics and 0.40 for English) and the antecedent variable of perceived homework value had a very strong effect on motivation application (0.87 for mathematics and 0.61 for English) and on worry (0.80 for mathematics and 0.79 for English).

Path analysis assumes that the *direction* of causation in the variables can be identified, that the data are at the interval or ratio level, that the relations are linear, that



The final structural model with standardized path coefficients.

Note

The figures outside the brackets refer to mathematics and those inside the brackets refer to English

the data meet the usual criteria for regression analysis, and that the model's parsimony (inclusion of few variables) is fair. Morrison (2009, p. 98) argues that path analysis is only as good as the causal assumptions that underpin it, nor does it prove unequivocally that causation is present; rather it only tests a model based on *assumed* causal directions and influences. Nevertheless, its utility lies in its ability to test models of putative causal directions, to establish relative weightings of variables, to look at direct and indirect effects of independent variables and to handle several independent variables simultaneously.

Structural equation modelling combines the features of confirmatory factor analysis (i.e. it works with *latent* factors) and of path analysis (i.e. it works with *observed*, manifest variables). Here each factor is a latent construct comprising several variables. This is shown in Figure 43.8, in which each factor appears in the ovals and each observed variable appears in a rectangle. Here the factor 'socio-economic status' (S) has three variables (S1, S2, S3), the factor 'part-time work' (P) has two variables (P1, P2) and the factor 'level of motivation for academic study' (L) has three variables (L1, L2, L3). Each variable has its own error factor (the small circles with 'E' inside them).

Structural equation modelling requires the researcher to:

- construct the model (the factors and the variables);
- decide the direction of causality (recursive or non-recursive);
- identify the number of parameters to be estimated (number of factor coefficients, covariances, observations);
- run the AMOS analysis (or another piece of software) and check the goodness of fit of the model to the data;
- make any necessary modifications to the model;
- report the findings.

This is a highly simplified overview of the process and nature of structural equation modelling, and the reader is strongly advised to read further, more details texts, e.g. Loehlin (2004), Schumacker and Lomax (2004), Kline (2005a; 2015) and Tabachnick and Fidell (2013).

43.5 A note on multilevel modelling

Multilevel modelling (also known as multilevel regression and hierarchical modelling) recognizes that individual characteristics are nested within group characteristics and, indeed, wider contextual factors and that these can be factored into data analysis simultaneously. Students are nested within classrooms, classrooms are nested within schools, schools are nested within neighbourhoods and so on. There are many

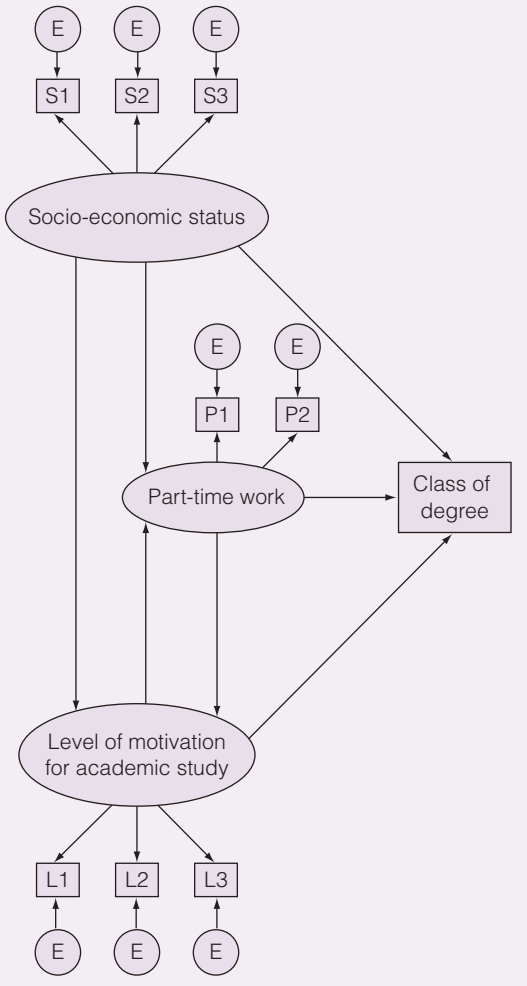

FIGURE 43.8 A structural equation model

levels of influences on outcomes or observed findings. Multilevel analysis addresses this (cf. Bickel, 2007; Seltzer and Rickles, 2012; Robson and Pevalin, 2016), recognizing that, if multilevel nesting is not addressed in statistical analysis then there is a risk of finding spurious results (e.g. statistically significant differences between individuals or groups) or of overlooking differences between smaller groups (e.g. minority groups). Multilevel analysis is frequently used in school effects and effectiveness research,

Typically in most schools, students are brought together in particular groupings for specified purposes and each group of students has its own different characteristics which render it different from other groups. Multilevel modelling addresses the fact that, unless it can be shown that different groups of students are, in fact, alike, it is generally inappropriate to aggregate groups of students or data for the purposes of analysis. Multilevel models avoid the pitfalls of aggregation and the *ecological fallacy* (Plewis, 1997, p. 35), i.e. making inferences about individual students and behaviour from aggregated data.

Data and variables exist at individual and group levels, indeed Keeves and Sellin (1997b) break down analysis further into three main levels: (a) between students over all groups; (b) between groups; and (c) between students within groups. One can extend the identification of levels, of course, to include individual, group, class, school, local, regional, national and international levels (Paterson and Goldstein, 1991). Data are 'nested' (Bickel, 2007), i.e. individual-level data are nested within group, class, school, regional etc. levels; a dependent variable is affected by independent variables at different levels (p. 3). In other words, data are hierarchical. If we are looking at, say, the effectiveness of a reading program in a region, we must recognize that student performance at the individual level is also affected by group and school level factors (e.g. differences within a school may be smaller than differences between schools). Individuals within families may be more similar than individuals between families. Using multilevel modelling researchers can ascertain, for example, how much of the variation in student attainment might be attributable to differences within students in a single school or to differences between schools (i.e. how much influence is exerted on student attainment by the school which the student attends). Another example might be the extent to which factors such as sex, ethnicity, type of school, locality of school, school size account for variation in student performance. Multilevel modelling enables the researcher to calculate the relative impact on a dependent variable of one or more independent variables at each level of the hierarchy, and, thereby to identify factors at each level of the hierarchy that are associated with the impact of that level.

Multilevel modelling has been conducted using multilevel regression and hierarchical linear modelling (HLM). It enables researchers to ask questions hitherto unanswered, e.g. about variability between and within schools, teachers and curricula, in short about the *processes* of teaching and learning. Multilevel analysis avoids statistical treatments associated with experimental methods (e.g. analysis of variance and covariance); rather it uses regression analysis and, in particular, multilevel regression. Regression analysis assumes homoscedasticity (where the residuals demonstrate equal scatter), that the residuals are independent of each

other, and finally, that the residuals are normally distributed.

Multilevel modelling is the basis of much research on the 'value added' component of education and the comparison of schools in public 'league tables' of results. It is not without its critics, e.g. Gorard (2007, p. 221) argues that multilevel modelling has 'an unclear theoretical and empirical basis', is unnecessarily complex, that it has not produced any important practical research results, and that, due to the presence of alternatives, is largely unnecessary, with limited ease of readability by different audiences. Nonetheless, multilevel modelling attracts worldwide interest.

Whereas ordinary regression models do not make allowances, for example, for different schools (Paterson and Goldstein, 1991), multilevel regression can include school differences, and indeed other variables, e.g.: socio-economic status, single and co-educational schools, location, size of school, teaching styles etc. Indeed Bickel (2007) and Seltzer and Rickles (2012) indicate how multilevel modelling can be used in longitudinal studies.

The Bristol Centre for Multilevel Modelling (www.bristol.ac.uk/cmm/) produces online courses, introductory materials, workshops and downloads for multilevel modelling, software downloads for conducting multilevel modelling, and full sets of references and papers. Further materials and references can be found at Scientific Software International.

Useful overviews of multilevel modelling can be found in Goldstein (1987, 2003), Raudenbush and Bryk (2002), Keeves and Sellin (1997b), Bickel (2007), O'Connell and McCoach (2008), Snijders and Bosker (2012), Tabachnick and Fidell (2013), and Robson and Pevalin (2016), whilst Heck, Thomas and Tabaska (2013) provide a comprehensive, if demanding, introduction to multilevel modelling with SPSS. There are useful publications from the Bristol Centre for Multilevel Modelling (www.bristol.ac.uk/cmm/research/).

Companion Website

Choosing a statistical test

CHAPTER 44

Having set out a range of statistical tests in the preceding chapters, this chapter guides the researcher on which tests to use with particular kinds of data and for specific purposes, i.e. to address fitness for purpose. The chapter proceeds thus, indicating different considerations which researchers must bear in mind when selecting the most appropriate tests:

- how many samples?
- the types of data used
- choosing the right statistic
- assumptions of tests

The chapter provides several tables to guide the researcher in making choices here.

44.1 Introduction

There are very many statistical tests available to the researcher. Which test one employs depends on several factors, for example:

- the purpose of the analysis (e.g. to describe and/or explore data, to test a hypothesis, to seek correlations, to identify the effects of one or more independent variables on a dependent variable, to identify differences between two or more groups, to look for underlying groupings of data, to report effect sizes);
- the kinds of data with which one is working (parametric and non-parametric);
- the scales of data being used (nominal, ordinal, interval, ratio);
- the number of groups in the sample;
- the assumptions in the statistical tests;
- whether the samples are independent of each other or related to each other.

Researchers wishing to use statistics will need to ask and answer questions such as:

- What statistics do I need to answer my research questions?
- What kind of statistic do I need (e.g. difference test, correlation, factor analysis, regression, grouping (of variables, of people);
- Are the data parametric or non-parametric?
- How many groups are there (e.g. two, three or more)?
- Are the groups related or independent?
- Have all the assumptions of the statistical test been met?

We have addressed these points in the preceding chapters. In this chapter we draw together the threads of the discussion of statistical analysis and address what, for many researchers, can be challenging: deciding which statistical tests to use. In the interests of clarity we use tables and graphics for presenting the issues in this chapter.

44.2 Sampling issues

In addition to the scale of data being used (nominal, ordinal, interval, ratio), the *kind* of statistic that one calculates depends in part on: first, whether the samples are related to, or independent of, each other; second, the number of samples in the test; and third, whether the assumptions (the 'safety checks' set out in previous chapters) have been met. With regard to the first point, as we have seen in previous chapters, different statistics are sometimes used when groups are related to each other and when they are independent of each other. Groups are independent when they have no relationship to each other, for example, in conducting a test to see if there is any difference between the voting of males and females on a particular item, say mathematics performance. The tests that one could use here are, for example: the chi-square test (for nominal data), the Mann-Whitney U test and Kruskal-Wallis (for ordinal data), and the t-test and Analysis of Variance (ANOVA) for interval and ratio data.

However, there are times when the groups might be related. For example, we may wish to measure the performance of the same group at two points in time – before and after a particular intervention – or we may

wish to measure the voting of the same group on two different variables, say preference for mathematics and preference for music, or under two conditions (e.g. working in a noisy and a silent environment). Here it is not different groups that are being involved, but the same group on two occasions, two variables or two conditions respectively. In this case different statistics are used, for example, the Wilcoxon test, the Friedman test, the t-test for paired samples and the sign test. Table 44.1 gives a frequently used example of an experiment.

In preceding chapters we have indicated which tests are used with independent samples and which are used with related samples.

With regard to the number of samples/groups in the test, there are statistical tests which are for single samples (one group only, e.g. a single class in school), for two samples (two groups, e.g. males and females in a school) and for more than two samples, for example, parents, teachers, students and administrative staff in a school. Tests which can be applied to a *single* group include the binomial test, the chi-square one-sample test and the Kolmogorov-Smirnov one-sample test; tests which can be applied to *two* groups include the chi-square test, the Mann-Whitney U test, the t-test, the Spearman and Pearson tests of correlation; tests which can be applied to *three or more* samples include the chi-square test, ANOVA, the Kruskal-Wallis test and the Tukey and Games-Howell tests. We set out some of these tests in Table 44.2. It is essential to use the correct test for the correct number of groups.

TABLE 44.1 IDENTIFYING STATISTICAL TESTS FOR AN EXPERIMENT

CONTROL GROUP ↑ t-test for independent samples for the pre-test ↓ EXPERIMENTAL GROUP	Wilcoxon test or t-test for paired samples (depending on data type) Wilcoxon test or t-test for paired samples (depending on data type)	CONTROL GROUP ↑ t-test for independent samples for the post-test ↓ EXPERIMENTAL GROUP

TABLE 44.2 STATISTICAL TESTS TO BE USED WITH DIFFERENT NUMBERS OF GROUPS OF SAMPLES

Scale of data	*One sample*	*Two samples*		*More than two samples*	
		Independent	*Related*	*Independent*	*Related*
Nominal	Binomial	Fisher exact test	McNemar	Chi-square (χ^2) k-samples test	Cochran Q
	Chi-square (χ^2) one-sample test	Chi-square (χ^2) two-samples test			
Ordinal	Kolmogorov-Smirnov one-sample test	Mann-Whitney U test	Wilcoxon matched pairs test	Kruskal-Wallis test	Friedman test
		Kolmogorov-Smirnov test	Sign test	Ordinal regression analysis	
		Wald-Wolfowitz			
		Spearman rho			
		Ordinal regression analysis			
Interval and ratio	t-test	t-test	t-test for paired samples	One-way ANOVA	Repeated measures ANOVA
		Pearson product moment correlation		Two-way ANOVA	
				Tukey hsd test	
				Scheffé test	

44.3 The types of data used

The statistical tests used also depend on the scales of data being treated (nominal to ratio) and the tasks which the researcher wishes to perform – the purpose of the analysis (e.g. to discover differences between groups, to look for degrees of association, to measure the effect of one or more independent variables on a dependent variable etc.). In preceding chapters we have described the different scales of data and the kinds of tests available for different purposes. With these considerations, Table 44.3 summarizes some of the main tests here.

The type of test used also varies according to whether one is working with parametric or non-parametric data.

44.4 Choosing the right statistic

Figure 44.1 and Table 44.4 draw together and present the kinds of statistical tests available, depending on whether one is using parametric or non-parametric data, together with the purpose of the analysis. Table 44.4 sets out the commonly used statistics for data types and purposes.

44.5 Assumptions of tests

Statistical tests are based on certain assumptions. It is important to be aware of these assumptions and to operate fairly within them. Table 44.5 sets out the assumptions which need to be met (the 'safety checks' of previous chapters) if the statistics in question are to be used. Unfortunately researchers often use statistics for parametric tests (e.g. t-tests, ANOVA, regression) when the assumptions have not been met, and this undermines the results. If the assumptions underpinning a parametric test have not been met then it is often wiser to revert to an equivalent non-parametric test. Some of the more widely used tests have the assumptions set out (Table 44.5).

The choice of which statistics to employ is not arbitrary, and we have set out in this chapter the considerations that must be addressed in selecting the correct statistic.

TABLE 44.3 TYPES OF STATISTICAL TESTS FOR FOUR SCALES OF DATA

	Nominal	*Ordinal*	*Interval and ratio*
Measures of association	Tetrachoric correlation	Spearman's rho	Pearson product-moment correlation
	Point biserial correlation	Kendall rank order correlation	
	Phi coefficient	Kendall partial rank correlation	
	Cramer's *V*		
Measures of difference	Chi-square	Mann-Whitney U test	t-test for two independent samples
	McNemar	Kruskal-Wallis	t-test for two related samples
	Cochran Q	Wilcoxon matched pairs	One-way ANOVA
	Binomial test	Friedman two-way analysis of variance	Two-way ANOVA for more
		Wald-Wolfowitz test	Tukey hsd test
		Kolmogorov-Smirnov test	Scheffé test
Measures of linear relationship between independent and dependent variables		Ordinal regression analysis	Linear regression
Identifying underlying factors, data reduction, grouping of people or variables			Multiple regression Factor analysis Cluster analysis

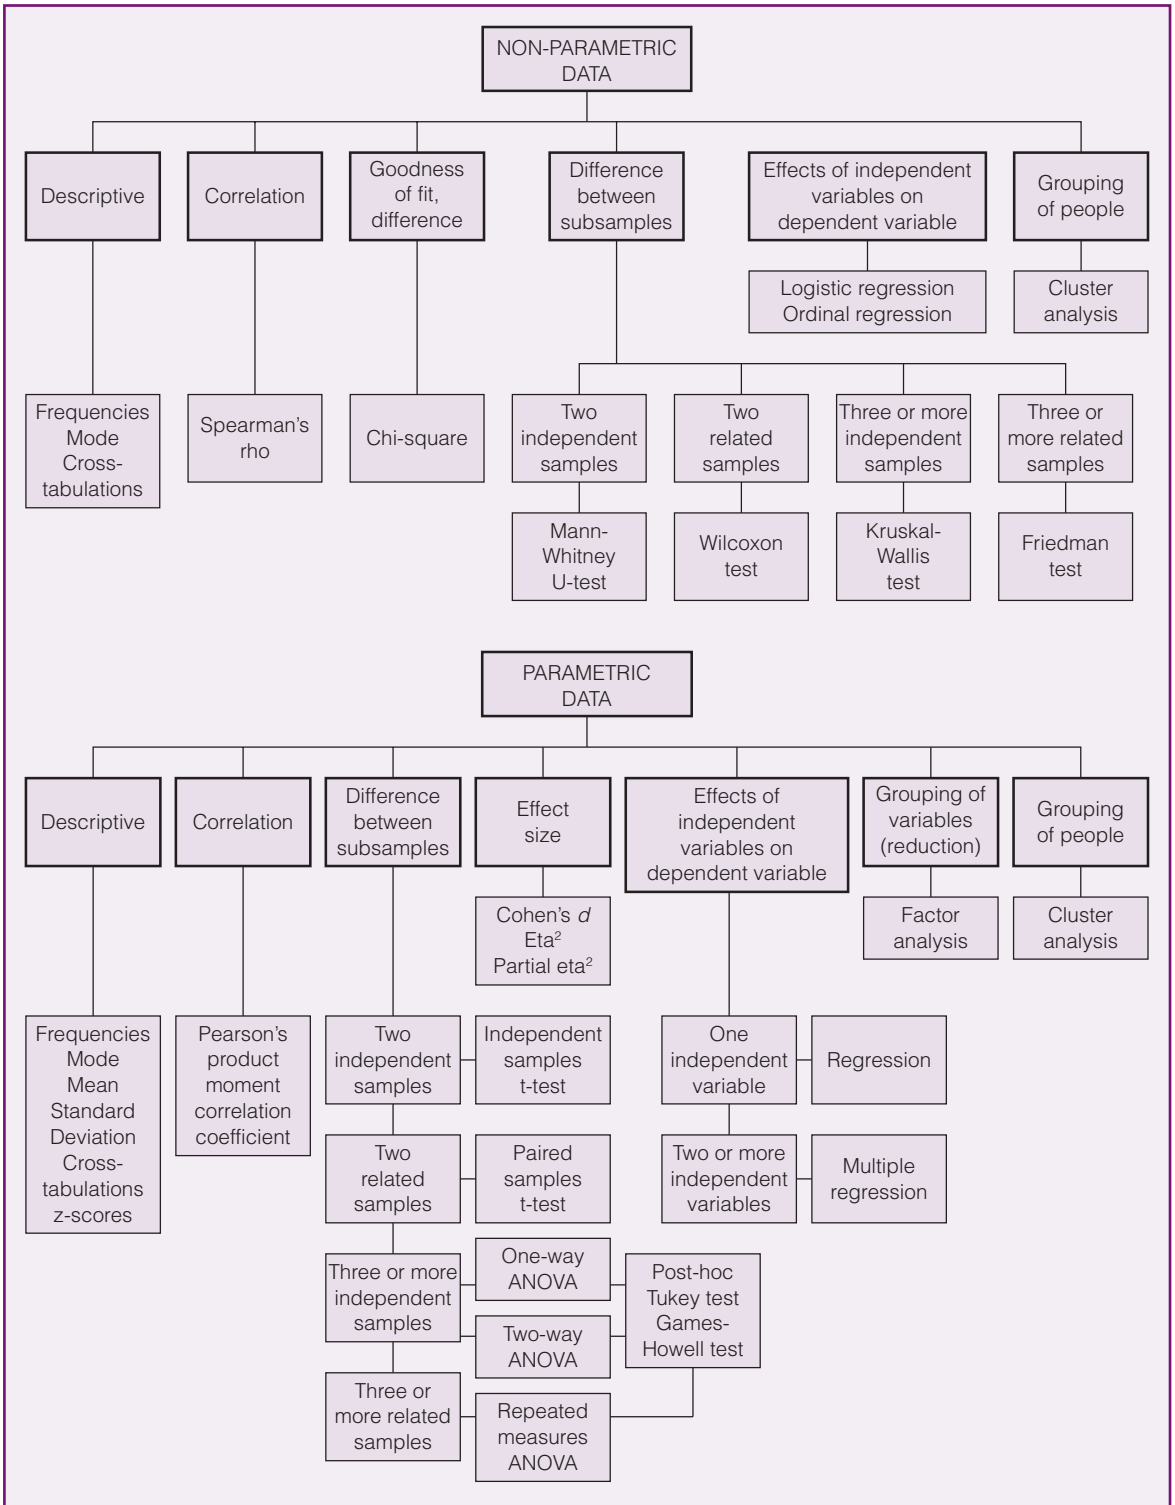

FIGURE 44.1 Choosing statistical tests for parametric and non-parametric data

TABLE 38.4 STATISTICS AVAILABLE FOR DIFFERENT TYPES OF DATA

Data type	*Legitimate statistics*	*Points to observe/questions/examples*
Nominal	i Mode (the score achieved by the greatest number of people)	Is there a clear 'front runner' that receives the highest score with low scoring on other categories, or is the modal score only narrowly leading the other categories? Are there two scores which are vying for the highest score – a bi-modal score?
	ii Frequencies	Which are the highest/lowest frequencies? Is the distribution even across categories?
	iii Chi-square (χ^2) (a statistic that charts the difference between statistically expected and actual scores)	Are differences between scores caused by chance/accident or are they statistically significant, i.e. not simply caused by chance?
Ordinal	i Mode	Which score on a rating scale is the most frequent?
	ii Median (the score gained by the middle person in a ranked group of people or, if there is an even number of cases, the score which is midway between the highest score obtained in the lower half of the cases and the lowest score obtained in the higher half of the cases).	What is the score of the middle person in a list of scores?
	iii Frequencies	Do responses tend to cluster around one or two categories of a rating scale? Are the responses skewed towards one end of a rating scale (e.g. 'strongly agree')? Do the responses pattern themselves consistently across the sample? Are the frequencies generally high or generally low (i.e. whether respondents tend to feel strongly about an issue)? Is there a clustering of responses around the central categories of a rating scale (the central tendency, respondents not wishing to appear to be too extreme)?
	iv Chi-square (χ^2)	Are the frequencies of one set of nominal variables (e.g. sex) significantly related to a set of ordinal variables?
	v Spearman rank order correlation (a statistic to measure the degree of association between two ordinal variables)	Do the results from one rating scale correlate with the results from another rating scale? Do the rank order positions for one variable correlate with the rank order positions for another variable?
	vi Mann-Whitney U-test (a statistic to measure any significant difference between two independent samples)	Is there a significant difference in the results of a rating scale for two independent samples (e.g. males and females)?
	vii Kruskal-Wallis analysis of variance (a statistic to measure any significant differences between three or more independent samples)	Is there a significant difference between three or more nominal variables (e.g. membership of political parties) and the results of a rating scale?

continued

TABLE 44.4 CONTINUED

Data type	*Legitimate statistics*	*Points to observe/questions/examples*
Interval and ratio	i Mode ii Mean iii Frequencies iv Median v Chi-square (χ^2)	What is the average score for this group?
	vi Standard deviation (a measure of the dispersal of scores)	Are the scores on a parametric test evenly distributed? Do scores cluster closely around the mean? Are scores widely spread around the mean? Are scores dispersed evenly? Are one or two extreme scores ('outliers') exerting a disproportionate influence on what are otherwise closely clustered scores?
	vii z-scores (a statistic to convert scores from different scales, i.e. with different means and standard deviations, to a common scale, i.e. with the same mean and standard deviation, enabling different scores to be compared fairly)	How do the scores obtained by students on a test which was marked out of 20 compare to the scores by the same students on a test which was marked out of 50?
	viii Pearson product moment correlation (a statistic to measure the degree of association between two interval or ratio variables)	Is there a correlation between one set of interval data (e.g. test scores for one examination) and another set of interval data (e.g. test scores on another examination)?
	ix t-tests (a statistic to measure the difference between the means of one sample on two separate occasions or between two samples on one occasion)	Are the control and experimental groups matched in their mean scores on a parametric test? Is there a significant difference between the pre-test and post-test scores of a sample group?
	x Analysis of variance (a statistic to ascertain whether two or more means differ significantly)	Are the differences in the means between test results of three groups statistically significant?
	xi Regression	What are the predicted scores on one variable if we know the scores on another variable?
	xii Multiple regression	What are the relative weightings of two or more independent variables on a dependent variable?
	xiii Factor analysis	What are the underlying, latent factors into which variables can be grouped?
	xiv Structural equation modelling	What is the causal model of relations between independent variables and factors on a dependent variable?

TABLE 44.5 ASSUMPTIONS OF STATISTICAL TESTS

Test	*Assumptions*
Mean	Data are normally distributed, with no outliers
Mode	There are few values, and few scores, occurring which have a similar frequency
Median	There are many ordinal values
Chi-square	Data are categorical (nominal); Randomly sampled population; Independent categories; Data are discrete (i.e. no decimal places between data points); 80% of all the cells in a crosstabulation contain 5 or more cases;
Kolmogorov-Smirnov	The underlying distribution is continuous; Data are nominal;
t-test and Analysis of Variance	Population is normally distributed; Sample is selected randomly from the population; Parametric data; Each group is independent of the other; The groups to be compared are nominal, and the comparison is made using interval and ratio data; The sets of data to be compared are normally distributed (the bell-shaped Gaussian curve of distribution); The sets of scores have approximately equal variances, or the square of the standard deviation is known; The data are interval or ratio.
Multiple Analysis of Variance (MANOVA)	Continuous parametric data for dependent variables; Independent variables are categorical, with two or more values; Independent groups; Random sampling; Adequate sample size (more cases in each cell than the number of dependent variables being studied); Normal distribution of the data; No outliers; Linear relationship between each pair of dependent variables; No multicollinearity (dependent variables are independent of each other but moderately correlated); Homogeneity (equality) of variances.
Wilcoxon Test	The data are ordinal; The samples are related.
Mann-Whitney and Kruskal-Wallis	The groups to be compared are nominal, and the comparison is made using ordinal data; The populations from which the samples are drawn have similar distributions; Samples are drawn randomly; Samples are independent of each other;
Spearman rank order correlation	The data are ordinal;
Pearson correlation	The data are interval and ratio;

continued

TABLE 44.5 CONTINUED

Test	*Assumptions*
Regression (simple and multiple)	The data derive from a random or probability sample; Adequate sample size; The data are interval or ratio (unless ordinal regression is used); Avoidance of singularity (where one variable is a combination of independent variables); Outliers have been removed; There is a linear relationship between the independent and dependent variables; The dependent variable is normally distributed (the bell-shaped Gaussian curve of distribution); The residuals for the dependent variable (the differences between calculated and observed scores) are approximately normally and consistently evenly distributed (homoscedasticity); Collinearity is removed (where one independent variable is an exact or very close correlate of another); The residuals are not strongly correlated with the independent variables; Each case is independent of the others.
Factor analysis	The data are interval or ratio; The data are normally distributed; Outliers have been removed; The sample size should not be less than 100–150 persons; There should be at least five cases for each variable; The relationships between the variables should be linear; *Intercorrelations between variables* should be between.3 and 0.6; The factors should not be highly correlated with each other (the principle of orthogonality); Each factor contains more than two variables; Strong theoretical underpinning of each factor; The data must be capable of being factored.
Cluster analysis	Same as for factor analysis except that data can be nominal ordinal, interval or ratio; If scales are different or if their standard deviations are large then standardized scores should be used.

Beyond mixed methods

CHAPTER 45

Using Qualitative Comparative Analysis (QCA) to integrate cross-case and within-case analyses

Barry Cooper and Judith Glaesser

This chapter provides a brief overview of situations in which methods might fruitfully be mixed before concentrating on one approach, Ragin's Qualitative Comparative Analysis (QCA). QCA facilitates the integration of quantitative and qualitative forms of analysis, providing a case-based method for selecting cases for in-depth analysis to supplement its rigorous cross-case analysis. QCA is based on set theory and Boolean algebra, relying on 'truth tables' as the basis of analysis. These truth tables provide a representation of data that enables researchers to focus easily on types of cases. The foundations of QCA are briefly introduced and invented data are used to illustrate how it may be used to integrate cross-case and within-case analysis in research settings.

This chapter is deliberately placed at the end of the book, as it is a fitting conclusion to the preceding chapters in Part 5 on quantitative and qualitative data analysis, showing how researchers can move beyond such dichotomous thinking. As its title suggests, the discussion moves beyond mixed methods approaches to examine QCA for integrating cross-case and within-case analyses, addressing:

45.1 Introduction

Mixing methods refers to combining quantitative and qualitative research in one study (see Chapter 2). As Small (2011) and Harding and Seefeldt (2013) note, the literature on mixed methods is enormous and growing, though mixing methods is hardly new (see, for example, Lacey, 1970). While we do not accept that the qualitative/quantitative divide is as clear-cut as some believe (Cooper *et al*., 2012), we should briefly note what these terms usually denote. Quantitative research *typically* focuses on cross-case analysis of large data sets, aiming to produce via correlation-based techniques generalizable knowledge concerning the relative importance of independent variables in explaining some dependent variable. The details of individual cases, or even types of case, tend to get lost during statistical aggregation (though see cluster analysis (Cooper and Glaesser, 2011) and latent class analysis (Vermunt and Magidson, 2002) for examples of quantitative techniques that do more to preserve the holistic case). Qualitative work takes many forms. It can also involve cross-case analysis, though usually of a smaller number of non-randomly selected cases. It is more likely than quantitative work to involve within-case analysis, focusing on interpretative, processual and narrative analysis. Rather than on supposedly independent variables, it tends to focus on the holistic case as the active agent.

In his review of mixed methods studies, Small (2011) employs an overarching distinction between studies mixing methods of *data collection* and those mixing forms of *data analysis*. He notes that mixed forms of data might be used primarily either to confirm findings or to complement each other's strengths and weaknesses, that these data might be collected sequentially or in parallel, and in either a nested or non-nested manner (where nesting involves choosing cases for in-depth analysis from the sample used in the large-n study). Regarding analyses, he discusses a range of types of combination. Discussing one, *integrative analyses*, he notes that a small number of researchers have integrated analyses by creating new techniques, adding, 'without a doubt, the most successful of these has been Ragin's (1987, 2000, 2008) qualitative comparative analysis (QCA)' (p. 77).

Small also discusses how mixing methods can help establish causal claims (see also Chapter 6). Harding and Seefeldt (2013) focus specifically on causal analysis. Assuming a backdrop of large-scale quantitative studies, they note the multiple roles which a qualitative component can play in causal inference, and discuss research design decisions arising when quantitative and qualitative methods are to be integrated. They

discuss the important distinction between cross-case and within-case analysis within qualitative research seeking causal knowledge, commenting that Ragin's set theoretic QCA is well suited to the former. However, having noted that it is conventional (correlation-based) quantitative methods that are more usually employed to undertake cross-case analysis in mixed methods studies, they choose to concentrate on discussing the logic of *within*-case analysis in qualitative research, arguing, with Mahoney (2000), that within-case analysis in the form of *process-tracing* and *pattern matching* can make important contributions to causal analysis. They provide a strong case that qualitative work can offer much to quantitative researchers seeking causal knowledge. They conclude that empirical studies should therefore more often include a mixed methods approach in their design.

We share this view, but in this chapter we will focus specifically on what Small (2011) claims is the most successful new integrative technique: Ragin's (1987, 2000, 2008) QCA. Ragin (1994b) argues that QCA, a Boolean analytic approach drawing on logic and set theory, can bridge the wide 'methodological gulf between intensive case-oriented research and extensive variable-oriented research' (p. 304), suggesting that it will be an appropriate approach for those willing to mix methods. This bridging requires 'tools that preserve the intensity of the case-oriented approach, especially its attention to combinations and configurations of causes and conditions, when examining many cases' (p. 304).

Ragin (2004, 2006a) notes that conventional linear quantitative methods typically aim to assess the relative importance of independent variables in predicting some outcome, i.e. to assess the net effects of variables having controlled for others. A well-known example is the debate between Breen and Goldthorpe (1999, 2002) and Saunders (1997) concerning the relative importance of social class and ability in explaining educational achievement (see also Chapter 6). Such work is clearly important. However, there is an alternative, and perhaps more fruitful, way of conceptualizing such questions. This, employing a model of conjunctural causation, draws on the concepts of necessary and sufficient conditions. We might hypothesize, for example, that, for individuals from higher class origins, high ability will tend to be sufficient but not necessary for later high educational achievement while, for lower class respondents, high ability will tend to be necessary but not sufficient (Glaesser and Cooper, 2011; Cooper *et al*., 2012). Such an approach can be developed in more complex ways. It might be, for example, that the conjunction 'being male, from a higher class origin, and of a certain level of ability, but *not* from ethnic background X' is sufficient for some outcome. QCA facilitates such cross-case analyses. QCA allows the cross-case component of a mixed methods study to focus more on the holistic *case* than do conventional quantitative techniques such as regression analysis. Not only is this, for us, a good thing in itself, but it also allows a theoretically coherent form of sequential integration of cross-case and within-case analyses.

In the next section we consider why researchers employing a broadly quantitative approach, but wishing to develop causal knowledge, might need to introduce a qualitative component into their research design. In the subsequent section, we reverse the direction of argument, and consider why a qualitative researcher wishing to undertake a small number of comparative case studies would be well-advised to introduce some rigorous mathematical considerations – of a particular type – into his/her research planning. We then illustrate the use of Ragin's QCA as one way in which quantitative and qualitative approaches may be integrated. We conclude by considering the implications of our discussion.

45.2 Starting from a 'quantitative' stance

We assume here that researchers prefer causal knowledge. This is not because descriptive knowledge is not useful. The fact, for example, that educational achievement varies by social class is important to know, but we ideally want the link explained. The boundary between description and explanation is not, however, clear-cut (see also Chapter 4). While Merton (1987) notes that ' "establishing the phenomenon" involves the doctrine … that phenomena should of course be shown to exist or to occur before one explains why they exist or how they come to be' (p. 1), this is not always straightforward. In the case of our earlier example, one needs to consider possible explanations for the class–achievement link before accepting it as a useful description. Perhaps cognitive capacity and/or attitudinal differences underlie the link and, once these are controlled, the class–achievement link is weakened. These considerations already move us beyond description and towards explanation.

We can also note that 'social class' is a summarizing variable, with social, economic, relational and cultural elements. Even having decided that the class–achievement link is not an artefact of our having omitted important factors from our analysis, we will still want to know what aspect of class produces the link. Or consider the more applied field of educational

evaluation. If a new pedagogic technique, in some randomized controlled trial (RCT), doesn't produce the average magnitude of gains that its developers had hoped for, we would want to understand why (see also Chapter 20). We would want, for example, to know something about the implementation process. Perhaps the technique was not actually introduced in classrooms because most teachers believed it to be a distraction from preparing students for tests. Or perhaps it required skills that teachers lacked. Without researching implementation it would be premature to report that the technique had no potential value. It would be especially useful to gain comparative knowledge about the classrooms in which it had 'worked'.

For these reasons, we believe that research in the social and educational field is usually more valuable when it delivers more than description, whether in words or equations, of the pattern of regularities that exist in some data set (such as 'higher' class → 'higher' achievement). There are, of course, scholars who argue that cross-case work – the analysis of regularities – can generate causal knowledge, at least in ideal circumstances. We would agree that an RCT, in ideal circumstances, can provide good grounds for accepting that some intervention has caused an average effect in some particular time and place. Similarly, in ideal circumstances, the quantitative analysis of regularities, via correlational or other techniques, can provide knowledge of the relative importance of the factors causing some outcome (Spirtes *et al*., 2001; Baumgartner, 2008; Pearl, 2009). In practice, there are many threats to the validity of such work (Lieberson, 1985; Freedman, 1991; Morrison, 2001). Here we will just briefly note two arguments that aim to qualify the claims made by the advocates of RCTs and survey techniques, and that provide additional grounds for combining qualitative work with quantitative analysis.

Discussing RCTs, Cartwright and Hardie (2012) agree that an RCT can show that some intervention worked in some particular time and place. Policy makers, however, want to know whether the same intervention will work in new settings. The authors stress that an RCT actually shows that an intervention worked *in conjunction with many other support factors*. Unless these, or substitutes, are present in the new settings we have no grounds for expecting the results of the RCT to be transferable. An example often used concerns class size. Even if an RCT shows that halving class sizes produces learning gains, we would need to know before halving all the classes in our country that there were enough *relevantly skilled* teachers available. While there may have been enough of these to staff the additional trial classes, we may lack this relevant support factor when scaling up. To gain knowledge about support factors, we would need to draw both on established theoretical understanding and to undertake some in-depth study of the processes of implementation of the intervention in context. Here is another compelling reason for combining case studies with quantitative analysis.

Analogous problems to those noted by Cartwright and Hardie apply to attempts to gain causal knowledge in social and educational settings via quantitative survey studies employing correlational techniques. Lieberson (1985) provides a thorough analysis of many of these. The coefficients in a regression equation provide an algebraic snapshot of the relationships between a set of independent variables and a dependent variable at some time and place, given the particular choice of variables in the model (see Chapter 42). They will also reflect existing relations between competing interest groups and between these and existing societal laws and regulations.

A regression equation may tell us that, having controlled other factors, a large part of the difference in earned income between ethnic groups A and B (with group A earning a higher income) is statistically 'explained' by prior differences in educational achievement. Policy makers may then decide that the route to improved income for members of group B is improved achievement. Measures are introduced to achieve this goal. However, members of group A, unsurprisingly, wish to defend their position. They use their existing resources to enhance the educational careers of their children by employing private tutors. They also use their social and occupational contacts to arrange internships for their children. As a result, the expected income gain for group B does not occur. Basic causes here, as is often the case, override more superficial ones (Lieberson, 1985). Once again, we think, in order to understand what are more basic and what are more superficial causes requires more than just the analysis of regularities that is usually delivered by quantitative research methods. Process-tracing (George and Bennett, 2005) through case studies, in conjunction with the use of established theoretical knowledge, offers, as we noted earlier, a way forward.

So far, we have considered what a qualitative component might add to quantitative studies. Now we reverse the line of argument. Why might a qualitative researcher benefit from some of the mathematical thinking that characterizes quantitative work? What type of mathematics might be most useful?

45.3 Starting from a 'qualitative' stance

In the previous section, we discussed situations in which a quantitative study might usefully be supplemented by qualitative research. It may also make sense for qualitative work to precede a quantitative study, for example when qualitative work is used in an exploratory, hypothesis-generating way and any initial findings are then confirmed and elaborated on by conducting a larger-scale study (e.g. Cooper, 1998; Cooper and Dunne, 2000). There are also other situations in which causally orientated qualitative work may benefit from the addition of a quantitative element, and we discuss one of these next.

Consider a postgraduate research student wanting to undertake case studies of individuals' educational careers, situating these within personal and social contexts in order to explain why some individuals, but not others, attend university. She has read widely and, on the basis of this reading, proposes a small number of key explanatory factors. These are social class, ethnicity, gender and early 'academic ability'. She takes a configurational approach to causation, claiming that the effect of any factor will depend on other characteristics of the individual (see also Chapter 6). For example, in order to reach university, high 'ability' may be necessary for individuals from some class and ethnic backgrounds but moderate 'ability' might be sufficient for individuals from other backgrounds, given the use of private tutors.

She also thinks that, given the intensity of case studies, she might manage twenty case studies. She intends to select cases to cover the various combinations of characteristics, exploring the processes by which they have their effects. In order to keep things manageable, she proposes using a simplified threefold class scheme and using a simple division of 'ability' into high, moderate and low categories. The society under study has a majority ethnic group (A) and two minority groups (B, C). A simple binary gender division is also proposed. The student has not calculated the number of possible distinct types of case this categorization generates. It is $3 \times 3 \times 3 \times 2$, i.e. 54. The supervisor explains this, pointing out that, even were just one case per type to be explored, the range of types cannot be covered with twenty cases.

The student wants, however, to study the whole range of types in order to explore the interaction of the full ranges of the various characteristics in producing the outcome, and also believes that only via case studies can she gain access to the chains of processes that produce the correlations that she has seen in the statistical literature. The supervisor sees such complete coverage as unrealistic and suggests that she will need to think about the selection of cases for in-depth study. She should also consider whether her study should include a quantitative element – in the sense of a larger n – to allow coverage of the types of cases that her case studies will not cover.

The research supervisor ascertains that the student has been reading regression-based quantitative studies and narrative-based qualitative accounts of educational careers (see Chapters 42 and 35 respectively). She has come across discussions of how to integrate regression-based studies with case studies (Lieberman, 2005; Rohlfing and Starke, 2013) and also much debate about mixed methods, but has not become aware of the tradition established by researchers who, while favouring case-based approaches, also concern themselves with what she has come to fear are 'positivist' concerns such as sampling, proof and rigorous logical analysis (Becker, 1958) (see Chapter 1). Referring to Becker's discussion of logic in his *Tricks of the Trade* (1998) and Ragin's QCA, the supervisor suggests to the student that she take seriously the idea of combining Boolean cross-case analyses of regularities and within-case analysis of processes in order to explore in a *configurational* manner her chosen research theme. This will allow her to develop, he claims, good grounds for choosing cases to develop her understanding of the complex processes she wishes to understand. With this plan in mind, we now introduce QCA.

45.4 Qualitative Comparative Analysis (QCA)

QCA can be used with 'crisp sets' representing binary conditions such as male/female, with multivalued conditions (Cronqvist and Berg-Schlosser, 2009) such as high/moderate/low social class, or by employing 'fuzzy sets' with fully continuous conditions such as measured ability (Ragin 2000, 2008). Since our focus is the core features of integrating cross-case and within-case analysis via QCA, we restrict ourselves to binary conditions. We should note that there are various free software packages available to undertake QCA analyses (e.g. Ragin and Davey, 2014; Duşa, 2016; Thiem, 2016).

QCA employs set theory as the basis for the Boolean analysis of conjunctural causation (Ragin, 1987, 2000, 2006b, 2008). It is important to note that this fundamentally differentiates QCA and related techniques such as coincidence analysis (CNA) (Baumgartner, 2009) from conventional correlation-based analysis

(Thiem *et al*., 2016). In QCA, cases are seen as members of various sets defined by conditions such as 'being male', 'having high ability', 'achieving a degree'. For a condition to be strictly sufficient, logically, for an outcome, all members of the condition set must also be members of the outcome set. This subset relation is equivalent to the condition logically implying the outcome, as it does in Table 45.1, where all cases with 'high ability' achieve a degree. Note though that 'high ability' is not necessary for the outcome here, since 5 per cent of those lacking 'high ability' achieve a degree (perhaps by purchase in a corrupt state). For a condition to be strictly necessary, logically, for an outcome, we need the outcome set to be a subset of the condition set, i.e. all cases with the outcome must be members of the conditions set, as is the case in Table 45.2. Here every case with a degree also has 'high ability' but it is not the case that 'high ability' is sufficient for achieving a degree.

These are simple examples. We must note four things. *First*, the condition can be more complex, for example, a conjunction of factors such as MALE*HIGH ABILITY*HIGH CLASS where * denotes set intersection (logical AND). Here a case must be a member of all three sets to belong to the *configuration*.

Second, given that the empirical social world is less tidy than Tables 45.1 and 45.2, we might relax the criterion for sufficiency, either by referring to quasi-sufficiency where, say, 80 per cent of those with a simple or complex condition achieve the outcome (Ragin, 2000), or by using the proportion of those with a condition who achieve the outcome as a measure of the *consistency* of the subset relation with strict sufficiency (Ragin, 2006b). Where a condition is considered sufficient, it is also possible to assess how many of the cases with the outcome it explains, via the concept of coverage (Ragin, 2006b). Similar procedures can be applied to necessity.

TABLE 45.1 DATASET WHERE CONDITION IS SUFFICIENT BUT NOT NECESSARY FOR THE OUTCOME

Condition 'high ability'	*Outcome 'achieves degree'*	
	Absent	*Present*
Present	0	2000
Absent	1900	100

TABLE 45.2 DATASET WHERE CONDITION IS NECESSARY BUT NOT SUFFICIENT FOR THE OUTCOME

Condition 'high ability'	*Outcome 'achieves degree'*	
	Absent	*Present*
Present	1000	1000
Absent	2000	0

Third, QCA uses Boolean minimization to simplify its analyses (Ragin, 1987). For example, were the conjunctions A*B*C and A*B*c (where upper case letters indicate the presence of a condition and lower case its absence) both found to be sufficient for the outcome Y, then, since the presence or absence of C makes no difference to whether the outcome is achieved, QCA will drop it, and say that the conjunction A*B is sufficient (though see Cooper and Glaesser (2012), for some discussion of what this minimization procedure might hide).

Last, it is sometimes the case, especially when the data set is small, that there may be no cases for some conjunctions. Such limited diversity raises difficulties for Boolean analysis since, to use the previous example, were we to have cases of A*B*C all achieving the outcome Y, but no cases of A*B*c in our dataset, we would have to reflect carefully – and counterfactually – about whether cases lacking C, were they to exist, would achieve Y. If we thought they would, then we could reduce A*B*C to A*B. If not, we would have to retain A*B*C as our solution. It is important to note that there is considerable debate concerning such counterfactual reasoning. Baumgartner (2009) has developed an alternative form of minimization as part of his Coincidence Analysis (CNA) that does not, when certain assumptions are met, require pairs like A*B*C and A*B*c. In addition, the use of counterfactual reasoning to allow minimisation beyond what the empirical data set would seem to warrant is also contentious (see Schneider and Wagemann 2012, 2015; Thiem, 2015; Cooper and Glaesser, 2016a).

We next discuss an invented example to illustrate how integration of techniques using QCA can be undertaken. This will also allow us to introduce 'truth tables', a key feature of QCA. To keep our example simple, we employ a two-fold class scheme (higher class of origin=1, lower=0), gender (male=1, female=0), two ethnic groups (majority group=1, minority=0) and measured academic ability (high=1, not high=0). We assume that there is a dataset available (n=2,160) with information on these and other factors.

45.5 QCA: sufficiency

Recall our research student who is focusing on what is sufficient for achieving admission to university and who believes that class and ability are two of the key factors. She begins by undertaking a simple Boolean cross-case analysis of the relation between entering university (U) and high-class origins (HC) and high ability (HA). Table 45.3, termed a 'truth table' because of its similarities with logicians' truth tables, provides a representation of the cross-case relations in a data set that, while containing just the same information as a complex crosstabulation, enables us to see more easily the 'types' of cases that are our concern and which of these types achieve the outcome. In the context of QCA, we think of the rows of the table as sets of cases, but also as types. Row 1, for example, comprises cases of high ability from high-class origins. We assume, for simplicity, that our sample accurately represents some population (see Cooper and Glaesser (2016b) and Thiem *et al*. (2016) on alternative scenarios). We use an illustrative threshold of 80 per cent of cases achieving the outcome to test for quasi-sufficiency. On this basis, we allocate a 1 in the U (outcome) column for any rows where the consistency proportion is at least 0.8, and a zero for other rows. It can be easily seen that the configuration HA*HC is (logically) quasi-sufficient for the outcome, since 95 per cent of these cases enter university (though only approximately 34.5 per cent of cases with the outcome U are 'covered' by HA*HC).

Our researcher is not satisfied, however, with this Boolean cross-case equivalent of a mere correlation and wants to develop an understanding of the mechanisms and processes that explain (causally) the link between HA*HC and university. For this purpose, she plans to make use of in-depth interviews with a small number of cases in order to explore, via process-tracing, what it is about class and ability that explain the patterns in Table 45.3. Considering class, for example, is it cultural or economic features of class, or both, that explain the link? Or can class patterns be explained by rational choice theory (Breen and Goldthorpe, 1997) (see Chapter 6)? To explore these questions via within-case exploration, she selects cases from row 1 that achieve the outcome. Our researcher also wants to understand what it is about the 5 per cent of cases in row 1 who do not achieve the outcome that explains this fact. She therefore selects from row 1 some cases for interview who have not achieved the outcome.

We shall also assume that this researcher would like, as part of theory development and testing, to improve the 0.95 consistency figure. She wants to find a configuration of factors that is nearer perfect sufficiency. In the context of sufficiency, as Ragin and Schneider (2011) note, theory development requires us to try to raise consistency measures by adding factors to the configurations that form the rows of truth tables. The basic idea is to move from X1 to 'X1 combined with X2'. If we add a single dichotomous factor X2 then each row of the truth table will be split into two, doubling the size of the table, and any causal arguments will be more detailed, i.e. less inclusive (p. 159). The question is, how should we find candidate X2s to add to our QCA cross-case analysis? Established theory will help, but so will in-depth case study. Our researcher, as a result of the interviewing of selected cases, alongside establishing what explains the *typical* cases in row 1 (who achieve the outcome), begins to suspect that the other two factors she was initially interested in, sex and ethnicity, indeed interact with class and ability in determining whether the outcome is achieved. In particular, she suspects that the combination of being an ethnic minority female with HA and HC will cover most of the *deviant* cases in row 1 – those who, atypically, do not achieve the outcome.

With this in mind, she returns to the data set to undertake another round of cross-class analysis, but this time incorporating the additional factors of sex and ethnicity. This produces the truth table in Table 45.4. Row 1 of Table 45.3 is now split into rows 1–4 of this table.

TABLE 45.3 TRUTH TABLE FOR U = F(HA, HC), USING 0.8 THRESHOLD FOR CONSISTENCY WITH SUFFICIENCY

Row	*HA*	*HC*	*number*	*Number entering university*	*U*	*Consistency*
1	1	1	220	209	1	0.95
2	0	1	240	110	0	0.458
3	1	0	600	255	0	0.425
4	0	0	1100	32	0	0.029

TABLE 45.4 FULL TRUTH TABLE FOR U = F(HA,HC,ME,M), USING 0.8 THRESHOLD FOR CONSISTENCY WITH SUFFICIENCY

Row	*High ability*	*High origin class*	*Majority ethnic*	*Male*	*Number of cases*	*Achieves university*	*Does not achieve university*	*Consistency for sufficiency re outcome*	*Quasi-sufficient for outcome*	*Quasi-sufficient for not outcome*	*Quasi-sufficient for neither*
1	1	1	1	1	100	99	1	0.990	1	0	0
2	1	1	1	0	100	99	1	0.990	1	0	0
3	1	1	0	1	10	9	1	0.900	1	0	0
4	1	1	0	0	10	2	8	0.200	0	1	0
5	1	0	1	1	200	100	100	0.500	0	0	1
6	1	0	1	0	200	100	100	0.500	0	0	1
7	1	0	0	1	100	50	50	0.500	0	0	1
8	1	0	0	0	100	5	95	0.050	0	1	0
9	0	1	1	1	100	50	50	0.500	0	0	1
10	0	1	1	0	100	50	50	0.500	0	0	1
11	0	1	0	1	20	10	10	0.500	0	0	1
12	0	1	0	0	20	0	20	0.000	0	1	0
13	0	0	1	1	500	20	480	0.040	0	1	0
14	0	0	1	0	500	10	490	0.020	0	1	0
15	0	0	0	1	50	2	48	0.040	0	1	0
16	0	0	0	0	50	0	50	0.000	0	1	0

Rows 1 and 2 of Table 45.4, where HA and HC are combined with being a member of the majority ethnic group, now have improved consistencies with sufficiency of 0.99. Whether the case is male or female makes no difference in this context. However, the consistencies of rows 3 and 4 have dropped below 0.95. In row 4, where HA and HC are combined with being a female from the minority ethnic group, only 20 per cent achieve the outcome.

The researcher, wanting to offer policy advice on how to improve the situation of this group, decides to carry out further in-depth case studies of cases with HA*HC*me*m. What is it about being a female from a minority ethnic background that explains this low percentage, given the positive class and ability factors? Similar questions can be asked about the other rows of our initial Table 45.3. What is it that explains the small proportion from row 4 who do manage, against the odds, to achieve the outcome? In rows 2 and 3, where only one of HA or HC is present, what determines whether a case does or does not achieve the outcome?

Similar moves between cross-case and within-case analysis can be undertaken in relation to the analysis of necessary conditions (Glaesser and Cooper, 2011; Schneider and Rohlfing, 2013; Glaesser, 2015). The disjunction 'HA or HC' is quasi-necessary for the achievement of Y, for example, with a consistency with necessity of approximately 0.95. There are, nevertheless, thirty-two cases who achieve U without being either HA or HC. Our researcher might decide to interview such cases with the outcome (from row 4 of Table 45.3, or rows 13–16 of Table 45.4), in order to explore how this occurs. She may find that type of ethnic minority background matters, and then return to her original categorization of two minority groups in addition to the ethnic majority.

45.6 Conclusion

In this chapter, following a brief discussion of the nature of mixed methods research (see also Chapter 2), we have presented one way of integrating within-case and cross-case analyses. We have argued for the use of QCA as a means of integration not only because we have found this useful in our own work but because we believe its case-based Boolean approach allows it to offer rigour to researchers who wish to explore configurational causation.

We end this chapter by pointing to some other relevant literature. For researchers who wish to explore the combining of case studies with more conventional techniques, there are many useful sources of advice (e.g. Seawright and Gerring, 2008). We have chosen, given

constraints of space, to use an invented example. For our application of the procedures we have described to real data, see Cooper and Glaesser (2012) and Glaesser (2015) where in-depth interviews are employed as the qualitative component of a study of educational transitions in England and Germany. For another example that combines the use of case study with Boolean cross-case analysis, see Berg-Schlosser (2012). For discussion of case selection when fuzzy set QCA is employed, see Schneider and Rohlfing (2016).

Companion Website

The companion website to the book provides PowerPoint slides for this chapter, which list the structure of the chapter and then provide a summary of the key points in each of its sections. This resource can be found online at: **www.routledge.com/cw/cohen**.
